We do not propose on this occasion to enter upon the history of the electric light at Leamington, but merely to give a straightforward description of the plant laid down by Messrs. Chamberlain and Hookham for the Midland Electric Light and Power Company.

The engine-room, a building 90 feet square, stands on the banks of the Warwick Canal, at a point where plenty of space is available for future extensions. The plant at present in use consists of four Chamberlain and Hookham dynamos,* two Robey engines, and two steel boilers of the locomotive type, together with a high-speed engine and a pair of smaller dynamos used for charging accumulators for the day service. The large Robey engines, which are each capable of developing 200 horse-power, are of the horizontal type, compound and condensing, with cylinders 15in. and 26in. in diameter and 2ft. 4in. stroke. They are provided with the Proell cut-off gear, controlled by Richardson's electric governor. The two boilers are connected to a common steam pipe, and each is provided with an injector, while there is also a feed pump common to both.

Power is transmitted to the dynamos by means of a countershaft and cotton rope gearing, with grooved pulleys. The engines have 9ft. fly-wheels, with nine grooves, which drive on to 4ft. followers, on a 6in. main shaft. The dynamo pulleys have four grooves, and are driven from 6ft. pulleys on the main shaft. The cotton rope employed is made by Mr. Thomas Hart, of Blackburn, and is known as the Lambeth rope. The fibres being laid together without twist, it is claimed that there is no liability to stretch.

The dynamos are shunt wound, and the four large machines are each of 800 lights capacity. At present there are about 1,500 lamps wired, so that only two machines are required at once. The current is taken to a large switch-board of enamelled slate, on which are mounted a number of Drake and Gorham's ring contact switches, by which any required change in the coupling of dynamos and mains may be rapidly and safely effected.

In the day time current is supplied from a set of accumulators of the E.P.S. 31L "1888" type. This battery is divided into two parts, each containing 63 cells, with a maximum discharge of 70 amperes. These cells are charged from two 10-unit dynamos driven by a 30 horse-power Robey high-speed engine, and cotton rope gearing is again adopted. The discharging current passes through a pair of relays, by means of which a bell is set ringing as soon as the limit of 70 amperes is exceeded. This is taken as the signal for starting the main engines. In changing over from the batteries to the dynamos, the latter, when running at the proper speed, are first switched on in parallel before the batteries are switched off. The cells are charged at night while the lighting is being done from the large machines.

Under the advice of Dr. Hopkinson, the three-wire system of distribution was at first adopted, but experience soon led the company to discard this system. The difficulty of balancing the circuits may be said to vary inversely with the total number of lamps in use, whilst the saving effected is not a sufficient set off for the additional complication entailed. The Leamington station is, therefore, now worked on a simple parallel circuit with feeders, distributors, and service mains. There are two lines of feeders, one 900 yards and the other 460 yards in length, with sectional areas of 375 and 300 sq. mm. respectively, the cables being of the well-known Callender make. They are laid in brick trenches having a sectional area of 4 sq. ft., and lying 5ft. below the level of the road. The cables are supported in cleats of paraffined wood, which rest upon slate shelves clear of the bottom of the trench, so as to allow room for a drain way. The feeders terminate at two iron distributing boxes placed above ground in the streets, from which the whole of the distributing mains radiate. These mains are also carried in brick trenches, of somewhat smaller area, and the section of the copper varies from 120 to 60 sq. mm., according to the distance and number of the lamps supplied. The service mains are connected to the distributing mains by a soldered joint made in the trench, no junction boxes being employed.

The most important indoor illumination at present carried out by the company is that of the Town Hall, which comprises 360 lamps. This is a new and handsome building, in the centre of the town, and the electric fittings are of a very appropriate and tasteful character throughout. The assembly room, which has a floor space of 3,200 sq. ft., is lighted by 186 lamps, each of which is provided with a silvered reflector. This reflector is so formed that while no light is thrown vertically downwards, the number of rays reflected at any other angle to the horizontal increases as this angle diminishes. The result is very pleasing, and the illumination of this room must be pronounced a great artistic success. We may mention that this method of diffusion was designed by Mr. Hookham, and might often be used with advantage elsewhere. In the Pump Room there is an installation of 170 lights, and there is also a large installation at the house of the Mayor of Leamington, Mr. J. Fell. This is the furthest point at present reached, and is distant 1,860 yards from the central station. A good many of the leading tradesmen in the High-street have adopted the light; and in some of the shop windows, by the use of opaline shades, which screen the light itself from the observer, some very pretty effects have been produced. We heard nothing but expressions of satisfaction with regard to the indoor lighting; and, taking things as we found them on the occasion of our visit, we have no hesitation in pronouncing this portion of the Leamington installation a complete success.

As regards the street lighting, we have already had occasion to state our impression that it is of an inadequate character, and the majority of the inhabitants seem to be of the same opinion, which also they are not slow to express. It may, nevertheless, be doubted whether a stranger standing at the top of the High-street, and supposing it to be lit by gas, would find any fault with the lighting. As we have already said, the question is largely one of sentiment. The magic phrase "electric lighting" arouses expectations which nothing but a 1,200 candle-power arc light can fulfil; and from a business

* For description of this machine see *Electrician*, Feb. 11th, 1887.

Digitized by Google

point of view this should be regarded as a conclusive reason for reserving low candle-power incandescents for indoor illumination, where alone they reign supreme.

The High-street, which is nearly a mile in length, is lit by 183 lamps of 16 candle-power (nom.). The lamp-posts are of handsome design, and the lamps are hung from short brackets projecting at right angles. These brackets extend alternately along the line of the street and over the footway, an arrangement which presents a somewhat ragged appearance when viewed from the middle of the street. At the crossings of the more important streets the lamp-post carries three brackets set at 120deg. from each other, and one of these posts is placed at each of the salient angles of the footpath; so that at a four-way crossing there are 12 lamps, and in these cases the effect is decidedly good. Eighty-three of the street lamps are on one circuit, and the remaining 100 on another. The first set are turned out at 11 p.m., and the remainder at hours varying from 1 a.m. to 6 a.m. The lamps are supposed to be lit at dusk. From our own experience, which seems also to be confirmed by the local newspapers, we think that in this and all similar cases the contractors would do well to be guided by the atmospheric conditions rather than by the almanac in determining the actual hour of lighting. The Town Council pay £2. 2s. per annum for each street lamp, and as this covers lamp renewals, it is certainly a very reasonable charge.

The distribution is effected at 110 volts, and, judging from the entries in the log-book, which are made each hour, it is very fairly uniform, the variations tending in general to be above rather than below the normal value. The regulation is effected in the first place by the Richards electric governor, which varies the speed of the engine from a minimum of 84 revolutions up to a maximum of 90 revolutions per minute. The final adjustment is made by means of a rheostat in the field-magnet circuit, which is varied in accordance with the indications of a Schuckert voltmeter specially adapted for the purpose, the fall of potential in the feeding main being compensated for by taking a turn of the feeder round the voltmeter at a certain distance from it. The effect of this is that the voltmeter indicates, not the difference of potential in the engine-room, but that at the distributing centre. We have already mentioned that there are two distributing boxes, each supplied by its own feeder, and the two dynamos in use are not coupled together at the station but work independently, one on each feeder, so that the whole of the regulating apparatus is duplicated. The load is, however, nearly equalised by means of a pair of connecting leads which are taken from one distributing box to the other. This system of regulation is certainly simple and effective, and requires no special skill on the part of the attendant. In practice it appears to work with perfect success.

The consumers are charged by meter, the instrument employed being one of Mr. Hookham's design. We shall describe and illustrate the arrangement in a later issue, when it will be seen to be of a particularly ingenious character. The tariff is as follows:—For a quarterly consumption not exceeding the equivalent of 12 units per lamp, 8d. per unit; for any further quantity exceeding the equivalent of 12 units per lamp but not exceeding the equivalent of 24 units per lamp, 6d. per unit; for any further quantity exceeding the equivalent of 24 units per lamp, 4d. per unit. This is equivalent to a charge per lamp-hour varying from ·54d. down to ·27d.

THE GLASGOW INTERNATIONAL EXHIBITION.

(FROM OUR CORRESPONDENT.)

Electric Welding and Riveting.

The application of electricity to the welding of metals has within the last few months been brought prominently before the public by the publication of the results of experiments on the subject by Prof. Elihu Thomson. Mr. Richard Miller, the agent for the Thomson-Houston system in Glasgow, has an interesting exhibit of this process in daily operation in the dynamo shed at the Glasgow Exhibition. As is to be expected in such a centre of engineering enterprise as Glasgow, this exhibit attracts a considerable amount of attention. The general principles of the process are now so well known to the readers of this journal that it seems only necessary to recapitulate the chief features of the system as shown in this exhibit. Suppose, for example, that two round rods of brass or iron are to be welded end to end. The ends to be joined are made slightly oblique or slightly convex, and the rods are then grasped respectively in the jaws of two powerful clamps fixed to a bench in such a way that the axes of the rods are in the same straight line. One of the clamps is fixed, while the other can be made to move parallel to the axis of the rod by means of a screw. The two clamps are insulated from each other, and are made to form the terminals of the low resistance circuit of a transformer having an adjustable ratio of transformation, the maximum ratio being about 500. The primary circuit of the transformer is supplied with current from an alternate-current dynamo, the potential at the terminals of which is about 220 volts. The primary coil of the transformer consists of six parts, all joined up in series, and a commutator is attached to the transformer, by means of which the current from the dynamo can be sent through all the coils in series or in parallel, or through $\frac{5}{6}$, $\frac{2}{3}$, $\frac{1}{2}$, $\frac{1}{3}$, or $\frac{1}{6}$ of the coils in series. The current for welding is further regulated by a set of spring resistances in series arranged as a shunt between the dynamo leads. By means of a switch the dynamo can be shunted by throwing in the whole or any part of these resistances, and the current in the primary coil of the transformer is correspondingly reduced.

These arrangements being premised, the operation of welding is comparatively simple. The movable clamp is screwed forward until the ends of rods just touch each other, and a small quantity of powdered borax placed on the junction. The current is then switched on to the primary coil of the transformer, and increased in strength until the metal at the junction becomes sufficiently hot for the two pieces to fuse together. The movable clamp is then screwed forward, so as to squeeze the two parts into perfect contact. The welded piece is then removed from the clamps and straightened, or otherwise hammered to the required shape, on an anvil while it is still hot. The part of the rod heated is quite short, most of the heat being generated at the junction, because of the high resistance of the contact in the first place, and the relatively high resistance of the hot part of the rod after the junction has become more complete. Should the weld prove on examination to be faulty, the specimen may be again put into the clamps and reheated. The bad weld will in most cases have sufficiently high resistance to localise the heating.

This method has obvious advantages for light work where electrical power is available. The appliances can be fixed to a bench in any part of the workshop, and the operation is clean, exact, and expeditious. Another great advantage is, that almost any kind of metal can be welded by this means.

The specimens most commonly used as illustrations of the application of the process are of cast iron, steel, malleable iron, brass, and copper, all of which weld perfectly. Some of the specimens were examined by the present writer personally, and with the exception of the cast iron they generally broke to one side or the other of the weld, showing that the weld was certainly as strong as the original metal. The cast iron was broken by holding one end in the hand and striking the other on an anvil. The fracture in the specimens tested took place at the weld, but not entirely across the original plane of division. The probability is that the specimens, which were taken at random from the box of newly-welded pieces in the Exhibition, had not been sufficiently heated. The current required to weld a rod of any given thickness depends, of course, on the metal of which the rods are composed, while for different thicknesses the current will vary approximately as the cross-section of the rod. The current required to quickly fuse the junction of a half-inch steel rod is about 450 amperes, but a somewhat smaller current suffices to maintain the welding heat after it has once been obtained.

A simple modification of the welding apparatus just described renders it applicable to the riveting of plates. The two plates

Digitized by Google

with the rivets inserted are placed in the fixed clamp, which is so modified that it serves to hold up the head of the rivet. The movable clamp is fitted with a head for closing the rivet which is screwed into contact with the end of the rivet. The current is then switched on and adjusted until the rivet is white hot, when the clamp is screwed up so as to close the rivet and form a head. This application is ingenious, but it is evidently only suitable for work where the highest strength is not required, because the fact that the rivet cannot be hot quite through, and the force applied being comparatively small, the rivet is not likely to firmly fit the hole in the plate.

A much more effective method of applying electricity to riveting is shown in the machinery section by Mr. F. J. Rowan, C.E., Glasgow. This is an electro-magnetic riveting machine, and it is shown at work suspended on the side of a ship's bulkhead. Mr. Rowan's apparatus was fully illustrated and described in *The Electrician* of March 11th, 1887. The rivet is prepared in the ordinary way, and when placed in the hole the head is held up by a powerful electro-magnet, which holds on to the side of the plate by magnetic attraction. A similar electro-magnet is attached to the opposite side of the plate and this magnet carries a powerful spring-hammer placed between its poles.

The hammer is pulled back by means of a small electro-motor, working through reducing gear, which causes a cam to revolve and to compress the spring to which the riveting hammer is attached. When the highest point of the cam is reached the spring is suddenly released, and it causes the hammer to deliver a powerful blow on the rivet. This can be repeated at a rate of 150 blows per minute, and its force can be adjusted by changing the position of the fixed end of the spring. The holder-up and the hammer apparatus are each suspended on convenient frames, fixed to the side of the ship or other plating to be rivetted. These will be found illustrated and described in the article above referred to. The various parts can be brought very readily into position, and the work well and quickly done. Mr. Rowan also exhibits two of his electro-magnetic drilling machines. These are of similar construction to the riveter, the drill taking the place of the rivet-hammer, and the electro-motor being geared to the drill. The holding-up magnet is of course unnecessary when the drill is being used.

All these tools have a most serviceable and efficient appearance, and especially in ship work, where the application of hydraulic and steam riveters is difficult, they will doubtless prove eminently useful.

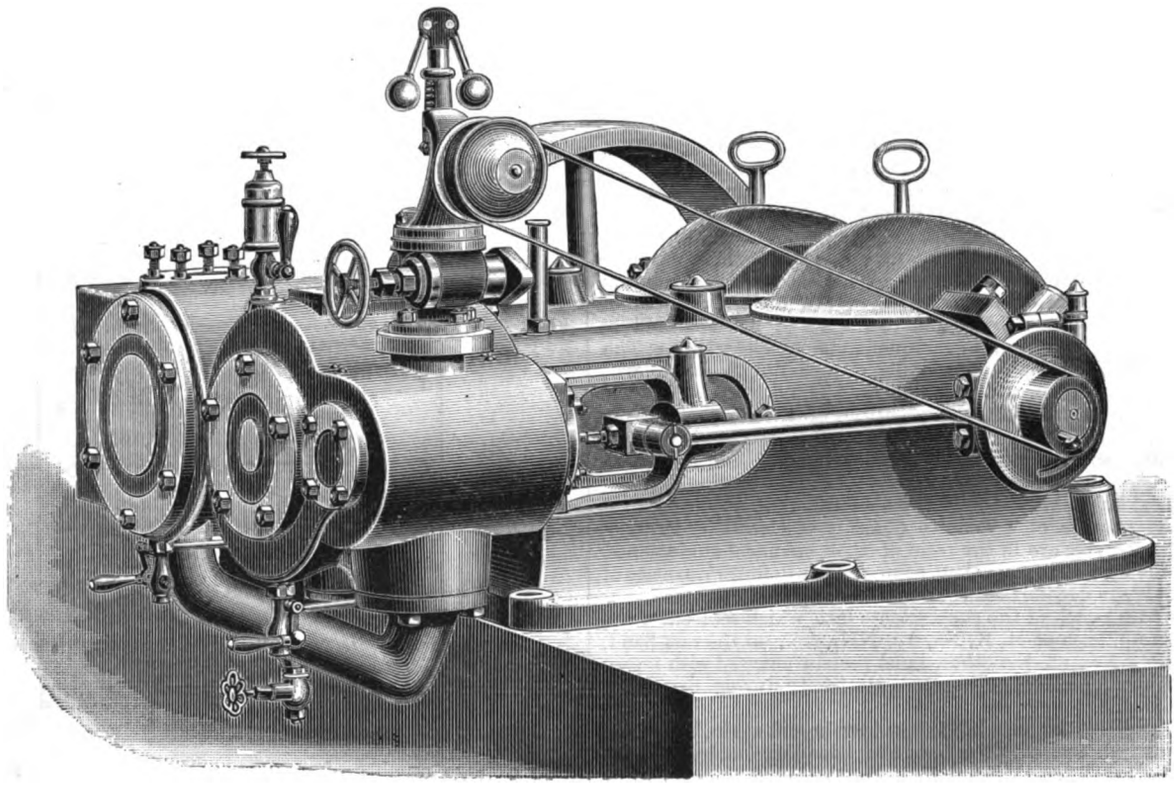
Messrs. Greenwood and Batley, Limited, of Leeds, also show an electro-magnetic drilling machine, similar in construction to one of those exhibited by Mr. Rowan. The drill, which is placed between the poles of a powerful electro-magnet, is driven, through bevel-wheel reducing gear, by a small electric motor, the feeding, as in the case of Mr. Rowan's machine, being done by hand.

High-Speed Compound Engine by Robey and Co.

Messrs. Robey and Co., the well-known engine makers, exhibit a small high-speed compound engine which has been specially designed for driving dynamos either direct or from the fly-wheel. This engine, which is represented in the accompanying illustration, runs at 500 revolutions per minute. The moving parts are all made of steel, the piston and rod being in one piece, and the number of pieces has been kept as few as possible. The crank is steel, and runs in very long bearings of gunmetal.

It will be noticed from the drawing that the whole of the working parts are enclosed within the base-plate, or hinged cones surrounding the crank, completely protecting it not only from dust and grit, but also preventing the splash of any oil. The working parts are lubricated from the inside, a licker fixed under the large end of the connecting rod taking up a portion of the oil at each revolution, and not only lubricating the crank pin but throwing it upon the connecting-rod, slipper, and piston-rod. There is thus continuous circulation of oil from the well underneath the crank through the piston-rod slide, and back again through a channel provided for it to the well.

In consequence of this arrangement the consumption of oil is practically *nil*, and the lubrication seems to be very perfect. The engine illustrated is designed for a working pressure of 150lb., and has a high-pressure cylinder 5¼in. diameter, low-pressure cylinder 9in. diameter, and is said to work economically up to 25 horse-power.



The Robey High-Speed Compound Engine.

Digitized by Google

The valve of the high-pressure cylinder is of the piston type, and runs practically without friction. There is little or no vibration perceptible, and compared with the ordinary single-acting engines for high-speed there can be no question that this engine works with a very economical use of steam.

A REVIEW OF THE PRESENT CONDITION OF THE THEORY OF THE ELECTROLYSIS OF SOLUTIONS.*

BY F. KOHLRAUSCH.

1. *Grothuss's Hypothesis.*—The hypothesis propounded by Grothuss† shortly after the discovery of the electrolytic decomposition of water,‡ still forms the essential basis of all inquiries into the nature of electrolysis. While in metallic conductors the passage of the electric current takes place apparently without producing any permanent change in the molecules of the body, in electrolytes, on the other hand, the molecules themselves carry the electricity with them.

The chemical molecule becomes separated into its positive and negative components; for example, Na and Cl, Ag and NO_3, Cu and SO_4. These components are assumed to contain, one the positive and the other the negative electrification, and they therefore become themselves acted upon by the electrical forces, which cause them to move in opposite directions through the fluid, carrying their charges with them.

Strictly speaking, therefore, electrolytes must be considered to be non-conductors, the transference of electricity being effected by the actual movement of portions of matter, much in the same way as the transference of heat in liquids and gases by means of convection currents.

2. *Faraday's Law.*—The hypothesis was first expressed in a quantitative form by Faraday,§ whose law is essentially that if an electrolyte be decomposed by an electric current, the quantity of any constituent separated will be proportional to the quantity of electricity which has traversed the electrolyte, and will be independent of the chemical compound used.|| For example, if silver be thrown down from fused chloride or iodide, or from a solution of the nitrate, sulphate or acetate, or of the double cyanide of silver and potassium, equal amounts of silver will be separated in each case by the passage of equal quantities of electricity. The same law holds good for other metals, as potassium, copper, &c., and also for hydrogen, and it holds for the negative as well as for the positive constituents, the quantities of the former set free at the anode being simply the remainders when the positive constituents are separated from the original compound, and set free at the cathode.

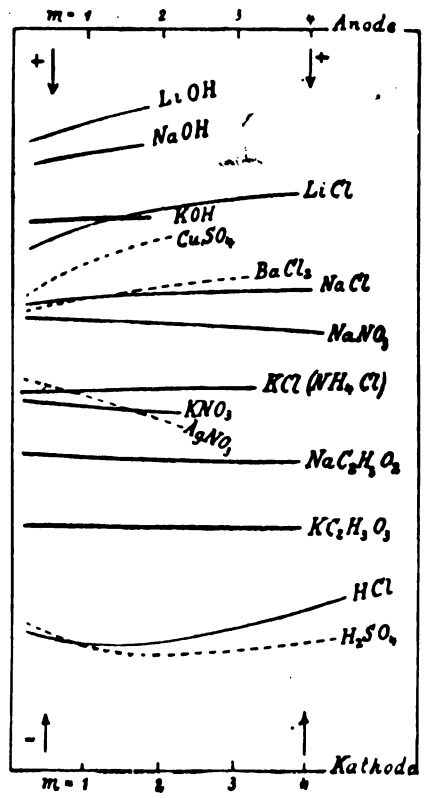
In chemical language, the quantities of different substances set free by the passage of a definite quantity of electricity through different electrolytes are in the ratio of their chemical equivalents, so that in the case of mono-valent compounds a definite quantity of electricity always decomposes the same number of molecules.

It follows that each of the constituents into which molecules are thus broken up, such as H, K, Na, Ag, NH_4, &c., on the one hand, or Cl, I, NO_3, &c., on the other, must remain charged with a constant quantity of positive or negative electricity during the whole of its electrolytic movements.

The truth of this law has been tested again and again,¶ and the more carefully all sources of error have been guarded against the more exactly has it been shown to hold, so that it appears to be an exact, and not merely an approximate law. This is the more remarkable, since the nature of the relation between the charge of a molecule of any substance set free at one of the electrodes and its chemical equivalent, on which the truth of the law depends, is not yet clearly understood. A solution of this question would be of the utmost importance both from an electrical and from a chemical point of view.

3. *Migration of the Ions.*—Twenty years after the statement of this law of definite electrolytic action a further question was opened up by Hittorf, a question which his great power of exact thought, combined with a most complete mastery of the resources of both physical and chemical science, enabled him to answer, and by so doing to make clear for the first time the essential mechanism of the electrolysis of solutions.* Faraday's law only deals with the final products which appear at the electrodes. Now, copper, for example, when deposited electrolytically from a solution of its sulphate, may actually pass through the solution to the cathode, or the other constituent, SO_4, of the sulphate of copper may be transferred in the opposite direction; or, again, both of these actions may go on simultaneously. We can no more obtain an answer to such a question in the case of an electrolytic decomposition from the knowledge of the products separated at the electrodes than we can determine from the flow of electricity in a metallic conductor whether positive electricity be moving in one direction, or negative in the other, or whether both be moving simultaneously in opposite directions. It is, however, possible to obtain an answer by means of a chemical analysis of the solution after the passage of the current. Hittorf's investigations led him to the conclusion that both of the oppositely-charged constituents of each molecule actually travel through the solution, but the distances traversed by them in a given time are not in general of equal length. For example, in a dilute solution of sulphate of copper, the negative constituent SO_4 travels with about double the velocity of the positive constituent Cu, and in the opposite direction. This ratio of 1 : 2 in the velocities of the two ions does not, however, obtain universally, but varies according to the nature of the electrolyte and the strength of the solution.

Fig 1



In a large number of cases these ratios have been represented graphically in such a manner that their nature may be seen at a glance (*see* Fig. 1).

4. *Molecular Concentration of Solutions.*—The strengths of the solutions from which this and the other diagrams were obtained were not made by weight, but according to the number m of electrolytic molecules contained in a given volume, the values of m being obtained by dividing the weight in grammes of a litre of the solution by the molecular weight of the electrolyte in the case of univalent molecules. In the case of divalent molecules the divisor will be half the molecular weight, *e.g.*, for H_2SO_4 the divisor will be 98/2 = 49, and so on.†

5. *Length of Path Traversed by the Ions.*—The results of Hittorf's researches for a large number of substances are given in Fig. 1.‡ The number of experiments which have been made is not large enough, especially considering the liability of the results to errors of observation, to enable the curves to be drawn with any certainty for all substances. I have endeavoured, with as little arbitrariness

as possible, to eliminate any want of uniformity in the curves. The curves for KOH, NaOH, LiOH and LiCl were obtained from the results of Kuschel's experiments.* Let any two portions of the upper and lower horizontal boundaries of the diagram (Fig. 1) lying between the same vertical lines represent respectively the anode and the cathode, separated by a column of liquid of the same length as that of the diagram, and of a molecular concentration represented by the corresponding value of m; then the vertical distance of any point of the curve from the lower boundary represents the distance traversed by the negative constituent, or *anion*, and its distance from the upper boundary represents the distance traversed by the positive constituent, or *cation*. In other words, two molecules (anion and cation) starting simultaneously from the electrodes will meet on the curve.

We see that in solutions of KCl, NH_4Cl, KNO_3 and $AgNO_3$, the two ions travel with nearly equal velocities, and meet therefore near the middle, but in the case of $AgNO_3$, the velocity of the constituent NO_3 shows a decided decrease as the concentration increases. For NaCl the ratio of the velocities is about Na : Cl = 1 : 2, and for LiCl about Li : Cl = 3 : 7, and the inequality increases with the concentration. In the case of sodium acetate, and still more in that of potassium acetate, the metal travels more rapidly than the constituent $C_2H_3O_2$.

The inequality is still greater in the case of the hydrogen compounds or acids, the velocity of the hydrogen being some five times as great as that of the negative constituent. In the case of the alkaline hydrates, KOH, NaOH, and especialy LiOH, the velocity of the metal is much smaller than that of the other constituents. (We assume that these bodies break up into metal and OH.)

6. *Part Played by the Solvent.*—The results of these researches of Hittorf's point to the conclusion that the water of the solution plays no part in the decomposition. Earlier theories which looked upon water as a conductor were, on the other hand, frequently founded on the assumption that the water was really the electrolyte, and that the products of the decomposition which were liberated at the electrodes were in part due to secondary action, as, for example, that of the nascent hydrogen. In so far as a direct investigation of this question was possible, Hittorf has proved, at any rate in the case of the stronger solutions, that no appreciable part of the conductivity is due to water.† In point of fact, it is indisputable that the so-called conductivity of water is always due to the presence of impurities of which it is extremely difficult to remove every trace. It is possible by using very great care in its purification to obtain water, of which a column, one millimetre in length, will have a resistance equal to that of a copper conductor of equal section and of a length equal to that of the moon's orbit, so that pure water may be considered to be a non-conductor.‡

7. *Electrolysis Due to Mixture.*—This behaviour of water is only a special case of a general property of bodies. All fluids, with the exception, of course, of metallic conductors, are at ordinary temperatures essentially bad conductors. Alcohol, ether, and sulphide of carbon are well-known examples of this. But, according to the researches of Faraday, Hittorf, Gore, and Bleekrode, anhydrous acetic, chromic, hydrochloric, and fluoric acids have a very low conductivity. Even sulphuric acid (H_2SO_4) is a very bad conductor.

Electrolytes with a high conductivity are principally obtained by mixture (solution).§ The most highly conducting aqueous solutions of sulphurous acid have about 100 times the conductivity of the pure acid, those of acetic acid about 30,000 times, and similarly aqueous solutions of hydrochloric acid conduct many times better than the pure acid. It has been found, too, that the addition even of alcohol to water will increase its conductivity.‖

8. *Metallic Conduction.*—A further conclusion may here be drawn with a probability practically amounting to certainty. It has been supposed that electrolysis is merely a kind of secondary result of the passage of the electric current, the constituents of the fluid being assumed to be separated by the current by a sort of friction. This assumption of a "metallic" conductivity in electrolytes has often been made, but the advance in our knowledge of the subject has made it quite untenable.¶ This is in agreement with the general property of bodies that metallic conductors are never transparent. Electrolytic conductivity, on the other hand, is quite independent of transparency to light and radiant heat.**

9. *Conductivity, Ohm's Law.*—The inquiry into the behaviour of electrolytes may be extended and simplified, and also, on account of the difficulty of the chemical investigations, be made more exact, by previously making an accurate determination of the conductivity. The investigation of this question has shown, in the first place, paradoxical as it may seem, that the laws which govern the conduction of electricity in metals hold good also for the current in all the electrolytes which have been experimented on. Every decomposable body has, in the sense of Ohm's law, its own definite resistance, so that the conductivity of an electrolyte, like that of a metallic conductor, may be expressed by a definite number, by comparison with that of mercury, for example. The transference of electricity by the motion of the electrolytic molecules must therefore be subject to a resisting force proportional to the velocity, just as in the case of the motion of electricity in metallic conductors. Such small E.M.F.'s even as the millionth of a volt, acting through a thickness of a centimetre of fluid, are subject to Ohm's law, and no effects due to inertia have been observed, even with rapidly alternating currents or currents of short duration.*

(To be concluded.)

THE EDISON IMPROVED PHONOGRAPH.

On Tuesday last Colonel and Mrs. Gouraud received a large party of visitors, principally representatives of the London press, for the purpose of inspecting an Edison phonograph of the latest type, which had just arrived from America. Everyone knows that the tinfoil of the instrument of 1878 has been replaced by a film composed of a composition of paraffin and wax laid upon a cardboard cylinder. We understand that the discovery of the suitability of films, consisting wholly or partly of wax, for receiving the records of phonograms was due to Mr. Chichester A. Bell, one of the inventors of the Tainter-Bell graphophone.

The substitution of wax for tinfoil totally alters the character of the record, which becomes a continuous wavy line instead of consisting of a series of separate indentations, and the improvement in the articulation is almost comparable with that which Graham Bell effected in the telephone by substituting an undulatory for an intermittent current. The wax cylinders have the still more important advantages that they can be removed and replaced on the mandrel of the same or another instrument, and that the sounds recorded may be repeated a very large number of times without any sensible diminution of distinctness. Colonel Gouraud illustrated this on Tuesday by placing in the instrument a cylinder containing the record of a cornet and pianoforte duet, which he informed us had already been through it more than a thousand times, and the reproduction was beautifully clear and distinct. He is now making arrangements for systematically testing the number of times the same record may be used without deterioration by means of an automatic electric apparatus, which will shift the cylinder back to its starting point as soon as it has passed through the instrument, and register the number of times the reproduction has been effected.

The instrument is driven by a small electric motor enclosed in a box forming the base of the instrument, and is energised by a single bichromate cell, and controlled by a small centrifugal governor. The motor, the details of which have not yet been made public, works noiselessly, and, as far as we could judge from the exhibition given on Tuesday, appears to be thoroughly satisfactory. The speed is adjustable, as it is desirable to run it at a much higher rate for the reproduction of music than for that of speech. The recording and reproducing styles and diaphragms are attached to a single rigid frame moving on an axis permanently attached to the instrument, and one can be substituted for the other in a moment. A knife blade is attached to the recorder, which shaves the surface of the film, and makes it truly cylindrical, and if it has been already used for a previous record it removes this as the new one is impressed upon it. The depth of the cut is adjustable, as records produced by very loud speaking or by loud musical notes are made deeper than those produced by more feeble sounds.

By fixing a sound trumpet to the reproducing mouthpiece, both speech and music can be rendered distinctly audible to a small audience, but the sounds are reproduced with much greater purity when tubes are used connecting the mouthpiece with both ears of the listener, and by attaching a branched tube to the mouthpiece and using several sets of tubes the sounds can be listened to by several persons simultaneously. During the afternoon Mrs. Shaw, commonly known as "La Belle Siffleuse," whistled into the instrument, and the tune was reproduced with exceptional clearness and loudness.

One of the cylinders had been spoken to by Mr. Edison, and the visitors were much interested in listening to his remarks, laughter and snatches of songs.

„ Aden, Borneo, Ceylon, China, India, Japan, Java, Labuan, Mozambique, New Caledonia, Persia, Philippine Islands, Siam, Transvaal, and Zanzibar	7 6	... 14 6	... 28 0
The rates for the United Kingdom remain as follows :—	5 0	... 10 0	... 19 6

TO ADVERTISERS.

"The Electrician" offers exceptional advantages to Advertisers. **It has the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application to this office.

Advertisements intended for the current issue must be handed in not later than 4 p.m. on Thursday.

TECHNICAL PRINTING.

"The Electrician" Printing and Publishing Company (Limited) beg to inform Electricians and Electric Light Engineers that they make a specialty of Technical Printing, and have a Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electrical Catalogues and Electro-Technical Literature generally.

The Electricians' Directory.

Royal 8vo. Cloth Boards, 3s. 6d. Boards, 3s.

At the end of December in each year is issued The Electricians' Directory and Handbook. *The Directory was established in 1883, and has now attained considerable proportions. Every care is taken to make the names and addresses of all persons engaged in the Electrical Industries absolutely accurate. Useful Tables and Electrical Formulæ are given, together with popularly-written Biographical Notices of the leading Electricians, accompanied in many cases by Portraits.*

THE DIRECTORY FOR 1889 IS IN PREPARATION.

"THE ELECTRICAL WORLD" IN THE UNITED KINGDOM.

Arrangements have been made by which "The Electrical World" of New York can be obtained from "The Electrician" Office, 1, Salisbury-court, Fleet-street, London, E.C.

The Rate of Subscription (payable in advance), including postage, is **£1. 1s. 0d.** *per annum to this Country and Abroad.*

Single Copies of "The Electrical World" can also be obtained, **price 6d. each.**

The Rates for Advertisements in "The Electrical World" of New York can be obtained on application to "The Electrician" Printing and Publishing Company, Limited, as above.

"THE ELECTRICIAN" IN THE UNITED STATES.

Similarly, "The Electrician" can be obtained in America at the Offices of "The Electrical World," 168 to 177, Potter-building, New York.

"The Electrician" can also be obtained from D. Van Nostrand, *23, Murray-street, and 27, Warren-street, New York.*

The Rate of Subscription for American Subscribers (payable in advance) is $6 per annum.

LOCAL AUTHORITIES AND ELECTRIC LIGHTING.

The passing of the Electric Lighting Amendment Act this Session has already resulted not only in the formation of several new companies with large aims for the supply of electricity within the metropolitan area, but in the revival of numerous demands for electric lighting in provincial towns where the original Act of 1882 had effectually extinguished such schemes. We hear rumours of fresh companies being started, of applications for licenses and provisional orders being projected, and, moreover, of local authorities being desirous of undertaking the business on their own account. The large experience which has been gained and the confidence inspired in the interval between 1882 and the present time certainly justifies this activity; and it does not surprise us that the attitude of local authorities, which was then extremely shy, or covertly hostile, is now almost uniformly favourable. The first question they will have to decide will be whether they shall permit the right of public lighting to pass out of their hands into those of private companies; and, on the other hand, one of the questions which existing or projected companies must consider is, whether they will approach the local authorities as undertakers—to quote the wording of the Act—or as contractors?

On these two points some misapprehension seems to prevail, although the wording of the Act is perfectly clear. Section II.

Digitized by Google

provides that any local authorities who have obtained a license, provisional order, or special Act, for the supply of electricity may contract with any company or person for executing and maintaining the same. Probably in a number of cases the local authorities will prefer this course, retaining the powers of the Act, but delegating their execution to more competent hands. Electric lighting undertakers, we imagine, will, on their part, have no objection to this arrangement; many would prefer it, as being less speculative and freer from the objectionable restrictions to which undertakers working directly under the Act are subjected. It should be noted here, however, that the Board of Trade still possess large powers of regulation and interference not defined by the Act either of 1882 or 1888. Rules framed by the Board of Trade from time to time are, it is true, to be laid before Parliament; but when this formality has been complied with, no vote being required, the rules acquire all the force of an Act of Parliament. The Board of Trade, however, will be bound to call in the assistance of professional advisers directly or indirectly connected with the electric lighting industry, so that little fear need be entertained of vexatious or obstructive rules being sprung upon the undertakers or contractors after the business has been entered upon.

On one or two other points we may here usefully draw attention to the wording of the Act. Inquiries have reached us as to applications for licenses or provisional orders, merely for the purpose of covering the ground. No doubt a very great number of such applications were lodged on the passing of the first Act—applications, some of which were never intended to be pushed forward, or only in order to dispose of the concessions, if obtained, at a profit. As, however, none of these projects went any further than the first stage, the question of their validity or permanency never arose. No doubt the covering of a given area may in certain cases be convenient and even necessary; or, to put it differently, the acquisition of certain parts or the whole of such area by other hands may be highly advantageous to all the parties concerned. The Act provides for this, the Board of Trade having power to sanction the transfer or assignment of rights obtained under its provisions. But it should be noted that, without the Board's consent, the original holders cannot divest themselves either of their powers or their liabilities. There is nothing to prevent more than one application being made for the same area; and within one local authority's district licenses or provisional orders may certainly be granted to several different companies or firms—possibly to more than one even in the same area. The Act does not prohibit such competition, and Parliament would, no doubt, permit it if the occasion arose, and provided the local authority did not itself propose to undertake the duty.

Local authorities supplying their own electric light would not be exempt from the contingency just alluded to, and this consideration ought to weigh with them in determining whether to undertake the business or to let a private company come in. Be the area large or small the installation must be carried out and maintained under the supervision of a competent electrical engineer—a personage rarely met with in the precincts of the parish vestry. He can easily be found, however, by paying for him, and where the areas are small a combination of towns or parishes to defray the professional charges would probably meet the case. Where the authorities already supply the town with water, they could utilise the premises, the engine power, and the engineering talent on the spot. This has been largely done in America, and the economy effected is said to be very considerable. There are about 170 towns in the United States wholly or partly lighted by electricity, 25 of which already are undertaken exclusively by the respective municipalities, and with results that are highly satisfactory. From the data supplied by Mr. F. H. WHIPPLE, in his pamphlet on "Municipal Lighting," in America we gather that, although the price charged for the light differs greatly in different places, it is always much less than the price of gas, and is supplied by the local authorities at about half the price charged by any private company. The accounts from all these places speak enthusiastically of the electric light.

Of course our expectations in this country are not based on what has happened in America, where the conditions are peculiarly favourable to the electric light. We shall have to rely at present more on its intrinsic merits and the preference of those who are once induced to use it rather than on its superior cheapness. And this being the case, we may be quite indifferent as to whether the earlier installations are undertaken by local authorities or by private companies. The plant and the professional help will be required in either case; and on whichever principle the business is started, if properly gone about, its success is almost certain, and its example is sure to be followed. Not improbably the new County Councils may develop great spending capacity; and it is worth while to remember that under the Electric Lighting Act the local authorities have power to borrow money on terms which no private firm can command. They have, also, the right to oppose any independent application for a provisional order within their district, and would probably do so effectually; for the Board of Trade are ordered by the Act to give preference to the local authorities, and will doubtless interpret this clause very broadly in their interests. This year's Amendment Act betrays the same jealous regard for local authorities; the first clause making it quite clear that, without their consent, practically the Board of Trade cannot grant a provisional order. This being the case, electric lighting undertakers will do well to make friends of the local authorities and not attempt to do anything over their heads. The list appended of towns in the United Kingdom, excluding the metropolis, where public electric lighting has already been established by or at the invitation of the local authorities, or where the negotiations are in an advanced stage, may be studied with advantage in this relation.

THE TESTING OF ELECTRICAL INSTRUMENTS AND APPARATUS IN THE JOHNS HOPKINS UNIVERSITY.

The following important notification has been issued by the Johns Hopkins University:—

In order to bring electrical measurements to a greater uniformity and accuracy, it has been decided to undertake at this University the comparison of electrical instruments and resistances, together with such tests as cannot be made without special or elaborate apparatus with which private individuals are not usually provided.

The rapid advance of electricity in this country—an advance which cannot but react favourably on physical research—and the necessary increase in the number of electrical instruments for measurements, make it important that means be provided for standardising these instruments, especially as their constants vary from time to time. There are many institutions also whose apparatus could be used for accurate experiments, provided the instruments could be compared with standards. Few laboratories contain the apparatus necessary for such comparisons.

Digitized by Google

This laboratory offers unusual facilities for the standardising of electrical instruments as well as for general physical work. Having been built especially for physical research, under the direction of Prof. Rowland, it has been provided with every requirement that experience and ingenuity have devised. In that part of the laboratory in which electrical and magnetic experiments are conducted, no iron nor steel has been allowed to enter into the construction, brass being the metal used. Moreover, the building has been furnished with a series of vaults, in which the variation of temperature is imperceptible, and which are of especial value in the measurement of resistances. Motive power is obtained from an 18 horse-power steam engine located at one end of the building, and current from a set of dynamos of different makers in the same room. The battery room is furnished with fifty storage cells, as well as a large number of the ordinary Bunsen and Daniell cells. Special dynamos have been provided for testing work, one giving continuous currents up to 400 amperes, the other giving electromotive forces to 1,000 volts.

Electrical Instruments.

The following is a description of those standard electrical instruments which will be used in the tests :—

Dynamometers.—The larger dynamometer is a very massive and sensitive instrument, made by Prof. Rowland for his recent Government work on the "Unit of Resistance." It differs in general plan only from the British Association instrument. The suspended coil is single, but the fixed coils, of which there are two sets, are double as in the Helmholtz arrangement. One set of coils is wound with heavy wire for the measurement of large currents, and one set with smaller wire. The coils of each set are at a distance apart equal to their radii respectively. This instrument will measure accurately currents ranging from 4 amperes to 10 amperes.

The smaller dynamometer is almost exactly like the British Association instrument, of which an excellent illustration, as well as the theory of the apparatus, is given in Maxwell, Vol. II., p. 337. With this dynamometer currents from a fraction of a milliampere to 4 amperes can be measured.

The constants of these instruments have been obtained by careful measurements and by comparisons with standard coils. On the former, particularly, the work has been done with the greatest possible care, and it is perhaps the most accurate current measuring instrument in existence.

Electrometers.—Of these there are two, and similar instruments have been so often described in electrical text-books that only a few words are necessary here. They are both of the Thomson form, and known respectively as the Thomson quadrant electrometer and the Thomson (or absolute) suspended-disc electrometer. The latter, however, was made from special designs, and a few important modifications of the original apparatus (Maxwell, Vol. I., p. 304) have been introduced. With this instrument electromotive forces from 1,000 volts upward can be determined, and the electrometer has been employed in several important researches.

Wheatstone's Bridge.—For resistance measurements Fleming's modified form of Wheatstone's Bridge will be used. In this apparatus the two fixed and equal arms are connected by a platinum-silver wire bent into a circle and provided with a scale alongside. The ratio of the arms is changed by making contact at different points along the wire. When the fixed coils are each one ohm, a change of one whole scale division gives a change of 1 part in 10,000 in the ratio, and by using a suitable galvanometer a change of 1 part in 100,000 can be detected.

Resistances.—The standards of resistance have been accurately determined by Lorenz's method in absolute measure, and by a modification of Kirchoff's method. They have also been several times compared with the British Association Standards at the Cavendish Laboratory. For measurements of current a fixed resistance has been prepared. This consists of three strips of German silver 4½in. broad by ·036in. thick, the ends of which are hard soldered into massive copper blocks. The whole is immersed in a tank of refined petroleum. To the copper blocks wires are permanently soldered, and to these the galvanometer leads can be fastened. When in use the oil is stirred, and its temperature noted from time to time.

Galvanometers.—The laboratory is provided with a number of galvanometers for various uses, some of which have been constructed for special work.

Thermometers.—There are several thermometers in the laboratory whose range is from 0 deg. to 100 deg., which have been directly compared with the air thermometer, and others for which indirect comparisons have been made. Tables have been constructed for all of these, and their indications are correct to within ·003°C.

Methods of Measurement.

Current.—For measuring currents up to ten amperes the electrodynamometers will be used, one or the other. For currents from 10 amperes to 400 amperes the "fixed resistance" method is used, the apparatus being calibrated before each measurement by comparison with the large dynamometer. This method has been used for measuring heavy currents at the Munich, Vienna, and Philadelphia Expositions ; a full description of the method of using it in the Philadelphia Exposition—where it was much improved—will be found in the *Journal* of the Franklin Institute, October, 1885. Briefly it consists in comparing the difference of potential at the terminals of a fixed resistance when a known current and the current to be measured are passing respectively. To the copper blocks in the fixed resistance before described are joined the terminals of a galvanometer, in whose circuit is a resistance box. A known current measured by the large dynamometer is first sent through the "fixed resistance," and the resistance box adjusted until a convenient deflection of the galvanometer is obtained. Then the current to be measured is sent through the fixed resistance, and the box is again adjusted until the deflection is nearly the same as at first. We have then, neglecting temperature corrections,

$$C = C_0 \frac{R}{R_0} \cdot \frac{d}{d_0},$$

where C_0 is the current corresponding to resistance R_0 and deflection d_0. In the actual observations of course the temperature of the different parts of the circuit are noted and corrected for. The only possible errors in this method outside of errors of observation, which are negligible, are in the current used for calibration, in the resistance box and in the temperature of the fixed resistance. The first of these measured by the dynamometer is correct to within one part in 2,000 ; the resistance box with the facilities at hand can be determined to one part in 5,000 ; and the temperature of the strip is known very accurately, there being no perceptible heating even with the heaviest current used ; moreover the temperature is certainly known to a few tenths of a degree, and one degree would cause an error of only one part in 3,000.

This method of measuring current possesses advantages over any tangent galvanometer, however accurately the measurements of the latter are known, since the constant of a galvanometer involves a determination of H, the horizontal component of the earth's magnetic force, a quantity more difficult of accurate measurement than is an ordinary current. In calculating current measuring instruments, they will be put in series with the fixed resistance and simultaneous readings taken with different current strengths ; and for smaller currents—below 8 or 10 amperes—they will be joined in series with one or the other of the dynamometers and measurements made directly.

Potential.—For potentials between four volts and 1,000 volts the instruments will be compared with a galvanometer which has been calibrated by connecting the ends of its circuit to the terminals of a fixed and known resistance, through which is flowing a known current. The resistance used for this purpose is of bare German silver wire immersed in oil, and its value known to 1 part in 10,000 ; the current is measured by one of the dynamometers. In the galvanometer circuit is a high resistance box, whose coils have been compared previously. If it is desired after calibration to measure a higher potential than was used, the resistance of the circuit is increased ; for a lower potential it is decreased. If E_0 is the difference of potential used for calibration, R_0 the resistance of galvanometer and leads, and d_0 the deflection, then the potential corresponding to any other deflection d and resistance R is, if we neglect temperature corrections :—

$$E = E_0 \frac{R\,d}{R_0\,d_0}.$$

For electromotive forces less than three or four volts a quadrant electrometer standardised by a Clark cell—of which there are a number in the laboratory—is used, and comparisons made directly with it. For instruments measuring very high potentials of several thousands of volts—electrostatic voltmeters, &c.—the absolute attracted-disc electrometer before described will be used, the necessary electromotive force being furnished by a modified Holtz machine.

Resistance.—Measurements of resistance will be made in the vault beneath the laboratory, whose temperature is practically constant. Boxes to be compared are placed in the vault at least 24 hours before any measurements are made, and standard resistances are immersed in water for at least an equal time, in order to allow all parts of the apparatus to acquire exactly the temperature of the vault. The Fleming bridge, described under the head "Instruments," will be used for comparing the resistance boxes. This apparatus is the one which was recently employed in the determination of the ohm made at the University.

In giving the values of resistances, results will be expressed in terms of Legal or British Association units, as desired, together with the value in *true* ohms, as determined from the most accurate measurements that have been made.

A special bridge has been constructed to measure small resistances by an arrangement of Sir William Thomson's method, known as the method of auxiliary conductors.

Digitized by Google

Capacity.—For the purpose of determining the capacity of the condensers ordinarily used in measurement, J. J. Thomson's modification of Maxwell's method (*Phil. Mag.*, August, 1884) will be used or they will be compared *directly* with a standard condenser. For small capacities comparisons will be made with an accurately known air condenser in the possession of the laboratory.

Efficiency of Dynamos.—The efficiency of dynamos ranging from one to twelve horse-power will be obtained from measurements of power by a Tatham transmission dynamometer, and of current and potential by the methods described above under their respective headings. The dynamometer is similar in principle to the larger one used at the Philadelphia Electrical Exhibition, which was accurately checked by a determination of the mechanical equivalent of heat. The value deduced from its records was 772·8 foot lbs. Fah., a value agreeing very closely with the most recent determinations. In all cases the dynamo will be run at its normal output until the effects of heating have become constant, both as regards the results of mechanical friction, and the rise of temperature due to the current. It will be possible not only to determine the efficiency with full load, but also with varying loads if desired.

Efficiency of Motors.—Tests of the efficiency of motors from 10 horse-power to 2 horse-power will be conducted in exactly the same manner as in the case of dynamos, and the same precautions to insure accuracy will be observed. The efficiency of motors below 1 horse-power will be determined by calorimetric methods by measuring the losses when running. For this purpose the motor will be enclosed in an air-tight box surrounded by a water-jacket, through which water runs in a constant stream. From the heating of the water when the motor is running the efficiency can be immediately calculated. The result gives the commercial efficiency, since all losses due to heating are measured.

ON THE USE OF BISMUTH AS A SIMPLE MEANS OF MEASURING THE MAGNETIC FIELD.*

BY DRS. LENARD AND HOWARD.

When metallic bismuth is placed in a magnetic field it is found to possess many remarkable properties which are not found in any other metals, or, at any rate, not in nearly such a marked degree. One of these peculiarities, which was discovered by Righi, is the increase of electrical resistance which it undergoes. Leduc has made use of this property for the purpose of measuring the strength of magnetic fields, and his method, from its accuracy and simplicity, appears to be an extremely valuable one for technical measurements. We have recently made several experiments of this character, a description of which may be interesting. The metal we used was in form of wire, and wound in a non-inductive spiral. When warm, bismuth can be squirted into wire just like lead. When newly made, especially if still warm, the wire can be fairly easily wound without breaking, though it becomes very brittle with age. For insulation we use two or three coats of thick collodion, which very quickly dries, and forms a thin but perfectly insulating and very strong covering. To wind the spiral two pins were fixed in the middle of a thick plate of lead, which was kept at a temperature of 70° C.; the middle of the wire was looped over one pin, and then the whole length wound up into a flat spiral, and consolidated by a few coats of some quick drying mucilage. Two strong copper electrodes were soldered on with Rose's metal, and finally the spiral was protected between two plates of mica. A convenient size is a spiral of 2 cm. diameter by 2 mm. thick, formed of one metre of wire; this will measure about 10 ohms—a convenient resistance for bridge measurements. On a field of 17,000 C.-G.-S. units per sq. cm. the resistance of our spiral increases nearly twofold; this is a greater increase of resistance than has ever been noticed before, and is due probably to the molecular structure of the squirted bismuth, and partly to the fact that the insulating film is of very low thermal conductivity.

For as Ettingshausen and Nernst have shown when an electric current is sent through bismuth at right angles to the lines of force passing it, a difference of temperature is set up in the bismuth, and thereby a thermal back E.M.F. is set up, which in the bridge measurement appears, of course, as an increase of resistance. If by any means the spiral is kept at an even temperature, this spurious part of the increased resistance is avoided.

The method is of course not an absolute one and can only be made use of by first observing the increase of resistance due to magnetic fields of known strength and curving, the results a_s in Fig. 1.

The ordinates are the various values of $\frac{R_2 - R_1}{R_1}$ when R_1 = ordinary resistance, and R_2 resistance under action of the field. The abscissæ being taken in absolute C.-G.-S. units; the curve G is for a wire measured by a galvanometer, and T the same measured by telephone. This greater resistance, when measured by telephone, is quite independent of the nature of the current, whether intermittent-direct or alternating.

For comparison the curves E E and L L are given. The first pair are those obtained by Ettingshausen and Nernst, from two cast plates of specially pure bismuth; the second are the extreme curves obtained by Leduc with electrolytically deposited metal. Care must be taken that the bismuth employed is free from tin, as even a few tenths per cent. diminishes the effect very considerably. For exact measurement each spiral should be separately calibrated, for which, however, only two readings are necessary, as Leduc's equation for increase of resistance of plates is also true for spirals.

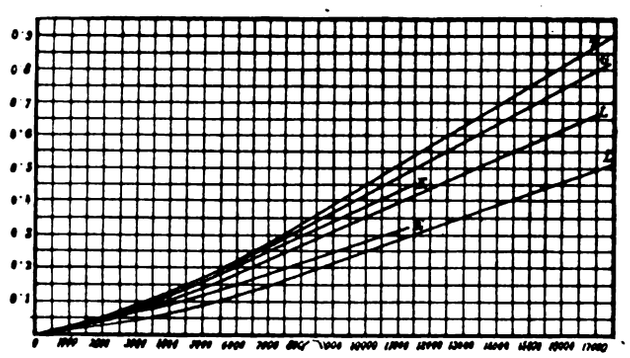

FIG. 1.

We also tried whether the spirals altered their constant with time, but no alteration was apparent in nine months. The mean temperature coefficient between 0° and 36°C. was 0·52 per cent., an impure sample tried having a coefficient of 0·21 per cent. This bears out Leduc's experiments that the temperature coefficient is positive with compressed bismuth. On the other hand, Ettingshausen and Nernst have shown that bismuth, when solidifying free from pressure, decreased in resistance with rise of temperature. In measuring dynamos care must, of course, be taken to prevent any rise of temperature in the spiral due to the dynamo itself being hot. In this case the measurement must be made very quickly, and it is as well to protect the spiral by a sheet of tin foil, for Righi has shown that at high temperatures bismuth loses these peculiar properties, as well as other magnetic ones. It is important that the plane of the spiral should be as nearly as possible at right angles to the lines of force. Within small limits the effect is not much decreased, but is diminished to half when the plane of the spiral is parallel to the lines.

* Abstracted from *Elek. Tech. Zeits.*, No. 14, July, 1888.

AMERICAN MODEL SPECIFICATIONS.*

CENTRAL STATION ARC LIGHTING.

HIGH-SPEED STEAM PLANT.

Engines.—Twelve engines of 125 horse-power each, engines to be of high speed, automatic cut-off, with hammered wrought-iron or cast-steel shafts. Each engine to be provided with throttle valve, two band wheels turned true and balanced, oiling devices of the most approved type, consisting of side feed lubricator, sight feed oil cups with stands, needle valves and wipers, full set of wrenches, foundation rods, anchor plates, &c., to cover complete engine ready to receive steam and exhaust pipes. Each engine to have a heavy cast-iron self-containing sub-base or coping stone. Said engines must develop the given horse-power under an initial pressure of eighty pounds to the square inch.

Boilers.—Twelve tubular boilers, each seventy-two inches in diameter, containing sixty-four four-inch tubes, sixteen feet long,

* From "Municipal Lighting," by F. H. Whipple, Detroit.

Digitized by Google

with shell extension of not less than twelve inches. Each boiler to be provided with two manholes, one located on top of shell at rear end, the other in front of heads below the tubes, said manholes to be not less than ten inches by sixteen inches. The material for shell to be best quality homogeneous flange steel, sixty thousand tensile strength per square inch of section, and not less than three-eighths of an inch in thickness. Material for heads to be of same material and of same tensile strength, and of not less than nine-sixteenths of an inch in thickness.

Nozzles.—Each boiler to be provided with two nozzles riveted to shell, and of proper size for steam pipe and safety valve connections, and of not less than six inches in diameter.

Bracing.—Heads to be thoroughly stayed to shells by long overlapping braces. Each stay-rod to be made of best Swedish iron of not less than one inch in diameter, and attached with solid crowfoot and strap head properly riveted to heads and shell plates.

Seams.—Seams to be tight fitting, and rivet holes punched to line true one with the other, and no drifting allowed to force holes in line. Holes out of truth to be reamed with sharp-edged cutting tool and rivet fitted to hole and driven straight and true. All joints to be planed or chipped and caulked. All longitudinal seams to be double riveted.

Testing.—Each boiler to be tested to one hundred and fifty pounds per square inch hydrostatic pressure.

Boiler Fixtures.—Each boiler to be furnished with a full line of fixtures complete, including full fire fronts, liners, grates, and bearing bars, return draft arch, ash doors and frames, wall binding rods and back stays, cast-iron wall brackets for supporting boiler, with wall plates and expansion rollers, all necessary gauges, steam and water stop valves, blow off check and safety valves, and firing tools. Each boiler to be set in separate arch and to be entirely independent of others.

Pumps.—Two duplex steam lift and force pumps, each capable of supplying twelve boilers of a capacity of one hundred and fifty horse-power each.

Injectors.—Two injectors as auxiliaries to steam pumps for feeding boilers, each capable of delivering 7,500 gallons of water per hour at a steam pressure of eighty pounds.

Heaters.—Two brass tube feed water heaters, each capable of supplying a boiler capacity of eight hundred horse-power.

Furnaces.—Twelve furnaces (state whether with or without automatic feeders and stokers), placed under boilers in batteries of six each, connecting with a brick chimney eight and one-half feet inside diameter and not less than one hundred and forty feet high. Said furnaces to be erected by the bidder, with the chimney.

Grates.—Grates to be either rocking or stationary (state which), and not to have less than fifty per cent. air space, with openings of not more than one-half inch.

Steam Piping.—From boilers to engines one main line of steam pipe, with straight-way stop valve, pipe to be of sufficient diameter to supply twelve engines, each of 125 horse-power, with branch pipes of sufficient diameter for each engine, in each of which there is to be straight-way stop valves. In leading pipes from boilers to main line there is to be straight-way stop valve placed near connection of said pipes with boilers.

Exhaust Pipes.—The exhaust pipes of each engine to be run to a main exhaust pipe leading to heaters, and this main pipe to be of sufficient diameter to allow of free exhaust from eight hundred horse-power. Straight-way valves shall be placed in each branch exhaust pipe leading to the main. From each heater there is to be an exhaust pipe leading to top of building of not less than sixteen inches diameter.

Water Pipes.—Steam and water pipes between main steam lines and pump and injectors, and all water lines between waterworks connection to conform to tabulated sizes required for pump as heretofore specified.

Protection.—All steam exhaust and water pipes to be thoroughly protected with sectional pipe covering.

Duty.—The bidder to estimate on preparing all foundations and masonry and to deliver, erect and connect all engines, boilers, heaters, pumps, &c., and turn the steam plant complete over to the purchaser ready for duty.

Estimates to be in detail, stating name and kind of each article and price, and guarantee amount of fuel per horse-power delivered.

CORLISS STEAM PLANT.

Engines.—Three compound condensing Corliss engines, each capable of developing six hundred horse-power, with a boiler pressure of ninety pounds. The material and workmanship to be first class in every respect. Bidder to state diameter and stroke of cylinders, diameter and length of engine shafts, diameter and length of main bearings, diameter, face and weight of fly-wheels. Each engine to be provided with a full set of graduating oilers, sight-feed cylinder oiler, and set of hand oilers with tray. The oilers to be so arranged that they may be refilled while the engine is in operation.

Air Pumps and Condensers.—Three air pumps and condensers of the spray or jet type, each to be connected to one of the above engines and to be of proper capacity for the engine. Bidder to state diameter and stroke of air pump, diameter of suction and overflow pipes, and state whether the air pump is driven by belt, connecting rod, or independent steam cylinder.

Boilers.—The boilers (state kind) to be of sufficient capacity to furnish the steam required to run the above engines up to 1,800 horse-power, each boiler to be as follows: Sixty inches diameter, sixteen feet long, containing forty-four tubes, four inches in diameter; shell of boiler eleven thirty-seconds of an inch thick; heads one-half inch thick; dome thirty inches in diameter by forty-four inches high, double riveted to shell; shell of dome five-sixteenths of an inch thick; head of dome seven-sixteenths inch thick; all to be homogenous steel, 60,000 pounds tensile strength. Longitudinal seams of boiler and dome to be double riveted. Two cast-iron brackets, riveted to each side of boiler. Boiler to have one manhole on top of shell and one manhole in front head under the tubes. One full front with anchor bolts, five feet grate bars, bearing bars, liners, ash door and frame, back plate for arch, binder bars and rods. One set of boiler fixtures, including three inch pop safety valve, two inch blow-off cock, one and one-half inch feed valve, one and one-half inch check valve, steam gauge, glass-water gauge and gauge cocks. Suitable breeching of No. 12 iron to connect all the boilers to brick stack.

Steam Pumps.—Two steam pumps, each large enough to feed the boilers required to run two of the above engines.

Piping.—All necessary pipes and valves inside of boiler and engine house to connect above engines, condensers, boilers and pumps. The steam pipe from all the boilers to be connected to one header. From this header one supply pipe to run each engine. The exhaust pipes to be so arranged that the engines can be used non-condensing when necessary.

Shafting, &c.—(State whether one or two) line shaft of suitable diameter and length to drive forty dynamos, each of thirty arc light capacity. A suitable number of ball and socket pillow block bearings to support above shaft. Three main driving pulleys, one to be driven by each engine, these to be arranged with hollow sleeves and jaw clutches. Forty friction clutch pulleys, each of proper size to drive one dynamo, each clutch to be provided with a lever for throwing clutch in and out.

Belting.—(State whether one or two) belt from each engine fly-wheel to the corresponding driving wheel on line shaft to be best short lap, oak-tanned double leather belting. Forty dynamo belts, one from each of the friction clutch pulleys to its corresponding dynamo, to be best double light leather dynamo belting.

Masonry.—The engines, condensers and feed pumps to be provided with suitable foundations of brick or rubble stone, with cut stone cap stones. The shafting to be supported on piers built of brick with iron cap plates. The boilers to have substantial brick settings. All the inner surfaces of the walls exposed to the flame to be lined with first-class fire-brick.

Tests.—The bidder to guarantee the number of pounds of water evaporated per hour per indicated horse-power required for each engine when developing six hundred horse-power, and also to guarantee the evaporation of the boilers, using (state kind of) coal.

ELECTRIC PLANT.

Dynamos.—Forty dynamos of thirty arc lights each, to be mounted on adjustable insulated bases, with belt tightening apparatus. Each dynamo to be provided with approved lightning arresters, automatic regulator, to fully govern and control the current, and regulate the same in proportion to the number of lamps in operation, from one lamp to the maximum capacity of machine, a test of twenty-four hours to be guaranteed. Each dynamo shall be provided with approved ampere-meters, and the terminals shall be taken to suitable switch-boards, so arranged as to enable the operator to manipulate the dynamos and circuits at will, with the least possible opening of circuit. Bidder to state lowest guaranteed horse-power required in each arc and to drive each machine. Lamp magnets and dynamo armatures must be guaranteed against burning out from short-circuiting of the current for two years. Dynamos shall admit of being coupled together to operate any multiple of their capacity.

Lamps.—One thousand double carbon, standard 2,000 candle-power arc lamps, each lamp to have automatic cut-out, and hand switch, with lifting and sustaining magnets of sufficient strength to enable the use of carbons one-half inch in diameter if desired; said lamps shall be thoroughly insulated and protected from the weather by hoods or other devices; bidder to state the nature of such devices. Bidder must state the number of amperes of dynamo running under normal condition, also the voltage per lamp.

Digitized by Google

Line Wire.—(State number) miles of No. 4, 5, or 6 B. and S. Gauge copper line wire, water, weather, and fire proof insulation, said wire to be subject to test of twelve hours under water, after which it must show (state) resistance, and shall be tested from reel supplied for work. Said wire shall not be less than 98 per cent. pure copper. Every joint to be soldered and wrapped with tape.

Poles.—Four thousand forty-five foot cedar poles, not less than six inches in diameter at the tip. Said poles shall be set six feet in the ground and covered with preservative, and the part above ground trimmed and painted with two coats of paint.

Cross Arms.—Six thousand four-pin cross arms, four and one-half by five and one-half inches by four feet in length, free from knots and cracks, and painted with two coats of paint.

Insulators.—Twenty-four thousand deep groove electric light insulators.

Pins.—Twenty-four thousand one and one-half inch standard locust or oak pins, painted with two coats of paint, also end protectors for arm of one-inch strap iron, one-quarter inch thick, to prevent end wire dropping into street in crossing.

Belting.—Belting to be leather and endless.

If the lights are to be placed upon poles, insert the following :—

Poles.—One thousand thirty-feet iron (or wood) ornamental poles with steps.

Or, if over street intersections, insert this :—

Intersections.—One thousand mast arms, arches, or other devices (state which), capable of holding the lamps forty feet high at street intersections.

If towers are desired, insert this :*

Towers.—One hundred standard one hundred and fifty foot electric light towers, description to be stated, with supports for six lights each ; one hundred standard one hundred and fifty foot electric light towers, with supports for four lights each.

Plant Complete.—The bidder to bid on furnishing the above plant complete in every particular, furnish all labour, including superintendence, and construct and build the circuits, &c., and turn over to the city ready for duty. Bids to be in detail, stating name and kind of each article and price.

Maintenance.—Bidder to accompany bid with a schedule showing the number and approximate salary of labour required and other cost of maintaining the complete plant per year, each item to be carried out in detail. The cost of steam and electrical plants to be kept separate where bidder is estimating on entire specifications.

Where the wires are to be placed underground, the specifications should provide that :

The cables shall have a carrying capacity equal to No. 4, 5, or 6 B. and S. gauge wire, bidder to give price on each. Said wire shall be thoroughly insulated and character stated. The cables shall have an insulation resistance of not less than ten megohms per mile when laid in the ground. The contractor must estimate on digging all trenches, furnishing all appliances, stating their nature, removing and repairing paving, and laying cables ready for use, guaranteeing them for at least two years.

ISOLATED INCANDESCENT PLANT.

Dynamos.—One dynamo capable of generating current for 250 incandescent lamps of sixteen candle-power each. The dynamos to set upon insulated bases and provided with belt tighteners and to be capable of generating the current as stated, for a period of at least twelve hours' continuous running daily, without excessive or abnormal heating or sparking at the commutator brushes, or unduly heating the journals. Ths dynamos will be practically automatic, and capable of permitting any number of lights to be turned on or off at will without affecting the others in use.

Lamps.—Two hundred and fifty lamps of sixteen candle-power. Bidder to state price of lamps for renewals.

Sockets.—Two hundred and fifty sockets for lamps.

Electrical Appliances.—Necessary rheostats for setting the candle-power of the lamps ; same to be of sufficient capacity to control the E.M.F. of dynamos without unduly heating. The rheostats to be connected with dynamos with good insulated copper wire ; necessary balancing rheostats for enabling dynamos to be operated in parallel (multiple arc) ; necessary potential indicators to put in the lamp circuit and remain continually in such circuit, to indicate clearly at all times electrical pressure at which lamps are being operated ; necessary ampere-meters to be also put into the circuit to correctly indicate the number of lamps in operation, and to denote any changes in the number of lamps burning ; necessary ground detectors to show instantly the location of any ground on the circuit ; necessary switches and switch-boards. All to be erected and properly connected and made ready to be attached to the power provided for.

* It should be borne in mind that if towers are used the number of lights necessary will not be so large as by the pole or intersection systems.

Wiring.—Furnish a complete system from the dynamo to the main switch or switch-board (as the case may be), and from the main switch (or switch-board) to the point of distribution, the mains to have sufficient conductivity to operate 250 lamps of sixteen candle-power. The wiring to be calculated and put up so that the loss in electrical pressure shall not exceed 5 per cent. between the dynamos and the lamps when the full number of lamps are burning. The mains to be of the best quality of copper, 98 per cent. conductivity, and of the best insulation. Mains to be put up in good and substantial manner, and have double-pole safety devices inserted where leaving the main switch (or switch-board).

Branch Wiring.—All branches from mains will be attached thereto by means of good soldered joints, and such joints will be thoroughly protected by insulating with some standard compound. Double-pole safety devices will be inserted at convenient points near the attachment to mains. The branch wires to be of best quality copper. The branches to be so calculated and put up that not to exceed 5 per cent. shall be lost in overcoming the resistance from the mains. The entire loss of current in mains and branches will not exceed 5 per cent.

Lamp Attachments.—Furnish suitable ceiling rosettes and affix same to the ceiling where lamps are to be suspended, and suspend the lamps from such rosettes by means of insulated flexible copper cord, and properly attach lamps thereto at such height from the floor as will be required, or attach lamps to such fixtures as may be provided by the purchaser.

Labour.—Furnish all necessary labour to fully erect the plant complete.

Miscellaneous.—The bidder will guarantee the plant to work properly and that the lamps will burn steady and not blacken.

Maintenance.—Bidder to accompany estimate with a schedule showing the number and approximate salary of labour required to run this plant ; also the cost of maintaining this plant per year, each item to be carried out in detail.

REVIEWS.

Principles of Dynamo-Electric Machinery, and Practical Directions for Designing and Constructing Dynamos. By CARL HERING. (New York : W. J. Johnson. London : 1, Salisbury-court, Fleet-street, E.C.)

The subject matter of this volume has for the most part appeared as a serial in the *Electrician and Electrical Engineer* of New York, and, therefore, must be taken as being fairly well known, even on this side of the Atlantic, where our contemporary has a considerable circulation. Serial articles in a technical journal are, however, not in a very convenient or accessible form for reference, and, without doubt, Mr. Hering and his publishers acted wisely in issuing these articles in book-form.

The dynamo has inspired many pens, and has already an extensive literature of its own. but we can only call to mind two works the positions of which on our shelves are known to us. One is Prof. Thompson's substantial volume, the other Mr. Kapp's smaller work on a separate department of the subject. Mr. Hering's book is intended for the workshop rather than the study, and probably contains in a well-digested form the practical rules followed in American factories, and will be found interesting and suggestive by all those who are commencing their dynamo education.

The author explains in his preface that he aims at securing readers amongst builders and attendants of dynamos, amateurs and students, and not amongst experts, physicists or theorists ; and taking it at this valuation there is very little cause to complain of the manner in which his readers' wants have been provided for. The book contains a very great deal of solid practical general information, and a careful perusal of it will do far more than that of any of the "introductory" treatises to prepare an amateur or a student for approaching the more advanced publications. It is only when the author ascends from the "how" to the "why" that he occasionally becomes a little disappointing. Thus, on p. 3 we must object to the statement that "a difference of electrical pressure cannot exist at two points of a conductor without generating a current between these two points." What is meant is, of course, that a difference of electrical pressure cannot exist between two points of a closed circuit without generating a current in that circuit. This is, however, evidently the author's meaning, as appears from a succeeding passage (p. 17).

Digitized by Google

We feel that we can heartily recommend the book to those for whom it was intended, but must express our regret that the author has not gone further, and carried his readers into the more recent theories and laws of construction, based principally upon a better understanding of the magnetic circuit and its resistance.

He alludes to recent work, certainly, but only to say that "until such theories have been thoroughly tested by repeated and varied applications in practice, and are reduced to such a form that they may be readily applied, the constructor of dynamos is recommended to use the well-tried but less direct methods." This regret is the keener as we feel that this task of making recent work easily intelligible to all is one for which the author is very well qualified; and with the large amount of practical constructive detail at his command the work of trial and proof of the methods should not be difficult.

We notice (p. 55) a statement, to which we call the attention of constructors, that the thin layer of blue oxide on iron sheets used for armatures should be removed by pickling, as it retards magnetisation and demagnetisation, and an experiment is described in support of this view. We always considered thin oxide as an advantage rather than a source of loss, on account of its insulating properties. The fact that it is the magnetic oxide (Fe_3O_4) may cause a slight loss, but it never occurred to us that its amount could be appreciable, and we shall be glad of further information on the subject from those who have experience.

THE HOLOPHOTOMETER, WITH STAND.

We described in our last issue the principle upon which this instrument is based, and the method of its use. We now illustrate the practical form of the holophotometer as made by the Woodhouse and Rawson Company. It will be seen that the instrument is mounted upon a stand, which moves freely on three castors, E, and after being placed in position is fixed by means of three screw-pins, D, which also serve for levelling purposes.

The solid casting (into which the support of the instrument slides) is capable of considerable vertical movement, so as to suit any height of photometer disc. The fly nuts A serve to clamp it firmly at the required height.

The whole body rotates about a centre pin moving in the casting; and the exact position of the arm at right angles to the upright is ensured by the pin B, which drops into a conical slot in the casting.

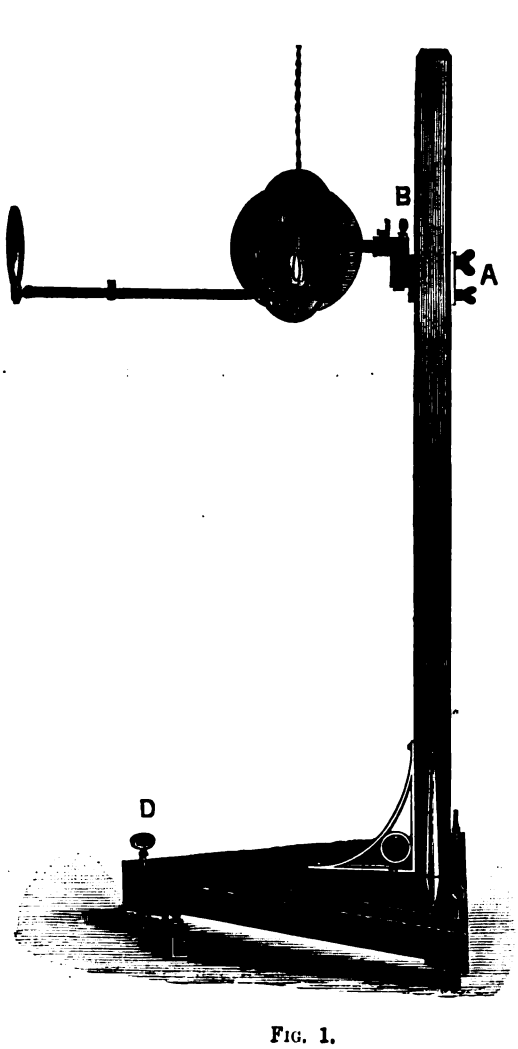

Fig. 1.

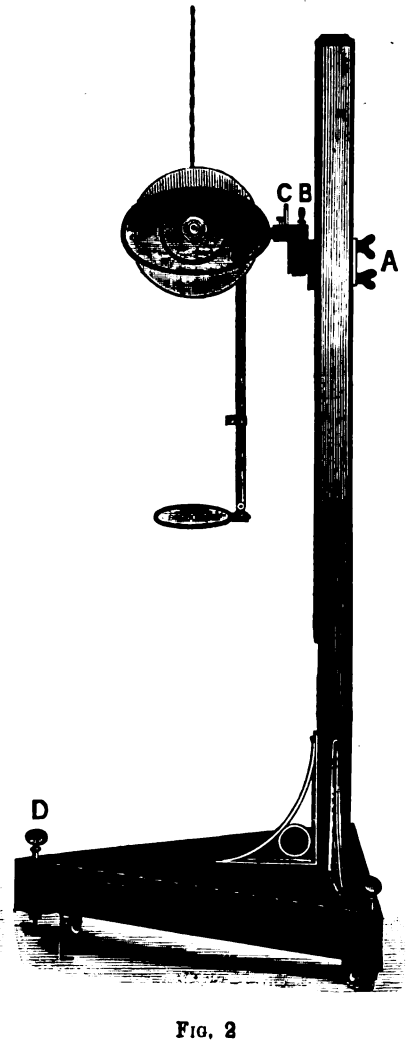

Fig. 2

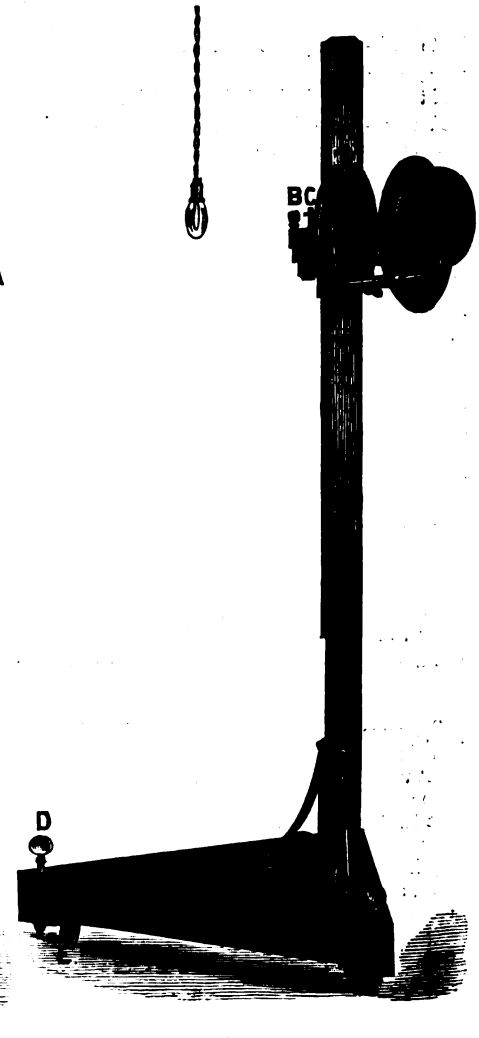

Fig. 3.

Rotation of the arm is prevented by the pin C and the adjacent set screw.

Fig. 1 shows the instrument as seen from the photometer disc, the rotating arm being in a horizontal position, and consequently the image in the mirror is a horizontal image of the incandescent lamp suspended behind.

Fig. 2 shows the arm vertical, and the image that of the lamp as seen from below.

Fig. 3 shows how the whole instrument is turned about B, so as to enable the direct horizontal light of the lamp to be measured in estimating the absorption of the mirrors.

LETTERS FOR LEARNERS AND UN-PROFESSIONAL READERS.

BY H. D. WILKINSON.

CHAPTER IX.—*Magnetic Fields.*

(Continued from page 445.)

123. *Graduation of Tangent Scale.* — It has already been shown (para. 98) that in a figure such as Fig. 90 distances measured from A along the line A B are proportional to the tangents of the angles which those distances subtend. For example, two equal angles are drawn at C (Fig. 90); the tangent of the first angle is proportional to A D and that of the two together to A E. It is evident that when the force by which a magnetic needle is deflected (from a zero position

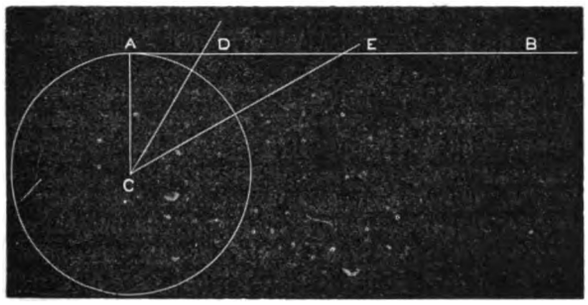

FIG. 90.

at A C) is proportional to the tangent of the angle of deflection, that it requires *more than* twice the force to move the needle through twice the angle, for A E is more than double A D. The object, then, of dividing out a scale in tangent divisions is to make the divisions proportional to the force moving the needle. This principle is shown in Fig. 91, where the distance A E is divided into two equal parts at the point F. Now, on drawing F C the scale is divided into divisions proportional to the force exerted on the needle; that is, the force which would move the needle from the direction A C to that of C E would be just double that required to move it from A C to C F, the needle turning, of course, about the centre C. The method is therefore to mark out a number of equal divi-

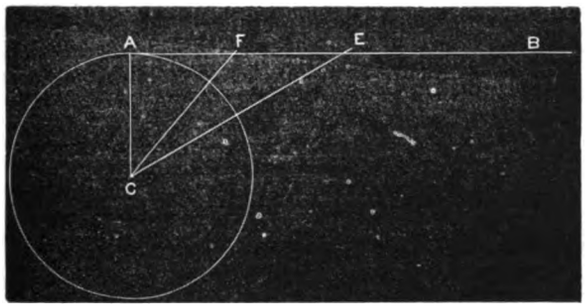

FIG. 91.

sions on the line A B, starting say from A, and then to draw lines from these divisions to the centre C, dividing the circular scale into divisions proportional to the tangents of the respective angles, and therefore proportional to the forces exerted on the magnetic needle. It only remains to decide as to the size of each division on A B. In the case of tangent galvanometers, the tangent scales of which are generally divided out up to 60°, the line C E is drawn, making an angle of 60° with the vertical A C. The horizontal distance A E is then marked out into 100 equal divisions, and the circular scale is graduated by drawing lines from these equal divisions towards C. This process is shown in Fig. 92, where it will be seen that the divisions become very crowded near 100, and it is useless to carry them beyond 60°, therefore it is usual to divide the scale on the opposite side of the circle in degrees of arc up to 90° on each side, by which means angles of deflection higher than 60° may be read off on the degree scale, and the tangents found by reference to tables. Now it should be understood that the numbers marked out are not the *actual* tangents of the angles, they are simply *proportional* to the tangents, for in the comparison of currents by the tangent galvanometer the actual or natural tangents are not required. With the instrument at present before us, however, we shall require for some measurements the natural tangents of the angles moved through by the needle, and therefore the scale is graduated in a different manner. The angle of 45° is selected as the standard (Fig. 93), and the distance which it cuts out on A B is divided into 100 equal parts, the scale being graduated by lines drawn towards

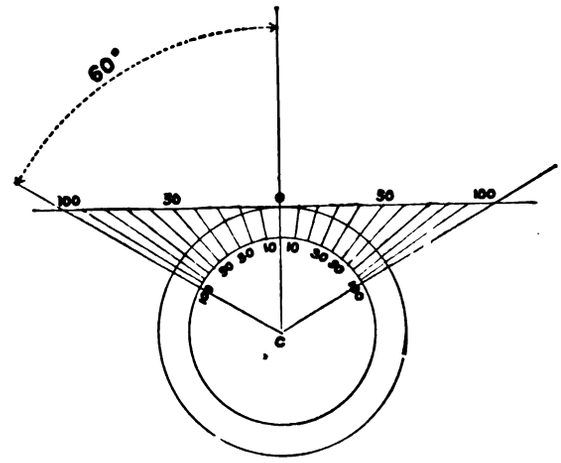

FIG. 92.

the centre as before, and the same numbers marked on the circular scale as exist on the divided line A B. Now, since the tangent of 45° is unity the natural tangent for this or any other angle is found by dividing the scale-reading by 100 —that is, moving the decimal point two places to the left. Suppose we had a deflection of 85 divisions; the natural tangent of this angle is ·85 and the angle itself need not be

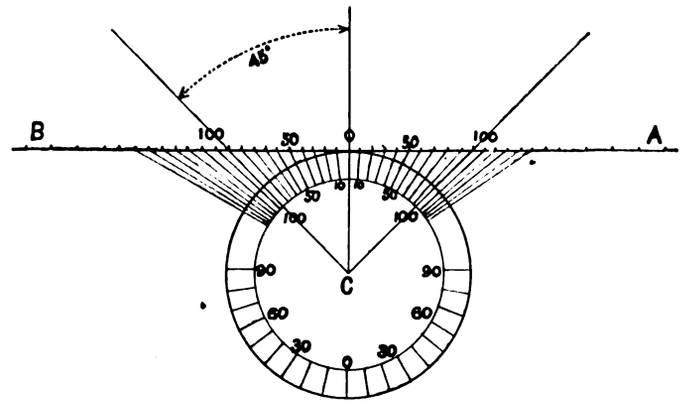

FIG. 93.

known. The line A B is marked out on both sides up to about 60° or 70°, the length of each division being the same all along. A straight rule is then placed in line between each division in succession and the centre, and the corresponding scale lines drawn at the edge of the scale circle for each position. The lines may be drawn from each single division near zero, but as the divisions become closer together they may be drawn from every second or fifth division, the intermediate divisions being judged by the observer when taking readings. The other side of the circle should then be marked out in degrees, up to 90° on each side.

124. *Adjustment of Magnetometer.* — To complete the magnetometer and set it up for use the wooden baseboard should have two fine lines *m m* and *n n* (Fig. 94) cut or

Digitized by Google

marked on it accurately at right angles to each other and passing through the centre; a circle should also be described on the board a trifle larger in diameter than the outside diameter of the scale, to act as a guide in placing the scale symmetrically with the centre. The scale is cut out ring shape and placed in position with its zero marks in line with the line *m m* on the baseboard. It is better to let the scale lie loose on the board, as once placed there is nothing to move it, and sticking it down causes bulging. Inside the scale there should be a ring of mirror glass as shown in the figure; this is for the purpose of reading accurately the position of the pointer, the reflection of which is seen in the mirror. At the centre of the baseboard there should be fixed a little brass point standing vertically, only to the height of about $\frac{1}{8}$ inch above the level of the board; this will be found very convenient for levelling the instrument, during which operation

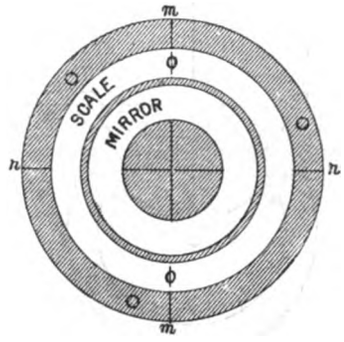

FIG. 94.

the eye may be kept on a level with the surface of the board, and the levelling screws turned till the centre of the suspended needle is seen to hang immediately above the centre brass point, viewed from all sides. The previous directions having been carried out for the removing of torsion from the fibre, the baseboard is placed with the line *m m* as nearly as possible in the magnetic meridian, and the inverted funnel carrying the suspended needle and pointer is then placed on the board, the rim of the same being placed symmetrically with the scale. The height of the needle can now be adjusted by raising or lowering, not turning, the wire suspension head; the stirrup should then just clear the brass centre point. It will most likely be found that the pointer is very near zero, but not quite. To bring it to zero, the baseboard of the instrument must be turned round, little by little, till the pointer is at zero. This adjustment is somewhat tedious, because the needle must be allowed to come to rest between each adjustment, and the slightest movement of the board often sets the needle swinging considerably, and alters the levelling.

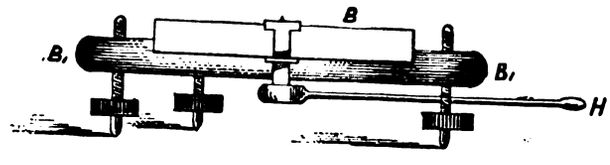

FIG. 95.

This inconvenience may be dispensed with in the following way: Mount the ordinary circular baseboard B (Fig. 95) on a second and larger board, B^1, countersunk to receive it. Attach the levelling screws to the lower board, and let the glass shade carrying the suspended needle rest on this. Through the centre of the upper baseboard fix a brass spindle, so as to enable the board to be turned by means of the level handle H. This lever should not be rigidly fixed to the spindle unless made short enough to work inside the levelling screws. It may be made like a spanner and fit on to a nut head at the lower end of the spindle, and can then be removed when once the instrument is adjusted. The scale and mirror are fixed to the upper board, so that these may be turned till the zero point is exactly under the pointer, while the needle itself and the levelling of the instrument are not disturbed. The brass spindle might also carry the centre point, as shown. Without this elaboration, however, once the adjustment is made it will never require repeating if the instrument is not moved. No magnets or pieces of iron must be anywhere near the instrument during this adjustment.

(To be continued.)

THE TURBO-ELECTRIC GENERATOR.

During the recent summer meeting of the Institution of Mechanical Engineers, which has just been held in Belfast, a discussion arose on the well-known turbo-electric generator made by Messrs. Clarke, Chapman, Parsons and Co., of Newcastle-on-Tyne.

Mr. STURGEON, Birmingham, wished to know whether Mr. Parsons had tried compressed air in his motor. They were wanting a motor in Birmingham suitable for driving dynamos by compressed air for electric lighting purposes. For private electric lighting he thought the best method was to convey the power to the user, and let him make use of it on the spot by some such apparatus as the one described. They should remember that an electric lighting company, supplying the light from a central station, had only the night hours during which to earn its profits, while during the whole of the day it had still to keep up its staff and its plant for the sake of a thousand hours during the year wherein it could turn them to profitable account, and they should consider that by taking power from a general company there were a number of other purposes to which it could be applied, so that they might have something like 3,000 working hours in the day time in addition to the 1,000 night hours every year. In Paris they had already applied compressed air very extensively to electric lighting purposes.

Mr. DAVEY reminded them of Mr. Aspinall's suggestion that the ancients were very prone to copy their ideas. It had occurred to him that a man named Hero, who flourished a century or two before the Christian era, had been copying Mr. Parsons; but he thought they had before them the first successful real rotary steam engine. They had had numerous so-called rotary steam engines, but they had been only reciprocating engines with the reciprocating parts nearly concealed. The Hero engine was a re-action steam engine, and this was an engine following on the lines of the first steam engine. He would like to know to what extent Mr. Parsons had reduced leakage; also whether he had considered the question of adapting the principle to engines of slower speeds. The speed appeared to be too high for general purposes at present. An obvious way of getting out of the difficulty would be by making the machine larger in diameter, more in the form of a fly-wheel. He wished to know whether Mr. Parsons had thought of applying a condenser to his engine, and, if so, what increase in economy might be expected. He suggested the possibility of applying a centrifugal air-pump to the shaft. In the matter of results, if the efficiency of the dynamo was 95 per cent., and assuming 80 per cent. efficiency for the generator alone, they had a total mechanical efficiency represented by 26½lb. of steam per indicated horse-power per hour. That was a very good result for an ordinary engine. Of course, first-class triple expansion and other engines had a consumption occasionally below 16lb., but such a return could not be expected in a new engine of this description.

At the suggestion of Sir Jas. Douglass, the PRESIDENT proposed that the discussion should be adjourned.

The proposition was carried.

The PRESIDENT then offered the opportunity of continuing the discussion to any Dublin man who could not be present in London at its continuation.

The Rev. GERALD MOLLOY, D.D., said he had used this engine to produce incandescent lights very successfully. With regard to the use of compressed air, it struck him that there would be no advantage gained by its use. It would involve the use of steam to compress the air at first, and then the use of the compsessed air to do exactly what the steam was capable of doing directly itself. The commercial efficiency of the dynamo was quoted at 95 per cent. If by commercial efficiency was meant the ratio of the electrical horse-power to the mechanical horse-power, it would be seen from the Paper that this dynamo had the highest efficiency of any dynamo yet produced. The Edison-Hopkinson dynamo, which had been most carefully tested, gave only an efficiency of from 85 to 90 per cent.

Mr. PARSONS, in replying, said that they had not yet tried compressed air. Theoretically they should get a much better duty than with steam, because the speed of outflow would more nearly agree with the speed of the blades. One difficulty that would come in would be that the air would require to be heated to 180deg. or

Digitized by Google

200deg., because in expanding it would cool down. The leakage was the principal cause of loss at present, but no doubt they would be able to reduce that. It occurred between the blades and the sides. The clearance space had been reduced to ·015. There was, however, 15 to 20 per cent. leakage of the whole quantity of steam used. There was no reason why the engine should not be used as a condensing engine. The very high efficiency was due to the high speed. The magnetising current was only about 1 per cent., so that they could afford to have a loss in other places. The largest loss was due to the energy required to magnetise and demagnetise the iron core of the armature, and that was a large loss, and must be got over. The core was composed of thin iron plates about $\frac{1}{100}$in. thick. Mr. Davey was quite right. The efficiency of the dynamo was 95 per cent., and of the engine 80 per cent., and the consumption of steam would be, therefore, 26½lb. per indicated horse-power per hour. The comparative efficiency of the engine is just over 50 per cent.

Mr. DAVEY asked how did Mr. Parsons get the 18lb. Was it by taking the efficiency of the motor at 50 per cent.?

Mr. PARSONS said the theoretical consumption of a perfect engine would be equivalent to 18lb. per indicated horse-power per hour with an initial pressure of 90lb.

The discussion was then adjourned until the London meeting.

THE LEAMINGTON TOWN COUNCIL AND THE ELECTRIC LIGHT.

At the last monthly meeting of the Leamington Town Council the following letter was read on the question of the electric lighting of the town, respecting which there has been so much public discussion both in the Council and in the press:—

"Midland Electric Light and Power Company (Limited),
Leamington, July 31, 1888.

"To the Town Clerk, Leamington.

"Dear Sir: We beg to acknowledge receipt of your favour of the 10th inst., informing us that our letter of the 21st ult. was considered by the Council, and that they have given permission for the erection of four arc lights, by way of an experiment (provided no charge be made on the Corporation), on some spot to be agreed upon, at a height not exceeding fifty feet, but that the Council object to the lights being placed on the Town Hall tower, as they considered the access undesirable, and the height (100 feet) far too great, and believe that a position facing the Parade would be more suitable. The essence of our offer was that the arcs should be placed on the tower, and therefore in a position not absolutely facing the Parade, should be at least 100ft. high, and though lent and fixed by us free of charge, should be connected to the present mains, and the current, therefore, paid for by the Corporation. We may take it, then, that the Council have given us permission to do as nearly as possible the exact opposite of what we offered to do. We do not call in question the wisdom of the Council in wishing to try the effects of four arc lamps of 2,000 candle-power each, placed not more than 50ft. high, and facing the Parade, which at its narrowest point is only 50ft. wide. We only say that we do not wish to try this particular effect a second time at our own expense. We have already at our own expense and on our own property tried the effects of arcs between 30ft. and 50ft. high for street lighting. There is no mistake about the light. Used as we have shown it in Wise-street, it would take the place of ten street lamps. If the Council have not given attention to this particular illustration of the power of electricity as an illuminant, they can see it any night from 9 till 11. But this is an illustration of street-lighting by arcs. What we last offered to do was to give the town an opportunity of seeing street lighting by incandescent lamps in combination with arc lighting of open spaces. The two are quite different problems. We think it extraordinary that so substantial and extensive a building as the Town Hall tower should only be available for the purpose of housing a clock, and we cannot understand how the man who attends to the arcs can do more damage to it than he who attends to the clock; but we accept the decision of the Council, and now withdraw our offer, and we take the opportunity to withdraw also, at all events for the present, our former offer made some three months ago, to bear half the cost of removing the arms that now suspend the 16 candle-power lamps from the posts and to exchange them for upright lanterns and 32 candle-power lamps. Our reasons are these: We find that our motives are not appreciated. We are supposed to be madly desirous for a continuance at any cost of our present contract for lighting the Parade, whereas, as a matter of business, we don't care about lighting the Parade at all. As far as the Parade is concerned, our chief desire was to assist the more public spirited members of the Council in bringing Leamington abreast of the times. The system of lighting recommended by us, we admit, discussed in full conclave and adopted unanimously, does not appear when in practice to please the Council; this is a matter of taste and not of electrical engineering. Still we were willing to assist the Council in any change they desired, but every offer we make is used by our opponents as the excuse for some attack on our reputation, and some fresh outpourings of local spite and local prejudice. When we have been personally present we have had no reason to complain of the result of the discussion, but behind our backs the matter is different. These statements are made to our disadvantage that are unsupported by any evidence that would be received in a court of justice, and that are untrue in fact; and no effort is made to distinguish between legitimate criticism of matters of taste and opinion, such as the method of distributing the light and the appliances by which it is distributed, and for which matters the Council are now alone responsible. That other matters for which only we are responsible—the candle-power of the lamps—we ask (and surely it is not an unreasonable request) as a condition precedent of any fresh offer on our part that the candle-power of our lamps should be regularly tested and published at the same time and in the same way as candle-power of the gas lamps is tested and published. As we noticed that the last one-sided discussion on the electric light which appeared in the papers was unaccompanied by our letter which gave rise to it, we shall feel obliged if on the present occasion you will hand this letter to the public press after it has been communicated to the Council.—Yours truly (for the Midland Electric Light and Power Company, Limited), Arthur Chamberlain."

The MAYOR said he thought it was a pity Mr. Chamberlain had not a wise man at his elbow when he sat down to write that letter.

Mr. CROWTHER DAVIES proposed that the letter be referred to the Watch Committee. The letter was such that, as a matter of taste, it was to be regretted that it had been written.

The motion was carried.

Mr. CROWTHER DAVIES had a motion on the agenda paper that notice be given the Electric Light and Power Company to terminate the present contract in twelve months' time, but when the time came for moving the same he asked permission to withdraw it. In doing this he explained that it was his desire to leave no means untried by way of arriving at a satisfactory settlement with Mr. Chamberlain. The desire of those with whom he was acting, and it was a feeling he shared, was that the electric lighting company should not feel that any hasty steps had been taken by the Council to put an end to the contract, but, on the contrary, that every means had been used to bring about a satisfactory settlement. It was undoubtedly a most unfortunate letter they had heard read—unfortunate for the writer rather than the recipient. He had formed a most unjust and unworthy conception of the Council as a whole, as well as of some of its individual members. The resolution he asked to withdraw was one he could carry, but as it was to be withdrawn, he hoped Mr. Chamberlain would come to the conclusion that it would be well to treat the Council as reasonable, just, and honourable men. There was no desire to throw cold water upon his company, but to secure an arrangement which would be just to the ratepayers and fair to the Company.

Mr. BRIGHT said he thought Mr. Davies had acted most generously in withdrawing the motion. As one who advocated the introduction of the electric light, he was not satisfied with it, but thought the defect was due, not to the light itself, but to the lanterns used. The letter sent by Mr. Chamberlain was extremely unwise.

Mr. DAVIES said he did not retract anything he had said about the light. What he had said he stuck to, and could prove it if necessary. If the light was not made satisfactory he should revive the subject at some future time.

Leave to withdraw the motion was then given, and the subject referred to the General Purposes Committee, a meeting of which is to be convened at an early date.

Luxemburg.—The central lighting station at Luxemburg, the concession of which has been granted to M. Hastert, is now under construction, and the firm of Siemens and Halske of Berlin are engaged in laying the main cables. The conditions imposed upon intending consumers appear somewhat vexatious. Nothing less than a yearly contract will be entertained. Incandescent lamps will be supplied by the company at five francs apiece; no others are to be used. All the internal fittings must be put up by the company. The current will be supplied by meter from dusk till midnight at the rate of 10 centimes per ampere-hour.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *August 4th*, 1888.

New York electricians have been very much amused, edified, and disgusted during the past week by an exhibition which Mr. Harold P. Brown has given at Columbia College of experiments on dogs, to show what are the limits of safety to animal life with varying pressures of direct and alternating currents. It will be remembered that Mr. Brown has lately appeared before the public as the advocate of "closed coil" machines for arc lighting, and of low-tension continuous currents for incandescent lighting. But a great many of his assertions were contradicted by various authorities whom I cited in my letter last week, and it seemed as though Mr. Brown had been "downed." Such was not the case, however, as he came up smiling, with a proposition to disprove by means of dogs certain of the statements made against him and his theories. Invitations were issued for the performance, and there was a very large attendance last Monday, when the tests were made. Mr. Brown had provided himself with an assortment of dogs, an Edison municipal machine of 1,200 volts continuous current, a Siemens alternating machine whose E.M.F. could be varied from 100 to 1,000 volts, and an arrangement for producing pulsatory effects with a continuous current. Before proceeding to make his demonstration Mr. Brown read a paper, in which he stated that with a continuous current, no provision being made to eliminate the extra current, dogs had been killed at 800 volts. With the extra current shunted a dog had stood 1,420 volts before being killed. With the alternating current, however, at 288 alternations per second, and an E.M.F. of 160 volts, the dog had been taken off in 15 seconds. An unfortunate cur was here introduced to the audience and subjected to the torture. It was first treated to an application of the continuous current at 300 volts. His resistance was determined as 15,000 ohms. As the experiments progressed he became at once a wiser and a madder dog, and so resented the treatment that in a short time he had released himself from muzzling straps and other gear, and stood free, glaring at his tormentors. At this juncture several of the spectators discovered that they had important business to attend to down town, and took their hats, but after the poor beast had once more been secured they reluctantly consented to stay a while and see the thing through. The potential of the testing current was run up to 1,000 volts, but the dog still stood it, although his resistance had fallen as low as 2,100 ohms. Mr. Brown was ready to go on raising the E.M.F. as high as possible, and when he had reached his limit he intended to vary the programme by giving the dog the alternating current, "to make him feel better," as he said. Some one suggested, however, that it would be more humane to dispatch the dog, whereupon Mr. Brown gave it a current of 330 volts alternating, which killed it at once. Resort was then to have been made to the cage for more dogs, but on the protests of some of the persons present, an officer of the Society for the Prevention of Cruelty to Animals interposed his authority, and the experiments were at an end. I do not mean it to be inferred that there was any intentional cruelty in what took place, nor that the results sought to be reached as to the effects of various currents fell short of the very first importance, but it does seem as if the wrong course was followed. Thus, it must be evident to everybody that the dog which served for the experiments must have been worn out by the continuous current long before the alternating was applied to him. The fall in his resistance shows this. Moreover, although I have not seen attention called to the point, it seems evident that the connections between the dog and the machine must have been much closer and much more intimate than would be the case with regard to accidental shock, which, after all, is the main point. As a rule, the man who gets a shock gets it from a casual, slight, and momentary contact, but in this instance everybody could see that a very large portion of the dog was in contact with the conductors. Hence each side of the controversy must draw its conclusions from imperfect data, unless the experiments should happen to be renewed.

If this sort of thing goes on, with the accidental killing of men and the experimental killing of dogs, the public will soon become as familiar with the idea that electricity is death as with the old superstition that it is life. It is interesting to note that from Philadelphia is reported the fact that electric light men are never troubled with rheumatism, and that people who are tortured with pains in their joints hang around the dynamos eager to subject themselves to the influence of the magnetic field, just as consumptives are said to hang around slaughter houses to drink the blood of freshly-killed bullocks.

Mr. M. D. Law, the very efficient superintendent of the Brush Company in Philadelphia, is quoted, however, as the authority for the statement that men engaged around dynamos are decidedly free from rheumatic and neuralgic troubles, and that continuance in the work is calculated to improve the health of men who had been subject to such ailments. Mr. Law gives his own experience, and mentions that although when he first entered the electric light business some years ago he was afflicted with acute rheumatism, in less than eighteen months he was a cured man. Another item of interest in this connection, bearing the other way, is to the effect that there may be some delay in carrying out executions by electricity in this State. The authorities do not seem to be as well satisfied as they might be regarding the advisability and practicability of the infliction of death sentences by electrical methods, and it seems possible that some time may elapse before the legislation on the subject is carried into effect.

We are beginning to have some very large isolated incandescent plants in this country. One of the largest and finest of these is that installed by the United States Company in the Equitable Insurance building in this city, where the fittings of the dynamo and engine rooms are of the most sumptuous order. This plant has been considered the largest of the kind extant; but it now bids fair to be eclipsed by an Edison installation for the new Auditorium building at Chicago. This plant will start, it is said, with no fewer than 8,600 lights. One of the special features of the installation is that the lights will be used to illuminate so large a hall, and the results obtained during the recent Republican Convention in the building promise a brilliant triumph. The lights in the Equitable building are not used in this way to illuminate large spaces, but are distributed over several floors and light up hundreds of distinct offices. If there is anything at all equal to these plants in Europe we have not heard of them, though it would seem that some of the magnificent halls and cathedrals of the Old World would afford even better opportunities for electrical display.

Last week I wrote you in regard to the statements which Mr. Whitney, of Boston, had expressed in regard to the desirability of the electric motor for street railway purposes. His language has attracted considerable attention here; but his action is even more likely to do so, for he has given evidence of the faith that is in him by ordering of the Sprague Company for Boston's suburbs an initial equipment for an overhead service of twelve miles of track and twenty cars. The cars will be specially roomy and comfortable, and everything about the road will be as ornate as possible. It will be running as soon as the work can possibly be done. Another large city to put in the Sprague system is Cleveland, for which place an equipment of eight miles of track and sixteen cars has been ordered. In fact, the motor business generally is in excellent shape. Despite the summer dulness, all the minor companies are busy, and seem to experience difficulty in filling their orders promptly. In Baltimore, the local Brush Company, of which Mr. Frank Morrison is the able president, is now running three large dynamo machines on motor circuits exclusively, and is operating from them about 200 of the Baxter motors, in the construction of which Mr. Morrison is actively interested. So great is the promise of the increase of electric lighting in con-

Digitized by Google

nection with electric power in Baltimore that the Brush Company there is already getting ready to build a new station. This again, like a few other things we have in America, is to be the largest in the world, and is to have a capacity of nearly 5,000 horse-power.

A great deal of interest is taken here in the reports which reach us in regard to the carrying out of the Pacific Cable plan for connecting Canada and Australia and the far East. We have just seen the completion of another ocean telegraph service in the cables laid and now put in operation between this country and Venezuela and other South American countries bordering on the Caribbean Sea. An interesting episode also has been the arrival in this city of Dr. Allen, secretary of the Corean Legation to the United States. Corea has been very much of a hermit among the nations, and little is known of the island, although we know so much of neighbouring Japan. One of the objects of Dr. Allen's visit has been to arrange, if possible, for some means of direct telegraphic communication between Corea and San Francisco. American officers are now reorganising the Corean army, and Californian miners will soon be developing the Corean goldfields, which are said to be extremely rich, and hence, with a greater trade between the two countries, the need of a cable is already felt.

At this time of the year, most of our associations, no matter of what nature, contrive to have a convention, and electrical bodies are no exception to the rule. Next week the Edison Association, which meets every six months, will hold its summer convention at Nantasket Beach, near Boston, when a large attendance is expected of the representatives of the parent and local companies. The week after the Telegraphic Old Timers and the Military Telegraphers meet in Chicago. At the end of the month the National Electric Light Association holds its convention in this city, and it will be followed a few days later by the annual meeting of the National Telephone Exchange Association. Pretty soon, I suppose, your electrical contemporaries here will be staggering along under a load of electrical oratory. All these conventions do but little harm and a great deal of good. They develop many interesting points, and they tend to secure uniformity of practice and of operation which, perhaps, would otherwise be unattainable. The electric light man who lives in Hoboken, for example, is apt to believe that he has the best way of doing things until he finds that his friend, operating perhaps the same system at Kalamazoo, has a great deal better method, and as soon as he learns of the difference he makes the change and gets his plant on a far more economical and profitable basis. This is the practical side of the convention, to say nothing of the pleasant opportunities afforded for renewing friendships and enlarging one's circle of acquaintances.

I had closed this letter, but I open it to add that another series of experiments on dogs was made yesterday by Mr. Brown at Columbia College, with the assistance of several well-known professional men, doctors, electricians, and others. The net result was far more satisfactory, if it may be stated that way, than was the case with the first trial. The attendant circumstances were by no means as repulsive; on the contrary, the experiments were all made in a neat and clean way, each demonstration being sharp and effective. The dogs were not subjected this time to any tests of the continuous current, but exclusively with the alternating, which proved fatal at E.M.F.'s of 272, 340, and 234 volts respectively, in this way corroborating the results which, it was said, had already been reached. The object of the experiments has obviously been to prevent the admission of alternating currents into this city. I do not think they will have this result, but they will certainly cause the authorities to be exacting as to the conditions under which they allow such currents to be distributed and used.

The idea of obtaining a practical facsimile telegraph has not by any means been given up, and the latest attempt in this direction on our side of the water is that of Prof. Elisha Gray, with whom your readers will be well acquainted as the leading telephone claimant and as the inventor of the harmonic multiple telegraph system. In the "telautograph," as Prof. Gray calls his new system, quite novel methods are employed, which consist in transmuting the movements of a transmitting pen into current pulsations, varying in number with the linear extent of movement, and their speed of succession with the rapidity of that movement, and in then transmuting these pulsations into like movements of the receiving pen. The system consists essentially of a transmitter and a receiver. In the transmitter the pen is connected by two cords at right angles to each other, and two devices which interrupt the current over two main lines in conformity with the movement of the pen. These currents thrown into pulsations are received on a receiving instrument, which consists of two pairs of magnets, which act upon two rods also placed at right angles to each other, and the movements of which rods are effected by the currents sent over the lines, and made to correspond exactly with the movements of the transmitting pen. Hence, any character traced by the latter is reproduced at the other end. I cannot here enter into the details of the apparatus, which, though quite simple, would require too much space, and moreover, the practical machine has not been brought out yet, only the patents having been issued. The laboratory tests are reported to be quite successful.

CORRESPONDENCE.

LIGHTNING DISCHARGES, &c.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The gap between the electrical phenomena of common practice and those concerned in the transmission of light and heat, a gap that it once seemed almost impossible to get over, is being gradually filled up, both from the theoretical and the experimental side; both from above, by the observation of dark heat and in other ways; and from below, by electrical means, as condenser discharges, vacuum tube experiments, &c. Dr. Lodge's recent work on lightning discharges, especially the experiments described in his second lecture, deserves the most careful attention, as a substantial addition to our knowledge of the subject, and also because it is, so far as I know, the first serious attempt to treat the subject electro-magnetically.

The fluids are played out; they are fast evaporating into nothingness. The whole field of electrostatics must be studied from the electro-magnetic point of view to obtain an adequately comprehensive notion of the facts of the case; and it is here that Dr. Lodge's experiments are also useful.

Independently of this, I should not be surprised to find that a *new fact* is contained in some of the experiments. Now a new fact is a serious matter, and its existence can only be granted upon the most conclusive evidence, of varied nature. There is already some independent evidence, viz., in Kundt's recent Paper on the speed of light in metals. But it is scarcely sufficient.

There is the plainest possible evidence that with waves of telephonic frequency the magnetic force and the flux induction are proportionate, and that their ratio is a large number in iron. I have observed, and I read that Ayrton and Perry have also observed, decrease of the inductivity with increased frequency of alternation. But, at least with me, it went only a little way, and I had not the opportunity to extend the experiments.

Now a conducting wire at the first moment of receiving a wave (in the dielectric, of course) performs the important function of guiding it and preventing its dissipation in space; and besides that, the nature of the conductor partly determines what impedance the wave suffers, causing a reflection back, with heaping up behind, so to speak, of the electric disturbance. But at first the conduction current is purely superficial. It is clear then that at the *very front* of a wave, where conduction is just commencing on the surface, the conductor cannot be treated as if it had the same properties (conductivity, inductivity, permittivity) as if it were a *bulk* of material, for

Digitized by Google

only a thin layer of molecules is concerned. We therefore do not know what the true boundary condition is when pushed to the extreme. And yet it may be that this unknown condition may serve to sometimes determine a choice of paths.

Thus, iron may behave, superficially, as if it were non-magnetic. (This does not mean that the inductivity of the iron wire is unity.) In Kundt's experiments, electromagnetically interpreted, the inductivity of iron is nowhere; the conductivity, too, must, in other cases as well, be less than the steady value. This corroborates Maxwell's remarks concerning gold leaf. Of course the application of electro-magnetic principles to the passage of light through material substances is at present in a very tentative state; so that too much importance should not be attached to the speculations one may be led to make in these matters.

[If a conductor could be treated as homogeneous right up to its surface, the initial resistance of unit of surface I calculate to be $4\pi\mu v$, where μ is the inductivity and v the speed of transmission in the conductor. But neither μ nor v can be considered to be known in the case of iron.]

Another matter I wish to direct attention to is this. Dr. Lodge has described some experiments relating to the reflection of waves sent along a circuit. It will also be in the knowledge of some readers that Sections XL. to XLVI. of my "Electro-magnetic Induction and its Propagationn," *Electrician*, June to September, 1887 (and a straggler, XLVII., December 31, 1887), deal with the subject of the transmission of waves along wires, their reflection, absorption, &c., by a new method.

Now I find that there is an idea prevalent that it is only possible for very advanced mathematicians to understand this subject. It is true that when it is comprehensively considered it is by no means easy. But I desire to call attention to the fact (as I did in one or more of the articles referred to) that all the main features of the transmission, reflection, absorption, &c., of waves can be worked out (as done there by me) by elementary algebra.

I was informed substantially that no one read my articles. Possibly some few may do so now, with Dr. Lodge's experiments in practical illustration of some of the matters considered.

My next communication, I may add (written in September, 1887), is on the important subject of the measure of the inductance of circuits, and its true effects, in amplification of preceding matter. It has also special reference to some experimental observations. It has also some valuable annotations by an eminent authority.—Yours, &c.,

OLIVER HEAVISIDE.

P.S.—In connection with lightning discharges, I may remark that it is usual and seems very natural to assume, that the discharge is initiated at the place of the visible spark—the crack, so to speak. But my recent investigations lead me to conclude that this is by no means necessary, and that the strongest dielectric can be disrupted by a suitable convergence of a wave to a centre *or an axis*, starting with any steady field.

For instance, if in a cylindical portion of a dielectric the displacement be uniform, and parallel to the axis, and it be allowed to discharge, the convergence of the resulting wave to the axis causes the electric force to mount up infinitely there, momentarily; hence disruption.

But I do not pretend to give a complete theory of the thundercloud. It is only a detail.

P.P.S.—In Dr. Fleming's recent articles on the theory of alternating currents, I observe that he calls the component Ln of the impedance $(R^2+L^2n^2)^{\frac{1}{2}}$ the "inductive resistance."

I should myself have scarcely thought that it deserved a name, for of course we must draw the line somewhere. But the fact that Dr. Fleming has given it a name is evidence that he found it convenient to do so. Taking it, then, for granted that it should have a special name, I can only object to the one chosen that it creates two kinds of resistance. I desire to recognise but one—*the* resistance. I might, for instance, call Ln the hindrance. Thus, in the case of a coil, R is the *electric* resistance, Ln the *magnetic* hindrance, and their resultant the impedance. But in any case it would not be a term for popular use.

August 13, 1888.

THE DELANY AND WHEATSTONE-STROH CABLE KEYS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In reply to Mr. Delany's letter in your last week's issue I think your descriptions and illustrations of the Wheatstone-Stroh apparatus in the previous number answer nearly all his questions.

I was not aware of the existence of a patent, or would have refreshed my memory from the specification; but the apparatus shown in your illustrations is that which was tried as I stated, and my description of it is substantially accurate.

The fly shown can be made to determine the duration of the contact independently of the manipulation of the operator, and when once adjusted to suit a particular cable will remain invariable.

I do not think it is correct to say that this method of signalling by currents of equal duration in opposite directions has been abandoned for an inferior system, because in the Wheatstone automatic, which is still in use, the signals are of this character.

Mr. Delany points out that the key is not "similar" to his arrangement. I did not mean by the use of this expression that the mechanical details were alike in the two instruments, but that the Wheatstone-Stroh key was, like Delany's, a hand-worked key, which produced the same results by signals transmitted in the same manner.—Yours, &c.,

F. HIGGINS.

17, Cornhill, E.C., August 13th, 1888.

UNIPOLAR INDUCTION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I have looked up the account on page 203 of *The Electrician*, June 22nd, of Messrs. Exner and Czermak's experiments to which Mr. Tunzelmann refers me for a demonstration of his theory, and find their apparatus described in part by a comparison with that designed by Fessel, which it resembles, and which is described on page 171, June 15th.

I note on this page that when Fessel's magnet and its jacket were rotated together, and either of the end centres was connected through a fixed wire and rubbing contacts with the middle of the jacket, a stronger current was observed than when the magnet rotated alone, and either of its end centres was similarly connected through a fixed wire and sliding contacts with the middle of the magnet. I should have expected the very reverse of this, seeing that a few of the lines would return within the jacket, without in the former case cutting either it or the wire. This neither helps the "stationary" nor the revolving theory, but it cannot be reasonably claimed for any of the experiments that they were exact quantitative determinations, the E.M.F. being so very low in relation to the difference between the resistances when the different sliding contacts were used. Probably also the fact was overlooked that a very tangible thermo-electric current is produced in the absolute surfaces of the rubbing contacts, which would account for all the difference observed according as the middle contact rubbed against the copper jacket or the steel magnet.

In Messrs. Exner and Czermak's experiments we have a cylindrical electro-magnet, one-half encased in a metallic jacket, the other half occupied by the exciting coil. The two ends of this jacket were connected "through a silver voltameter placed inside the jacket," the voltameter and connections rotating as one with the jacket, or remaining stationary with it as determined. Here I may point out the incontestable fact that the one condition necessary in all cases of current induction is, not that the number of lines within the circuit shall vary, but that at any given moment the E.M.F.'s induced in any circuit by the lines of force traversing the several parts of the conductor which composes it shall *not* balance. This necessarily involves the use of sliding contacts, or their equivalent, in all cases in which the *position* of the circuit is fixed in an invariable field; as in Forbes's dynamo, for instance. The rule may be stated thus:—If any circuit be chosen in any conductor, situate in an invariable revolving field, and the whole of the material constituting such circuit be fixed, no current

Digitized by Google

can be induced in that circuit, because it is simply impossible to find any two points in it the lines passing between which do not cut that portion of the conductor on one side of the points chosen (say, at entering the circuit) exactly as fast as they cut the remaining portion of the circuit (say, at leaving), so as to produce two balanced E.M.F.'s. But if some portion of the material in the path of the current (*i.e.*, the circuit, which is fixed in position) moves relatively to the rest, either in the same or in the opposite direction to that in which the lines are supposed to be revolving, it will cut the lines faster or slower than if it were stationary, and a current one way or the other results accordingly, because now two points may be found in the current's path (this seems the proper definition of a circuit) between which on either hand an unequal number of lines cuts the conductor, so that the E.M.F.'s no longer balance.

To say that in such cases "the circuit continually increases in area," or "the number of lines passing through the circuit continually increases," is most incongruous language. These considerations, I think, answer the points raised in the last two paragraphs of Mr. Tunzelmann's letter in your last impression.

If now we take the two ends of the jacket in Exner and Czermak's apparatus we inevitably find that the sum of the lines traversing the voltameter and connections when the field revolves exactly equals the sum of those which traverse the jacket in the same direction; the induced E.M.F.'s would therefore equilibriate, and I fail to account on any theory for the effects noted by these observers. For, even allowing that the lines in their experiments did traverse their circuit when the magnet rotated, the small quantities of + and – electricities which would be developed could not perceptibly polarise the voltameter. Much, however, might depend upon the conductivity of the implement, and upon the agility exercised in the act of disconnecting the terminals of the voltameter while the apparatus was working; and, perhaps, also upon the anxiety of the experimenters for tangible results.

With regard to the observations put forward by Mr. Tunzelmann, on pages 232 and 233, in support of the revolving theory, it is, of course, granted that no tangible alteration takes place in a magnet's field when it is simply rotated; but there is connected with every magnet a certain seat of "coercitive" power, fixed, no doubt, in the case of a permanent magnet, so that the rays, so to put it (Figs. 14 and 15 on the above pages illustrate my meaning), of this coercitive force act constantly in the same *radial* direction and with the same power relatively to the magnet, so that it is not unnatural to suppose that when a magnet revolves the form characteristic of its field may be preserved by new lines being thrown out and others retracted radially like the pseudopodia of a rhizopod, as may be required, just as well as if it were actual vortex rings which rotated. To make clearer my meaning, suppose a bar of some substance impervious to magnetism to be placed parallel to the axis of a magnet, it casts a shadow on that side remote from the magnet, comparatively free from lines of force, and if the bar were close to the magnet the only way in which the magnetic energy could pass the obstruction during the magnet's rotation would be by radial retraction and collapse of lines on the front side of the obstruction and the shooting out of lines on the further side. This, however, is rotation in much the same sense as that intended by Mr. Tunzelmann, in the interpretation he gives in the above pages, but he holds that an electro-magnet with stationary exciting coil holds its lines fast, so that they rotate only when the iron rotates. Surely in this case the coercitive force has its seat in the current circulating in the exciting coil, which neither rotates one way nor the other; and what reason can there be for supposing that the iron core through which the lines pass possess a special power of driving round or holding fast the line than a core of nickel, of copper, or of wood? In this connection there is a difficulty which Mr. Tunzelmann hardly disposes of in the second paragraph of his letter, page 450. I will put it in a different form. A fixed exciting coil occupies the space between two concentric iron cylinders of the same length; this coil magnetises the core, it also magnetises the outer cylinder; we may suppose them to be magnetised to saturation. If, therefore, either of these rotates, so do the lines of force, and in the same direction; but the same lines are common to both cylinders, and supposing the cylinders to rotate in contrary directions, it is necessary to suppose that so many lines as traverse the two must be at the same time revolving in both directions. This actual rotation of the same thing in two directions at once admits of no physical interpretation, although it might do very well for ordinary purposes to regard the lines as virtually rotating both ways simultaneously, so as to neutralise each other; but that is a different matter.

From the very nature of the case all the experimental evidence advanced in favour of one or other theory appears equally as compatible with one as another, and probably a more accurate physical conception of the nature of magnetic energy than that of vortex motions may be required to establish the truth. Confining attention to the conventional lines of force, my own way of regarding them is as if they were of the nature of (1) closed curves of force; (2) always possessing the same amount of energy in a given length; (3) entirely free from all restraint with regard to revolution about the magnetic axis; (4) expanding or shrinking in length, as the distribution of force may require in the various parts of its revolution about the magnetic axis; (5) traversing conductors, in which current cannot be set up to resist their passage with as much ease as if they were dielectrics; (6) preferring to move round the magnet's axis rather than traverse, or be traversed, by any conductor which may advance relatively to them, and in which they would induce current, excepting when hemmed in, so to speak, or so approached as to be compelled to undergo such a degree of deformation, or displacement from their normal figure, that their elastic effort to resume the form and position of least magnetic resistance supplies the reaction necessary to force them to traverse such conductors.—Yours, &c.,

R. SNOWDON.

Staveley Ironworks, Chesterfield, August 12th, 1888.

THE BEAUMONT EPICYCONOIDAL AND EPICYCLICAL GEAR.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I am greatly obliged to Mr. Beaumont for drawing my attention to the modified form of his epicyconoidal gear, and for the figures illustrating it; the mechanical conditions here are very different to those in the form I commented upon.

In the gearing now under consideration, the velocity ratio between the wheels C and A, B being supposed fixed, will be the same as though C geared direct with A, D making no difference so far as velocities are concerned beyond changing the direction of the transmitted motion, so that A and C turn in opposite directions instead of in the same direction, as they would do if they geared (internally) directly with each other. Considered as a means of transmitting power, however, the introduction of the idle wheel D just about doubles the loss from friction that would occur if the wheels C and A geared directly together, inasmuch as there is the loss due to C working with D, as well as that due to D working with A, and in each case the pressure is the same (omitting the difference due to the loss by friction in transmission to A through D), as it would be if C and A only were working together.

I believe the loss due to friction in the other parts of the mechanism would be, or should be, small; in the first place, because these parts are only brought into action when it is necessary to reduce the normal velocity, and in the second place because there are no great pressures between these parts, and their velocities are comparatively small. It may be that the loss due to the introduction of the idle wheel D would be a more serious matter; but if the apparatus were well designed, and well made, it should not absorb much more power than would be taken up if a second motion shaft were used, and the perfect control which this mechanism gives over the transmitted velocity is worth something, even when it has to be paid for in foot-pounds of work.

I am pleased to hear that this gearing is used for transmitting large powers, and regret that I have not had the opportunity of seeing it in use; the form of it now under considera-

Digitized by Google

tion is well adapted for transmitting such powers. I, however, am concerned with the transmission of power upon a tramcar, and the source of power I feel most interest in is a storage battery. In this storage battery there is a very definite, and a very limited amount of power accumulated, and it may be that after the tramcar is sent out in the morning with its normal store of power that it will get an extra lot of hard work to do; encounter a snow storm, perhaps, or some other of the many ills that tramway life is heir to, and have all this accumulated power used up before it can get home again. Under these circumstances, one or two cog wheels, with a substantial amount of pressure between teeth having quite the usual amount of slip between them, may make a great deal of difference. Where the power is so limited it does not do to throw much of it away. Again, it must be remembered that this mechanism has to be stowed away under the floor of a tramcar, in a situation of difficult access, and exposed to much dust and dirt; hence the necessity for looking out for possible difficulties in the lubrication. Car-drivers, who are paid at the market rate of wages for the number of hours they "put in," will not look to these little matters until they are convinced that for some reason or another it is necessary that they should do so. If the machinery does not get what is necessary from the oil-can it will immediately make increased demands on the source of power, and a bit later on it will cause trouble in the repairing shops.

These are some of the reasons why on, or rather under, a tram-car, it is so necessary to economise mechanism, and why I thought the gearing discussed in my last letter was not suitable for the purposes for which it was proposed. The modified form shown in your last number is much better, but for these same reasons I still think it too elaborate; still no one will be better pleased than I shall be to hear that it has been tried on a tramcar, and has, for a reasonable period, successfully withstood the racket it will get in regular service.—Yours, &c.,

Birmingham, Aug. 14th, 1888. T. ARNALL.

THE UNITED TELEPHONE COMPANY v. THE NEW PUBLIC TELEPHONE SYSTEM.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: My attention was only yesterday called to the letter from Mr. Hawes in your issue of April 27th. It will presently be apparent how sorry I must be not to have seen it earlier. The task I proposed to myself in writing the series of articles has involved much experiment and calculation, but I hope to conclude them very shortly. Meanwhile I have much pleasure in analysing Mr. Hawes's criticisms on my multiple-switch system. I think I am justified in saying at the outset that in dealing with Mr. Hawes's criticisms I am dealing with the ablest and most critical expert in the employ of the United Telephone Company.

My answer, I fear, will be rather lengthy, but on the essential points it will be thorough, and the subject is getting more important every year; indeed, the United Telephone Company have in London a greater task to perform than is imposed upon any other company in the world, but what is apparently lost sight of is that there are compensating advantages in the case of London which make some other companies covet the neglected opportunity. The remarks of Mr. Hawes are so courteous that I trust there will be nothing in my reply to prevent him saying whether he is answered or not.

The first objection I have to meet is that my general scheme of one large central exchange on the multiple system and forty small exchanges is "a distinctly retrograde step," and contrary to the view dictated by practical experience in both London and New York. My answer is that mathematical laws and New York experts are all in my favour. More than a month before Mr. Hawes wrote, the "American Notes" in your journal contained the information that the large new exchange on the multiple system in New York was to be supplemented by a number of auxiliary exchanges, the latter being found necessary. The reasons why this must ever be so, in order that the multiple system may effect the main object I am fully prepared to enter into when occasion offers. The objections to my method of insulating outdoor wires must also remain unanswered till then, as neither objection has any necessary connection with the merits or demerits of my multiple switch.

Mr. Hawes admits that my multiple switch-board "looks well on paper," and then goes on to show that his own criticisms fall to the ground when transferred from paper to practical experiment. He says six feet in width is the greatest width that can be allowed for each section, and that two hundred subscribers are as many as could be properly attended to on one section. Well, I adopt the latter figure, and instead of six feet in width I provide for 5,500 in the space of five feet square. The 26 sections necessary to work that number would thus require 130 feet of "wire" (which it would be more accurate to call chain). Now, as Mr. Hawes makes out that 90-feet lengths might stretch 1½ inch, which would be fatal to the system, it naturally follows that 130-feet lengths would be out of the hunt altogether. But let us see. Mr. Hawes says that before any man should undertake the duty of keeping such a system in order his first duty would be to insure his life.

I propose to act differently. Any multiple switch-board must cost a great deal of money—which to a capitalist counts first—and I propose that the first duty of a maker or buyer of a multiple switch-board shall be to ensure *its* life.

I was a mechanic before an electrician. Mr. Hawes is an electrician, above the average, but not yet a mechanic, otherwise he would have known that a composite chain, made of steel, to the size and shape shown in the drawings in *The Electrician* of April 13, and measuring 130 feet, could not be stretched *even one eighth of an inch* by the direct pull of the strongest man in the service of the United Telephone Company. I would ensure the life of these chains by testing every one with a strain ten times greater than ordinary rough usage would put upon them. This would be a wider margin of safety than civil engineers allow in cases where many lives are at stake. Nearly all the objections hang upon this imaginary weakness.

With regard to the criticism referring to Fig. 12, if there were any ground for the stricture, then the steering gear at the stern of every ship and the chronometer in every captain's cabin are jeopardising the lives of thousands daily.

I may, however, admit that Fig. 12 *does not obviously* show what it, in fact, provides for, viz., that there is contact between X and Z during a half-inch of movement of the insulator plug W.

In spite of all care and tests, suppose one of the chains should happen to break, what then? Not a stoppage of nearly the whole telephone system of London for six weeks, such as an extraordinary snowstorm causes, but the stoppage of that individual line for *one hour*. I admit the facility of repair is not obvious, but it was fully provided for before I put the scheme on paper. To describe the process to anyone but an experienced mechanic would require drawings and much letterpress space, but the necessary appliances for taking out a broken chain and putting in a new one will enable the repair to be done in an hour, and will cost only a few shillings for a permanent outfit for a 5,000-line exchange. Mr. Hawes or Mr. Morgan may have the explanation whenever they may think it worth while.

The assumed difficulty of leading the wires to the plug-holes is not reconcilable with Mr. Hawes's familiar acquaintance with large groups of wires. I am quite sure that it *is* "one of the principal difficulties of the present form of multiple boards," but I should have thought Mr. Hawes had long ago seen the needlessness of the self-inflicted difficulty. It is quite true that my drawings show no provision for obviating the difficulty, but it will be found that the general construction of the front board provides for a simple and safe method; but I fancy it would be unreasonable to encumber the question with details of such a kind as could be interesting only to a few experts in public telephony.

Looking at my scheme generally, and in detail, it will be found that every separate part can be made accurately without any more expense than common toy work costs, because if the thing is wanted at all, there will be required for one exchange only no less than 125,000 of each of the pieces on

Digitized by Google

boards P and Q, and 5,000 of each of the pieces on board V. The outlay and skill called for is not, therefore, to produce so many pieces with skilled accuracy, but to produce a set of machine tools that cannot fail to turn out every part with speed as well as accuracy.

I am afraid to encroach on your space by further remarks, but shall be glad to return to the subject if Mr. Hawes is satisfied on the points already enlarged upon. I am quite prepared for the trouble of defending my scheme against all comers, for the same reason as Mr. Hawes has taken the trouble to attack it, viz., because the future success of public telephony will be controlled by the best multiple-switch system.

In New York, December 31st last, £60,000 was expended on an incompleted multiple switch-board for 6,000 subscribers; perhaps Mr. Hawes can ascertain what further outlay was necessary to complete it. And will he then say that my system would cost more? If he does, I will produce some of the best manufacturers in the country who will contract to do it for very much less with far greater efficiency.

Hitherto, New York has been years in advance of London in telephony and electric lighting, and since Mr. Hawes quotes New York unsuccessfully on one point, I will conclude by quoting a New York precedent on another, viz., the space occupied by large multiple switch-boards. In connection with the quotation above referred to, it was stated that the switch-board then nearing completion was for 6,000 subscribers and measured 300ft. long, whereas my board for 5,500 will measure only 130ft. long.—Yours, &c.,

WALKER MOSELEY.

DETERMINING PERCENTAGE OF COPPER IN A CYANIDE SOLUTION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Could the editor or any reader of the paper inform me of any ready method of determining chemically the percentage of copper, also of cyanide of potassium, in a liquor in use for the electro deposition of copper on iron by the cyanide process?—Yours, &c.,

D. CORRIE.

Polmont Station, Stirlingshire.

THE INSTITUTE OF MEDICAL ELECTRICITY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: As you and many of your readers have expressed considerable interest in this institute, the directors would feel obliged if you will allow me an opportunity of making known in your columns the reason why the opening of our London establishment has been so long delayed.

In the end of March last the directors proceeded to the appointment of medical officers, and, after consultation with the medical "Visitors," selected two distinguished London physicians, well known in scientific circles for the great attention they have long given to the medical applications of electricity.

These gentlemen, however, happen to be, one a Fellow and the other a Member of the Royal College of Physicians, and, though they were personally willing, unexpected difficulties of a purely professional character have been encountered in connection with their acceptance of the posts offered to them. The directors hoped at one time that a memorandum on the subject, which was signed by ten of the leading men in the electrical profession, all being members of the Council of the Society of Telegraph-Engineers and Electricians, and six of them being also Fellows of the Royal Society, would have aided in removing the difficulties, but I regret to say that they are still unsurmounted.

I need hardly assure your readers that this unfortunate *contretemps* will in no way alter the character and tone of the Institute; but that, being more than ever convinced of the need for such an undertaking, and of the good that may come from it, the directors will proceed with a medical officer who is not a member of the Royal College of Physicians.

These premises are now being fitted up rapidly with all the necessary apparatus, and the directors hope that they will be ready to receive patients early in September. They think it expedient, however, to defer the formal opening until October, when they hope to gather their friends around them.—Yours, &c., H. NEWMAN LAWRENCE, Managing Director.

The Institute of Medical Electricity (Limited),
24A, Regent-street, London, S.W., August 11th, 1888.

PATENT RECORD.

RECENT APPLICATIONS FOR PATENTS.

NOTE.—*The undermentioned applications are not open to public inspection until after the acceptance of the complete specification. The names within parentheses are those of communicators of inventions.*

10,941. I. A. TIMMIS. London. Improvements in the arrangements for the lighting of railway trains by electricity. July 28, 1888.

10,945. W. H. AKESTER and G. HOPKINS. London. An improved cut-out for electric circuits. July 28, 1888.

10,952. L. S. M. PIKE and H. T. BARNETT. London. Improvements in dynamo-electric machines. July 28, 1888.

10,954. E. H. GEIST. London. Improvements in or connected with dynamo-electric machines. July 28, 1888.

10,956. C. SMITH. London. An electrical lighting apparatus for medical and surgical purposes (R. Blaensdorff, Nachfolder, Frankfort-on-Maine). July 28, 1888.

10,982. T. PEASE. Birkenhead. Improvements in electric battery cells and combinations of same for electric lighting, power, signalling purposes, firing torpedoes, &c. July 30, 1888.

11,019. W. MOSELEY. London. Improvements in electric bells. July 30, 1888.

11,055. W. P. THOMPSON. Liverpool. Improvements in or relating to apparatus for regulating the brilliancy at which lamps included in secondary circuits of induction coils or electric converters may be caused to burn (G. Westinghouse, jun., United States). July 31, 1888.

11,082. P. A. NEWTON. London. An improved mode of an apparatus for transmitting electrically autographic messages, signs and markings (E. Gray, United States). July 31, 1888.

11,092 G. M. CAPELL and J. S. RAWORTH. London. An improved combination of a steam engine, having a vibratory and partly circular motion, with a dynamo-electric machine. July 31, 1888.

11,100. J. KINCAID. London. Improvements in permanent way for vehicles propelled by electricity. July 31, 1888.

11,106. H. H. LAKE. London. Improvements in electrical signalling apparatus (E. Davis and E. B. Welch, United States). July 31, 1888.

11,174. T. PARKER, of the firm of Elwell-Parker (Limited). Manchester. Improvements in and connected with the method of and apparatus for electrically lighting railway trains. August 2, 1888.

11,182. F. S. HARWOOD and H. G. CHEESMAN. Doncaster. Motive power for driving electric and other machinery. August 2, 1888.

11,184. F. TEAGUE and F. E. TEAGUE. London. Improvements relating to electric arc lamps. August 2, 1888.

COMPLETE SPECIFICATIONS ACCEPTED.

NOTE.—*All persons interested in opposing the grant of a patent on any one of the undermentioned applications may, at any time within two months from the dates in italics, give notice at the Patent Office in the prescribed form of such opposition.*

COMPANIES' MEETINGS.

Bell's Asbestos Company (Limited).

The first ordinary general meeting of this Company was held on Wednesday at the Cannon street Hotel, Mr. John Bell in the chair.

Mr. R. LAUDER McLAREN (the secretary) having read the notice convening the meeting,

The CHAIRMAN said: Gentlemen, it gives my colleagues and myself great pleasure to meet you at this the first ordinary general meeting of our company. You are aware that this is the meeting convened in conformity with the statute, and that no accounts are to be presented; in fact, the only business we have to transact to-day is the appointment of the auditors, as to which I shall presently propose a resolution. It seems, however, fitting that on this occasion I should give you some idea as to how we stand in regard to the fulfilment of the programme set forth in the prospectus on the faith of which you invested your money in this Company. It is very satisfactory to me to state that the applications for capital from the public were so liberal that the shares applied for amounted to several times over the number we had to allot, and we finally allotted the shares to 300 applicants. As soon as the minimum amount stipulated by the Stock Exchange had entered our coffers, we made an application for a special settlement in the shares and a quotation in the Official List. That matter is going through its ordinary course, and will in due time be settled according to the decision of the Stock Exchange. The titles to our properties over in Canada were investigated by your solicitors, and found to be in perfect order, and it seemed good to the Directors, instead of waiting until November next—over which period we had to pay for the properties—to pay for them in full at once. We have done so, and the properties are now completely vested in your Company as security for the debentures which we have issued. We have had one or two motives for doing this so rapidly. In the first place, we saved some interest, which is not unimportant; but the real reason was that we might at once complete the security of the debenture holders, and take the operations in Canada into our own hands. Those operations are of some considerable importance. They are now being conducted by our staff under our direction. I am glad to say that, like the rest of our business, an expansion has taken place in the demand for the crude material. As a rule, the manufacturers take the produce from the mines in Canada towards the end of the year; the summer is the period for working, and about October or November the produce is delivered to the manufacturers, and this led me to inform my brother directors we should have to advance a considerable amount of capital for working the mine during the summer, but it would come back with a handsome increase in November; that up to that time it would be all outgoing and no incoming. It is a very interesting fact that this year that has all changed. The indications are that the stocks taken into hand by the manufacturers last year are completely exhausted, because, instead of waiting till October to take delivery, they have begun during May and June to take considerable quantities, and instead of having to advance several thousands of pounds of capital, the funds necessary for the working have been provided by the sales on the spot, and in addition to that we have received a cash remittance of considerably more than is necessary to pay the redemption of the debentures in January next. The new company has made such a bargain in respect to the purchase of these properties that—I say it advisedly—no other company will ever be able to make such a bargain again. You have a third of the total supply of asbestos in the world, and you have the whole of the best asbestos, known for years past as Bell's Selected, which is only used, and can only be used, in the manufactures of this country. We have long been the first manufacturers—everybody has admitted that; we are now the first as producers of the raw material, and so our circle is completed, and we hold a position from which no one can shake us. This is of the utmost importance, not only with regard to our revenue, but with regard to the security of our debentures. We have to provide, as you know, about £5,000 for the interest and sinking fund of the debentures every year. At the present moment the revenue from our properties in Canada is more than double that amount, and the trade is expanding day by day. I look forward to the time when this fibre which we possess—which is unique, and unlike any other in the world, unconsumable and incorruptible—will extend to a variety of purposes unknown now, and whatever may be the good or evil fortune of our ordinary trading manufactures we are rapidly approaching a time when the produce of the mines will constitute a constant and splendid dividend on the capital of the company. So much for your property on the other side of the Atlantic and its bearing on the debentures.

Now let us look at home, and I will say a few words upon what you do with this produce when you get it over here and what you get for doing it. Let me show you first of all a sample of the stuff as it comes out of your quarries in Canada. This is as it comes out of the quarry [exhibiting sample]. The beauty of our invention is this, that we are not trading on an invention which is valuable to-day and which is superseded to-morrow. We are not dependent on any one establishment or railway, and—I say it with all respect—we are not even dependent on Governments. We possess a broader and a stronger basis than that. We have 13,000 customers in the general public on our books, who trade with us regularly, and whatever might happen to shake the patronage of one great establishment, it would scarcely touch our dividend-paying power. That rests on the fact that we make stuff which is useful to every steam user, and to every man who has to deal with electricity. That is a trade, gentlemen, which is certain to expand, and from which I take it we can never easily be shaken. In following the programme, as set forth in the prospectus, I should tell you that we have faithfully carried out all that we told you we would carry out. I have told you we have paid for the properties; you can infer from my remarks we have taken over the business. The solicitor has carried through all the formalities, and you are now in absolute possession of the business of the Company, and it is being carried on by your Directors in the way I have described. Going a little into details, there is one clause in the prospectus:—"The plant and machinery have been written down annually, and are to be taken over by the Company at the value at which they stood in the books on the 31st December, subject, however, to this value being ascertained to be fair and reasonable by competent valuers to be appointed by the company and vendors. The vendors stood on one side, and the Company appointed their own valuer. The result of the severe writing down on the part of the vendors during years past of the machinery and their effectual upkeep was that the independent valuers valued it at 60 per cent. more than it was in the books; therefore, in a word, you get the machinery and plant at 60 per cent. below the value. You will recollect that the business was bought as from January 1 last, so that a very few weeks after the constitution of the Company we found ourselves at the termination of the first half year of working, and it became due to you to have an investigation and to see what had been the result of that working. The stock was strictly taken, both at the head establishment and at all our depots, under the supervision of public accountants. A very strict investigation was made, because we wanted to begin as we intend to go on. We shall render our accounts annually, and I may tell you that the profits of the half year, not taking into account anything received from Canada at all, because all that comes into the second half-year, is considerably over £10,000. We have no bad debts, but we have allowed a handsome sum in case they should arise afterwards. The net profit handsomely exceeds £10,000, and we therefore thought, seeing that this is the lean half-year, that we might prudently give you an interim dividend of 7s. 6d. a share, which absorbs £7,500. We look forward to rendering to you a satisfactory statement at the end of the year. It is not my habit to prophesy—I will not do anything of the kind; but I may say that we are trading vigorously and prosperously, and I see no reason for any temerity about meeting you as early as possible after the close of the year. Now, gentlemen, we have entered into relations with you. Our main object was to obtain capital to purchase properties in Canada, and we, who are vendors, have sold our interest, not to run away, but shall remain most largely interested in the working of this undertaking. The resolution that I have to propose to you is:—

"*That Messrs. Cooper Brothers and Co., of George-street, Mansion House, London, be appointed the auditors of the Company till the next general meeting of the shareholders, and that their remuneration be fixed at 50 guineas.*"

It is quite unnecessary for me to add anything in support of that resolution, and therefore I leave it to some shareholder to second it.

Mr. HART seconded the resolution, which was carried unanimously and without discussion.

The CHAIRMAN said that he should be happy to answer any question that any shareholder might wish to ask.

Mr. HART proposed a vote of thanks to the Chairman and Directors for the careful and able manner in which they had looked after the affairs of the Company.

Mr. SPENCE seconded the motion, which was carried unanimously.

Mr. LIGHTFOOT, in acknowledging the compliment, said that the position of the Company was greatly due to the exertions of the Chairman.

The proceedings then terminated.

A. Smith, 1, Cuba street, Millwall, E.	1
G. Binswanger	1

The company is registered without Articles of Association.

THE LINEFF ELECTRIC TRACTION AND LIGHTING SYNDICATE (LIMITED).—Registered by Shaen, Roscoe, Massey and Co., 8, Bedford-row, W.C. Capital £10,000, divided into 10,000 shares of £1 each. Object, to acquire, introduce, work, develop and manage certain new inventions for operating tramways or railways by means of electricity, for which letters patent have been granted, one of which bears date June 10, 1887, and is numbered 8,380, and the other of which bears date October 4, 1887, and is numbered 13,447, and all the benefits, privileges, and advantages of, or to be derived from, the said inventions and letters patent, and to take out and acquire letters patent for the said inventions in any colony or foreign country; to light roads, thoroughfares, houses, shops, or public buildings. The first subscribers are:—

	Shares.
R. Applegarth, 11, Queen Victoria-street, E.C.	1
A. G. Lineff, 88, High-street, Chiswick	1
E. H. Bayley, 42, Newington-causeway, S.W.	1
R. G. Applegarth, 11, Queen Victoria-street, E.C.	1
A. E. Stone, 11, Queen Victoria-street, E.C.	1
E. G. Church, 120, Pollock-road, New Kent-road	1
J. S. Reay, 90, Ladbroke-grove, W.	1

There shall not be more than five directors, and the first shall be E. H. Bayley, J. S. Reay, A. G. Lineff and R. Applegarth. Each director shall hold at least 250 shares in the company. The remuneration to the directors shall be fixed by the company in general meeting.

LAURENCE, PARIS AND SCOTT (LIMITED).—Registered by F. G. Monkland, 78, Gracechurch-street, E.C., with a capital of £30,000 in shares of £10 each. Object, to adopt and carry into effect an agreement dated June 24th, 1883, and made between E. A. Paris and W. H. Scott of the first part, R. Laurence of the second part, and G. Cruikshank, as trustee of the company, of the third part; to acquire and carry on the business of E. A. Paris and W. H. Scott, electrical engineers. The first subscribers are:—

	Shares.
E. A. Paris, King-street, Norwich	1
A. J. Laurence, 13, Copthall-court, E.C.	1
W. H. Scott, King-street, Norwich	1
R. Halewood, Cairon Works, Norwich	1
T. W. G. Taylor, Norwich	1
P. E. Laurence, 13, Copthall-court, E.C.	1
L. Laurence, Clapham Park	1

The number of directors shall not be less than three nor more than eight, and the first shall be R. Laurence, E. A. Paris, and W. H. Scott. The qualification of a director shall be the holding in his own right of at least 100 shares in the capital of the company. The remuneration of the first directors shall be the sum of £250 per annum each, and 25 per cent. of all net profits after 5 per cent. per annum dividends have been paid.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended August 10th, 1888, amounted to £4,944.

GREAT NORTHERN TELEGRAPH COMPANY.—This company announces that their route to the Far East, Japan, China, Hong Kong, Manila, &c., is working well.

THE LONDON PLATINO-BRAZILIAN TELEGRAPH COMPANY.—This company notifies that the half-yearly coupons, which fall due on Sept. 1, 1888, of its £100,000 Six per Cent. Debentures, will be paid by Messrs. Glyn, Mills, Currie and Co., of 67, Lombard-street, E.C., on and after that date; and also that coupons must be left with the bankers three clear days for examination.

THE MADRID TELEPHONE COMPANY (SOCIETE TELEPHONES DE MADRID).—This company has recently held its general meeting, at which the first balance-sheet was presented, covering a period of sixteen months. The profits shown amounted to 115,490 pesetas, out of which it was proposed to distribute a dividend of 26 pesetas 66cs. per share (250 pesetas paid) for the sixteen months. It has been decided to increase the nominal capital from 1,200,000 pesetas to 1,800,000 pesetas by the issue of an additional 1,200 shares of 500 pesetas each, upon which 250 pesetas are to be called up. The paid-up capital will thus be increased from 600,000 to 900,000 pesetas, say, from £24.000 to £36,000, with a reserve liability of a similar amount. Considering the expenses incidental to the first operations of a new company, the results are considered very satisfactory. The growth of the company's business, as judged by the number of subscribers, has been as follows:—At the initiation, 683; 31st December, 1885, 821; 31st December, 1887, 1,287; date of general meeting, 1,321.

MAXIM-WESTON ELECTRIC COMPANY.—We are informed that Mr. Samuel J. Boyce (of Messrs. Boyce and Ramsay, chartered accountants), has been appointed secretary of this company in place of Mr. J. Wright. All communications should in future be addressed to Mr. Boyce, and all accounts due to the company should also be paid to him.

THE SOCIETE GENERALE DES TELEPHONES OF FRANCE.—At the general meeting recently held a dividend was declared of 25fr. per fully paid-up share, and of 18fr. 75c. per share with 315fr. paid. This is equal to 5 per cent. per annum, the shares being 500fr. shares. Some particulars of the operations of this company were given in Vol. XIX., No. 10, p. 195 of *The Electrician*, and Vol. XX., No. 496, p. 25.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended August 10th, 1888, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company, were £4,141.

WESTERN COUNTIES AND SOUTH WALES TELEPHONE COMPANY.—The warrants for the interim preference dividend for the half year to 30th June, at the rate of 6 per cent. per annum have been posted.

Offices—**WINCHESTER HOUSE, OLD BROAD STREET, LONDON, E.C.**

The principal objects of the Corporation are:—

1. Performing the duties of Trustee, Executor and Administrator.
2. The Insurance of Bonds, Shares and all other Securities lodged with the Corporation against risks of all kinds.
3. The Issue of Warrants and Certificates against Securities deposited, and making and procuring advances on such Warrants.

The Office of Trustee or Executor is to private persons usually a thankless post, involving much anxiety, time and money, and frequently leads to serious actual loss; whilst death, illness and change of residence necessitate frequent fresh appointments, and consequent expense to the parties interested. The Corporation undertakes all the duties of Executor, Trustee or Administrator for reasonable remuneration proportioned to the work and responsibility in each case.

The Corporation insures existing Trustees and Executors against all risks attending those positions, where the business is conducted by the Solicitors to their Trusts under the supervision of the Corporation, it not being the desire of the Corporation to interfere in any way with the duties of the family solicitor.

The Corporation acts as Trustees for the Debenture Holders in Public Companies.

For terms, &c., application should be made to the General Manager at the Company's Office.

GEORGE PEARSON, *General Manager and Secretary.*

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL SCIENCE, INDUSTRY AND ENGINEERING.

No. 536.—Vol. XXI. FRIDAY, AUGUST 24, 1888. Price 4d.

NOTES.

Electrical science has no reason whatever to complain of the degree of recognition which is accorded it by the British Association. In addition to the numerous Papers which are read by its devotees in Section A and Section G, it has of recent years almost invariably occupied a prominent place in one or more of the Presidential Addresses and in the evening lectures. This year, indeed, it lays claim to at least three of these special events. Nevertheless, we venture to suggest that the time will soon arrive for the General Committee to take into consideration the advisability of forming a new section,—Section H—for electricity. The present arrangement, whereby electrical topics are discussed in two separate sections, meeting sometimes in widely different quarters of the town, has certain very obvious disadvantages. Apart from the admitted difficulty of being in two places at the same time, an electrician who is anxious to hear a particular Paper in either section sometimes wastes much time, and has to listen to things which he is quite incapable of comprehending. It is true that the Secretaries, with their invariable tact, endeavour to mitigate this difficulty by placing the electrical Papers as far as possible together, though this is not always feasible. But there are other considerations of at least equal weight which may be urged in favour of the proposal. At present both A and G sections have quite as much business as they can possibly get through, and discussions of the highest interest and importance are often hurried over for lack of time. That the electrical profession would gain by the increased importance conferred upon it in the Parliament of Science we are well assured; and although the expenses of the Association would no doubt be augmented, it may be taken for granted, on the other hand, that the roll of members would be considerably increased from the ranks of those interested in electricity. We trust that the Committee will before long see their way to give this suggestion such consideration as it may deserve.

The details of the Telautograph which are now to hand prove it to be one of the most elaborately ingenious pieces of electro-mechanism which has ever been devised. The receiving instrument dots its i's and crosses its t's, writes on stationary paper of any size, and begins a fresh line when necessary, as if it were held by some invisible hand. We cannot but admire the immense ingenuity and skill which Mr. Elisha Gray has brought to bear, yet we could wish that this ingenuity had been expended upon some problem of more immediate practical importance, and from which the inventor himself might have gathered a more commensurate return. As it is, we fear that even in the limited sphere of writing telegraphs the delicacy and complexity of the Telautograph will go far to outweigh its advantages in other respects.

In the case of an alternating-current motor, such as the Rechniewski, with a Gramme commutator, the machine is of course self-starting, though not self-regulating *per se*. It is, however, worth while to inquire what will happen if, the motor being at rest, the current is switched on at a time when the brushes happen to rest on two adjacent commutator bars. It is obvious that these two coils, being short-circuited, will have a tremendous current generated by induction from the core, quite sufficient in a very brief time to burn them out; in fact, the remaining coils act as the primary, and these two as secondary coils of a transformer. On the other hand, it seems most probable that the armature will begin to move before there is time for any mischief to be done—more especially as the effect of the two coils, being out of circuit at the moment, will diminish the impedance of the armature.

The coincidence of duplicate cables giving way simultaneously at two different points widely apart is singular, to say the least of it; and we are not surprised to hear that the latest incident of this kind gave rise to some alarm in the Australian Colonies, where it afforded a pretext for calling out the naval and artillery reserves to meet the contingency of war having broken out. Had the colonists been aware that the interruption of their own cables was speedily followed by that of the cables between Aden and Bombay, their apprehensions would have been intensified. If anything could compensate the proprietors for the loss they sustain in the damage to these cables, it would be the lesson it ought to teach us that reliance cannot be placed on their integrity in time of war, and that to multiply them, as some people would have us do, not for the requirements of commerce, but merely with the idea of giving the enemy a little more trouble in destroying them, would be a senseless piece of extravagance.

In a recent number of the *Electrotechnische Zeitschrift*, Drs. Lenard and Howard announced to the world that they had succeeded in preparing bismuth wire which, when placed in a magnetic field of 17,000 C.-G.-S. units, has its resistance in-

Digitized by Google

creased two-fold. In the current number of the same journal we find a note as follows:—"A CORRECTION. . . . . The sentence stating that in a field of 17,000 C.-G.-S. units the resistance of the bismuth wire is about doubled should be omitted as not expressing the truth." There is a charming *naïveté* about this way of putting it which leaves us quite in the dark as to the amount of correction which this statement requires. Since we not only printed an abstract of the Paper in our last issue, but also called attention in our editorial columns to the extreme value of the discovery, we now feel entitled to ask Drs. LENARD and HOWARD what increase of resistance their bismuth really does undergo in a field of 17,000 units.

AT a time when the question of street lighting by electricity is once more occupying the attention of the local authorities in various parts of the country, the experience of the Eastbourne Electric Light Company should afford a wholesome lesson to those who may be tempted to undertake this class of work at a tariff based on the cost of gas lighting. The Eastbourne Town Council has been paying £25 per annum for each of their 16 10-ampere lamps on the Parade, and the company now confesses that the contract has resulted in a serious loss. They are prepared to continue the supply at the rate of £35 per annum, although whether they will find it necessary to decline the offer of £30 made by the Corporation we have yet to learn. Of course the price at which arc lighting can be made remunerative depends largely upon local circumstances; and whether £25 would necessarily be too low in all cases is open to question. Nevertheless we trust that this episode—of which further details may be found on a later page—will meet with the consideration which it deserves. No one can be more anxious than we are ourselves to witness a permanent extension of street lighting by electricity in this country, but as a commercial speculation no extension can be permanent which is unable to pay its way.

WE are sorry that the Pilsen-Joel Company has been unable to find a purchaser as a going concern. Mr. GWYNNE'S offer of £6,000 seemed to us a fair and reasonable one; but the shareholders have taken a different view, and the Company now goes into voluntary liquidation. It is to be hoped, however, that means will still be found to carry on the working of the two small central stations owned by the company.

IN a recent issue of the *Electrical World* of New York, there is an interesting Paper by Mr. DAVID BROOKS on the size of telephone conductors. The conclusions arrived at are thus summarised in the editorial columns of the same paper:—

"Mr. BROOKS, contrary to received opinions as dictated by the experience of recent years, thinks that the resistance of the wires may, within quite large limits, be practically neglected, and that the electro-static capacity should be kept down by decreasing the size of the wire. This brings us to the consideration of the fact that there must be a mean between the resistance and the electro-static capacity of the wires at which the best effects are obtainable."

There is thus a strong resemblance between Mr. DAVID BROOKS'S ideas and those set forth by Mr. PREECE in his Papers on "Copper Wire" and "On the Coefficients of Self-Induction in Telegraph Wires," read before the British Association last year (see *Electrician*, September 9th and 16th, 1887). Doubtless it was an oversight which led Mr. BROOKS to omit a reference to these Papers. It will be remembered that at the time Mr. PREECE'S theoretical views met with some adverse criticism; and additional interest is imparted to the present position of the controversy from the fact that whereas the *Electrical World* speaks of the theorem as being contrary to American experience, yet the experience of the English Post Office is, we understand, entirely in its favour.

THE experiments of Mr. HAROLD BROWN on the electrical execution of dogs are absorbing a great deal of public attention in the United States; and some of the papers devote several columns to post-mortem examinations which have been held with due solemnities. Our New York correspondent has already furnished as many details of the experiments as our readers will probably care to have. There appears to be no room for doubt that an alternating current is, or may be, fatal (to a dog) at a lower voltage than a continuous current. As a general rule the animals succumbed under about 230 volts—in one case as low as 160. But we cannot help thinking that Mr. BROWN has either proved too little or too much to justify the conclusion which he is endeavouring to support. Does any one believe that under any ordinary conditions 160 volts alternating can administer a fatal shock to a human being? Mr. BROWN'S opponents asserted again and again that they had received shocks of 1,000 volts alternating with little or no injury; and these cases could, we know, be paralleled in this country. Mr. BROWN replies that these gentlemen are mistaken, that the voltage could not possibly have been as high as they suppose. To still further prove his case, he relates several ghastly tales of injury and death from alternating currents, and although in the majority of cases the results were not of a fatal character, yet we cannot avoid the impression that the number of mishaps from high-tension currents in America, both alternating and continuous, has been greater than we have been led to suppose. Considering the terrible condition in which their overhead wires are acknowledged to be, there would be little room for surprise at almost any number of fatalities to the linemen in some of the larger cities.

ON the whole, we are inclined to think that Mr. HAROLD BROWN'S researches have so far led to the establishment of two results, one of which is chiefly interesting to physiologists, namely, that an electric shock which is harmless to a man may prove fatal to a dog; and the second is of interest to all practical men, namely, that it is a foolhardy thing to run any risk whatever with high-tension currents. Finally, we are driven back to our old conclusion that the question is far more complex than appears on the surface—that the issue depends upon the condition of the skin and of the general temperament of the subject, upon the part of the body receiving the shock, and upon many other things besides the voltage of the current; and the practical application is—**Caution!**

Digitized by Google

Hansthohn.—The Hansthohn (Denmark) lighthouse will shortly be furnished with the electric light. The plant will be supplied by M. de Meritens.

Colliery Lighting.—The Consett Iron Company has decided to light the workings of its Westwood Colliery by electricity, and the contract for the work has been entrusted to Messrs. Clarke, Chapman, Parsons and Co., electrical engineers, Gateshead.

Johore.—His Highness the Sultan of Johore, G.C.M.G., K.C.S.I., has commissioned Dato James Meldrum, Edinburgh, to visit the Glasgow Exhibition and report on the subject of electric lighting. The Sultan intends to light the town of Johore with electricity.

The New Garrick Theatre.—The new Garrick Theatre, now in course of construction in Charing Cross-road, will be opened in January. Mr. W. S. Gilbert has had it built upon the most approved of modern principles, and auditorium and stage will be electrically lighted.

The Palais-Royal Central Station.—The excavations for the central lighting station at the Palais-Royal have led to the discovery of a large sheet of water at some feet from the surface. The plans have therefore been completely altered, and the idea of an underground building has been abandoned. The work is, however, being rapidly pushed forward.

Preservation of Telegraph Poles.—Telegraph poles are preserved in Norway by making an auger hole about two feet from the ground, in which four or five ounces of sulphate of copper are placed, and plugged in. The salt is gradually absorbed by the wood, until its whole outer surface turns a greenish hue. It is said to be a perfect preservative.

The Lighting of the Lyric Theatre.—A daily paper contains the following:—"It is said that the new Lyric Theatre in Shaftesbury-avenue is to be the best-lighted house in London. M. Emile Sechehaye, who 'controls the electric installation' at the Vienna Opera House, has come over here especially to personally superintend the illuminating department."

Bath.—In view of the decision of the Town Council to adopt electric lighting in one part of the city the Bath Gas Company, with the consent of the Council, has decided to fix improved lamps in Milsom-street, in order to show what gas can do. The experiment will continue for a period not exceeding six months, and the extra cost will be borne by the company.

The Bath Meeting of the British Association.—The Telephone. — By the courtesy of the directors of the Western Counties and South Wales Telephone Company the whole of the section rooms will be telephonically connected with the reception room, and, through the Telephone Exchange, with all important places in the neighbourhood, free of any expense to the local executive committee or members and associates for the meeting.

Doncaster.—We learn that Messrs. Hammond and Co. have received an extensive order from the Great Northern Railway Company to light their waggon repairing shops and offices at Doncaster. The plant to be supplied consists of three horizontal steam engines and three dynamo machines, and the lighting will be effected by means of 70 arc and 200 incandescent lamps. Storage batteries will be provided to supply the incandescent light at the offices, as the machinery will not be constantly running.

An Improvement in Relays.—In horseshoe magnet relays there is always a small amount of residual magnetism when the current ceases, and to overcome this the spring on the tongue has to be stronger than would otherwise be needed, this in turn necessitating a stronger current to actuate the relay. Messrs. Siemens and Halske are now making delicate relays with a small steel short-circuiting piece across the poles, which is said to greatly reduce the effect of residual magnetism, and allow much greater sensitiveness to be obtained.

Telegraphic Extensions in the North.—The Post Office authorities have just sanctioned several important telegraphic extensions in the north. An additional wire has just been laid between Aberdeen and Peterhead. A re-arrangement of the system in the Banff, Buckie and Macduff districts is in course of construction. Old Meldrum and Methlick are also to be connected with Aberdeen; but the most important extensions are those direct from Aberdeen to Newcastle and Kirkwall. In future all the Orkney work will circulate direct to Aberdeen, when it can be distributed to the various centres in the south.

Cologne.—We have just received the programme of the sixty-first meeting of the Deutsche Naturforscher und Aerzte at Cologne which we mentioned some weeks back. From it we gather that the proceedings will be very much on the lines of our own British Association meetings, with a strongly predominating medical tendency. Beginning on Monday evening, September 17th, with a reception, the rest of the week will be occupied with meetings of the various sections from 8 a.m. (*sic*) till 5 p.m., and festive gatherings at night. All foreign scientific men are warmly invited to attend the meeting, of which full particulars may be obtained from Prof. Dr. Bardenheuer, Koeln, Berlich, 20.

Ilfracombe.—A special meeting of the Ilfracombe Local Board was held last week to decide how the Victoria Promenade shall be lit. A letter was read from the gas company offering to fix pattern lamps with Doulton ware shafts free of charge to the Local Board if gas was accepted as the illuminating power. If not, and the company had to remove the lamps, they would require five guineas to assist in defraying the expenses.—Mr. Russell advocated that the chairman get the place lit by oil lamps temporarily until the Board had decided respecting the electric light.—This was seconded by Mr. Thomas, but it was eventually decided that the offer of the gas company be accepted.

Theatre Lighting at Liverpool.—Messrs. A. H. Fletcher and Co., of Liverpool, are carrying out an installation at the Grand Theatre in that city. The whole building will be lighted by incandescent lamps of varying power, from 1,000 candle-power to 16 candle-power, all at 100 volts. The lime light will be replaced by an electric light projector made by Messrs. J. G. Statter, who will also supply the dynamos. The stage, footlights, and scenery are all lighted, and arrangements are made for reducing the brilliancy of any or all of the lights (three different degrees for those on the stage). The installation will be temporarily worked by a 50 horse-power Otto gas engine in the basement. The auditorium and refreshment rooms will be ventilated by fans driven by electromotors.

Electrical Firedamp Indicator.—A M. Molas has devised an automatic electrical firedamp indicator, for the purpose of warning both the men in the mine and the engineers at pit's mouth. It is merely a system of electrical contacts actuated by the upward pressure of the escaping gases. When these contacts are made, bells are rung and indicators lowered at the surface, and warning lamps are lit in the mine itself. By this means both the engineers in charge at the surface and the miners at work are instantly informed of the presence and

Digitized by Google

locality of dangerous gases. Moreover, by the extinction of the lamps and the stopping of the bells immediate notice is given of the disappearance of the danger. M. Molas maintains that in mines thus fitted special safety lamps can be dispensed with.

Benardos' Electric Welding Process.—A full description of this process was given in *The Electrician* of 25th November, 1887, and among its many applications that of boiler repairing was mentioned. A striking example of its utility in this respect occurred recently at Struck's factory in St. Petersburg, where the boiler became leaky and the factory had come to a standstill till repairs were made. A neighbouring engineering firm undertook to effect the work at a cost of 1,400 roubles within three weeks. Hearing of this, Messrs. Benardos and Olszewsky volunteered to repair the boiler in a much shorter space of time. The boiler was duly transported to them, and was repaired in *one hour*. Having been finally tested, it was reinstated in its place three hours later, and the next morning the factory resumed work.

The Sparking Distance of Alternating Currents.—E. G. Acheson (*Electrical World*, July 7, 1888) has made some measurements on the sparking distance in air of alternate currents. He finds that it varies with the capacity of the circuit and with the *cube of the E.M.F.* It is expressed by

$$d = \frac{E^3 K}{a},$$

d being the sparking distance in inches, E and K being in B. A. units and a a constant = 135. Two thousand volts, with 0·0032 microfarad in circuit, sparked about 0·2in., and 1,000 volts about 0·02in. These results are very different from those obtained by Warren de la Rue with his great battery, who found that with direct currents 1,200 volts sparked across 0·012in. and 2,400 volts across 0·021in., but the capacity present is not given.

Telegraphs and Telephones in Mexico.—The *Economista Mexicano* of July 28th, quoting from the half-yearly statistical bulletin of the Mexican Government, gives the following summary of the extent of the telegraphs and telephone wires in the Republic:—

	Kilometres.
Federal telegraphs	17,925
Provincial „	6,887
Private „	4,098
Railway „	6,244
Cable Company	2,926
Federal telephones	43
Provincial „	1,621
Private companies' telephones.....	2,887
Railway companies' „	471
Total.....	43,102

Artillery Practice against Electric Light Projectors.—A correspondent of *The Times*, writing from Okehampton, says:—"Some interesting experiments have been made here lately in firing at night against the reflector of an electric light. On the first night the range was ascertained, or thought to to be ascertained, to be 1,680 yards, and 16 rounds of shrapnel were fired, with the result that only one bullet pierced the reflector. The following day the range was found to be 1,580 yards, but the following night the observation gave again 1,680 yards. That night, accepting the daylight observation of 1,580 yards as correct, 16 shrapnel shells were fired, with the result that six bullets pierced the reflector, which, however, was practically not the least damaged. The Artillery officers are unable to explain the fixed difference be- the day and night observations of the distance. Had a shell struck the reflector before bursting complete destruction would, of course, have ensued." The engine and dynamo for these experiments were placed underground.

Tinning by Simple Immersion.—Argentine is a name given to tin precipitated by galvanic action from its solution. This material is usually obtained by immersing plates of zinc in a solution of tin containing 6 grammes (about 90 grains) of the metal to the litre (0·88 quart). In this way the tin scrap can be utilised. To apply the argentine according to M. P. Marino's process, a bath is prepared from argentine and acid tartrate of potash rendered soluble by boric acid. Pyrophosphate of soda, chloride of ammonium, or caustic soda may be substituted for the acid tartrate. The bath being prepared, the objects to be coated are plunged therein, first having been suitably pickled and scoured, and they may be subjected to the action of an electric current. But a simple immersion is enough. The bath must be brought to ebullition, and objects of copper or brass, or such as are coated therewith, may be immersed in it.

Photographs of Lightning Flashes.—In the last number of the *Comptes Rendus* M. Ch. Moussette has a short note on the precautions which it is necessary to take when photographing lightning flashes. According to the author, most of the peculiarities noticed in photographs of this description arise from accidental vibrations caused by the wind, the thunder, or the shaking of the earth. In order to prove this, M. Moussette made a white on black drawing of flashes inclined at different angles. This drawing was photographed in two ways: firstly, with the camera carefully secured from vibration; secondly, with the camera slightly jerked at the moment of photographing. In the first case the flashes came out fine and clearly defined; in the second case the flashes presented the appearance of striated ribbons, except where the lines of the drawing were parallel to the direction of motion of the camera.

The Tudor Accumulator.—It will be remembered that in our issue of 15th June we gave an abstract of a very favourable report by Prof. Kohlrausch on the above cell. Since then we see from the *Zeits. für Electrotechnik*, Vienna, the learned professor has tried the effect of a full charge in the wrong direction. The cell appears to have stood this rather severe ordeal in a very satisfactory manner, none of the oxides dropping off, and the liquid remaining perfectly clear the whole time. At the end of the second hour's charge the E.M.F. of the cell had dropped to zero; after the 3rd hour it was −1·7, then −2·34, −2·20, and −2·15. After the 4th, 5th, and 6th hours, and after 10 hours −2·12. It then received 105 ampere-hours in the right direction (the normal charge being 50 ampere-hours); after which it gave only 15 per cent. less return than the normal. It was then recharged with 75 ampere-hours, or 25 ampere-hours excess, and all effect of the reversal was found to have disappeared.

Mica.—As referring to a substance now so much used for electrical purposes, the following description of an American mica quarry may be of interest:—One of the best American quarries is some two miles from Rumney, on the Boston Montreal line. It lies rather high up, and consists of two gullies some 35ft. deep, with sides of almost pure mica bedded between feldspar and quartz. The mineral occurs in veins from 1ft. to 5ft. thick, and is got by blasting in pieces from 20lb. to 40lb. each. These are then broken up and removed to the works, where they are split up, shaped to wooden templates by shears, and packed in 1lb. bundles. The finer material is split by female labour in another workshop. The

Digitized by Google

mica is sent out wholesale in 100lb. boxes, of an average value of $500. The works show as curiosities a sheet of mica 2ft. by 1½ft., perfectly transparent, and also a six-sided crystal of nearly pure beryl, weighing 80lb. The scrap mica and cuttings are ground up to powder with oil, and used as a lubricant.

Statistics of Injury by Lightning.—In his work on "The Thunderstorm" ("De la Foudre: de ses Formes et de ses Effets") M. Sestier has collected the following statistics relating to this subject:—"Only a minority of lightning accidents are fatal; in 601 cases there were only 250 deaths. Fatal accidents are more frequent in men than in women; of 307 men struck by lightning, 165 were killed, while of 137 women only 51 perished. In the vast majority of cases (340 out of 354) death was instantaneous. The danger is greatest in buildings and places (churches, schools, &c.) where crowds of people are gathered together. The part most often struck is the head, then the chest and limbs. In cases in which the head is struck, the mortality is double what it is when only the trunk or limbs are injured. Among the results of lightning-stroke are the following, according to the authority quoted above:—Loss of consciousness, lasting a few minutes to seven days; paralysis, lasting from half an-hour to four months; deafness, lasting from a few seconds to several months; blindness, lasting from three days to seven months; lastly, a state of apparent death lasting from a few minutes to six hours after the accident."

Edison and Swan v. Shippey Brothers.—We are requested to insert the following, for which, however, we accept no responsibility:—"Mr. Arthur Shippey has paid the taxed costs of the Chancery proceedings incurred in this matter, and therefore, according to law, in the cross action brought by Shippey Brothers against the Edison and Swan Company for intimidation of their customers from using the Shippey lamps (upon which action at the trial, it may be remembered, Mr. Justice Mathew directed a non-suit pending the appeal) legally this places Mr. Shippey in his former position to commence a fresh suit, taking into account the recent decision of Mr. Justice Kay, and the recent awards granted in favour of the validity of the Zanni-Shippey patents on the Continent. It is not unlikely that the Shippey system will be upheld by the owners, who claim the right to manufacture and supply all high candle-power vacuum lamps of 100 candle-power and upwards, as specified in the patents, also for their low resistance composite semi-metallic filaments of the improved King and Harrison types suitable for battery lighting. It may be mentioned that the validity of the Shippey patents has not yet been tested in an English court of law, as is generally supposed, as owing to mechanical difficulties no rebutting evidence was produced at the trial to support the validity of their patents."

Gas and Electricity at Taunton.—The *Taunton Courier* says:—"The statements made and the figures presented at the meeting of gas shareholders amply bear out the contention of the promoters of the electric light company that the competition would be a healthy competition, and that it would be beneficial rather than otherwise to the gas company. The improvement in the quality of the gas and the increased use of gas cookers has brought about a steady increase in the consumption, notwithstanding the discontinuance of the gas lighting in the central streets of the town. The shareholders have little cause for complaint inasmuch as they are receiving the full amount of dividend allowed by the Act, and the maintenance and improvement of the works is paid for out of revenue without affecting their dividends in the slightest. Thus, the establishment of a rival lighting company has not only conduced to the better lighting of the town, but has saved the gas company a capital expenditure which would otherwise have been necessary to enable the directors to cope with the growing demands upon them. The 'scare' which attended the introduction of the electric light is found to be entirely unjustified, as the spheres in which the two lights work are entirely distinct, and it will be a long time before the more brilliant illuminant becomes so widely adopted as to interfere with the success of the older and more established light, and gas shares will remain a valuable and profitable investment as long as Englishmen like good meals well cooked—a desideratum which housewives will more and more find attainable by the use of gas for cooking and heating purposes. The superiority of the electric light as an illuminant is fully recognised, and the recent action of the Bath Town Council in deciding upon an installation of twice as many lights as that at Taunton indicates that its claims are gradually being appreciated."

Eastbourne Central Station.—The Lighting and General Purposes Committee of the Eastbourne Town Council presented a report on the lighting of the town at the meeting of the Council last week, in which it states:—"A deputation from the Eastbourne Electric Light Company explained fully the reasons which prompted them to give the Corporation three months' notice to determine the contract for the lighting of the Grand and Marine Parades, and stated that the Company had incurred a serious loss in the working of the contract up to the present date. The Corporation are paying the Eastbourne Electric Light Company at the present time £25 a lamp per annum for 16 lamps on the Grand and Marine Parades, which amounts to the sum of £400 per annum, and the company are prepared to supply the light for the future at the rate of £35 per lamp per annum, which means an increase of £160 per annum upon the present contract price. As an alternative the company are prepared to supply the light by meter, charging 1s. per unit and a sum not exceeding £2 per week for the supply of carbons and cleaning. With regard to the lighting of the Royal Parade, the Company are only willing to supply the electric light at £35 per lamp per annum, or at the alternative charge per unit of force, provided the Corporation will enter into an agreement for five years for the lighting of both the Royal and the Grand and Marine Parades. The company offer to light the shelters on the parades (by meter) upon the same conditions as their present charge for lighting the Town Hall, viz., 1s. per unit, together with the cost of fittings and renewals. The following is a comparative statement of the cost of the electric light and gas on the parades, viz.:—Present cost of lighting Grand and Marine Parades: 59 gas lamps, £171. 15s. 11d.; 16 electric lamps at £25, £400; total, £571. 15s. 11d. Cost when price of electric light is raised: Gas, £171. 15s. 11d.; electric light, £560; total, £731. 15s. 11d. Estimated cost of lighting by gas only: 27 large lamps, at £10. 15s. 8d., £291. 3s.; 32 small lamps, at £4. 4s. 5½d., £135. 2s. 8d.; interest and repayment on £156 for 26 new Suggs' lamps, say £15; total, £441. 5s. 8d. Present cost of lighting Royal Parade: 9 large lamps, at £10. 15s. 8d., £97. 1s.; 6 small lamps, at £4. 4s. 5½d., £26. 6s. 9d.; total, £123. 7s. 9d. Cost of lighting by electric light: 6 electric lamps, at £35, £210; 15 gas lamps, half night, £40. 10s.; total, £250. 10s. In conclusion, the committee may mention that they have ascertained that the Corporation of Hastings pay £30 per annum for each arc lamp lighted on the parades, and at Brighton none of the public streets are lighted by the electric lamps, all such lamps being provided by tradesmen for the purposes of their business." At

Digitized by Google

the meeting of the Town Council it was resolved to offer £30 per lamp per annum, the lamps to be extinguished at 11 instead of 11:30 as at present.

Mr. Willoughby Smith's System of Telegraphic Communication with Lightships.—It is well known that considerable difficulties are found in effecting telegraphic communication with lightships, and even with lighthouses on rocks at a distance from the shore. Mr. Willoughby Smith has, however, devised a method of effecting the object, which he has protected by patent, and which may probably be applicable to other purposes. He points out that at the present time, wherever electric telegraphic communication is established between the shore and a lighthouse, either floating or on a rock at a distance from the shore, it is effected through an insulated conductor or a telegraph cable; but much difficulty is experienced owing to the rapid wearing of the cable, so that it is liable to break whenever a storm comes on, and when consequently it is most required to be in proper working order. By his invention he is able to effect communication between the sending station and distant point without metallic connection one with the other. This is effected in the case of a lighthouse erected on a rock at a distance from the shore by submerging one or more metallic plates or masses on opposite sides of the rock, so that the two plates or sets of plates may be as far apart as practicable, and from each plate or sets of plates he leads an insulated conductor to a telephone in the lighthouse. A two-conductor cable is led from a signal station on the shore towards the rock. At a distance from the rock one of the conductors of the cable is led to a metallic plate submerged on one side of rock at such a distance from it as to be in water deep enough for it not to be affected by waves. The other conductor of the cable is similarly led to another metallic plate or mass similarly submerged at a distance from the opposite side of the rock. To communicate from the shore to the lighthouse an interrupter or reverser and battery are connected to the shore ends of the two insulated conductors, and the telephone in the lighthouse responds to the repeated makes and brakes or reversal of the current, so that communication can readily be carried on by the Morse alphabet. If a vibrating interrupter or reverser be used a short or long sounding of the telephone can be obtained by a contact key held down for short or long intervals. A more convenient way is to use two finger keys, one of which by a series of teeth on its stem, or in other more convenient way, produces a few breaks or reversals of the current, whilst the other key when depressed produces a greater number of breaks or reversals. In the same way communication could be carried on from the shore to a vessel at a distance from it, if the vessel were in the vicinity of two submerged plates or anchors, each having an insulated conductor passing from it to the shore, and if two metallic plates were let go from the vessel, so that these plates might be at a distance apart from one another. The position of the two submerged plates coupled to the submerged insulated conductors might be indicated by buoys. In this way communication might be effected between passing vessels and the shore, or between the shore and a moored lighthouse or signal station. A similar result might be obtained with a single insulated conductor from the shore by the use of an induction apparatus with the ends of the secondary winding coupled by insulated conductors to submerged plates at a distance apart.

The Holtz Machine as a Motor.—Historical Note.——Prof. E. L. Nichols contributes the following "Historical Note" to the New York *Electrical World*:—"A gentleman who witnessed the driving of a Holtz machine as a motor during one of the lectures of the regular course on electricity before the Sophomore class of Cornell University, has given a description of that experiment in the *Electrical World* in the issue of February 4th, 1888. Although not new, this is one of the most striking of lecture experiments. It is, however, not very generally known, if we may judge from the notice which the above-mentioned article received, and a few words concerning its origin may be of interest. Silvanus P. Thompson, in his text-book, 'Elementary Lessons on Electricity and Magnetism,' p. 53, makes mention of the reversibility of the Holtz machine, the discovery of which he ascribes to Mascart (*see* "Traité d'Electricité," Vol. II.). The first to notice this phenomenon was, however, undoubtedly Holtz himself, who describes the same in 1867, only two years after the appearance of the earliest form of his influence machine. After describing two other peculiarities of the machine, which was of the original type, with two horizontal plates driven in opposite directions, Holtz says:—'A third peculiarity of the apparatus showed itself when I connected the poles of the same with the poles of another influence machine. When the latter was put into motion, both plates, previously detached from the driving belt, began to revolve, but in opposite directions. The lower plate, however, soon came to rest, whereupon the other moved with redoubled velocity. When this one was held fast the lower one began to revolve very rapidly again. The force of these motions increased with the quantitative performance of the other machine; that is to say, with the force which the driving of that machine demanded. A comparison of these forces showed, however, great electrical losses. When the apparatus [previously used as a motor] was driven as an influence machine, the other machine, if freed from its belt and started in the reverse direction, would maintain its rotation alone. In this case the relation between the two forces in question was still more unfavourable. We may, then, assume that every apparatus which, through influence and mechanical motion, performs electrical work, will also, on the other hand, through influence and electrical work, perform mechanical work; that, however, the construction of a given machine will in each case be better adapted to one of these functions than to the other. The two pieces of apparatus which I connected were indeed good electrical machines, but poor machines for the development of power, and to this fact in particular we may ascribe the great loss of power or electricity' (*Annalen der Physik und Chemie*, Vol. CXXX., p. 170, 1867). We have here, then, from the inventor of the Holtz machine, not only a description of the phenomena upon which the experiment of that machine driven as a motor is based, but also a general statement of the reversibility of all forms of the influence machine. His statement of that principle is not couched in the precise terms now in vogue, but it is as clear a statement as could have been expected at that early stage in the development of the doctrine of energy. The matter was immediately taken up by the celebrated founder and editor of the *Annalen der Physik*, who described various elements of his own in subsequent volumes of that magazine (Poggendorff, 'Reaction zweier Influenzmachinen auf einander,' *Annalen der Physik und Chemie*, Vol. CXXXI., p. 495; also Vol. CXXXIX., p. 513), and later by Christiansen (Christiansen, *Annalen der Physik und Chemie*, Vol. CXXXVII., p. 490), Gruel (*Annalen der Physik und Chemie*, Vol. CXLIV., p. 644), and others; but the origin of the experiment unquestionably lies with Holtz; unless, indeed, we see fit to trace it to still earlier attempts to convert static electricity into motion. In such a case our quest would lead us backward into the eighteenth century, to end perhaps with Benjamin Franklin and his electrical turnspit."

THE WOODHOUSE AND RAWSON FACTORIES.

Amongst the very limited number of private firms who achieved distinction during the earlier years of the electric lighting industry, undoubtedly one of the most prominent and successful was that of Messrs. Woodhouse and Rawson. Avoiding the temptation to enter upon the manufacture of dynamo machinery, to which nearly all their competitors of the same standing succumbed, Messrs. Woodhouse and Rawson devoted their energies chiefly to the manufacture and supply of the minor requirements of the trade, such as switches, cut-outs, electric bells, and measuring instruments for which, as they no doubt foresaw, electric lighting has created an almost inexhaustible demand. At an early date they commenced the manufacture of incandescent lamps, working out important processes, the details of which have never been made public. These lamps were held in high reputation by electrical engineers, and at one time the turn-out reached upwards of 2,000 per week. Notwithstanding the threats of proceedings on the part of the Edison-Swan Company they always had more orders than they could possibly execute, until the result of the action for a time established the plaintiffs' claims, and the Woodhouse and Rawson lamp factory, as far as manufacturing for England was concerned, was necessarily closed. They continued, however, the manufacture of lamps for abroad until they required to be exhausted, when they were sent over to the French factory to be finished. The tables having now been turned, the business has again been got under weigh. In the year 1885 part of the concern was turned into a limited liability company or rather into two companies, called respectively the Woodhouse and Rawson Electric Supply Company and the Woodhouse and Rawson Electric Manufacturing Company, there being two other companies, Woodhouse and Rawson (Limited) and the Woodhouse and Rawson Electric Contract and Maintenance Company (Limited) in Yorkshire. The extensive premises of the manufacturing company, of which Sir Leopold McClintock, of Arctic fame, is chairman, known as the Cadby Hall Works, are situated in the Hammersmith-road, West Kensington, close to Addison-road station.

Four large blocks of buildings, of which the front one is only partially occupied by the company, comprise the chief portion of the works, and in addition there are testing rooms, an engine and boiler house, and a smithy in separate buildings, together with a good-sized piece of waste ground in the rear affording room for future extensions. These premises, it may be mentioned, are the property of two of the shareholders of the company.

The most unique and therefore the most interesting portion of the establishment is, of course, the incandescent lamp factory, which occupies the two upper floors of one of the large buildings and the top floor of the next. Since the recent judgment by which the lamp trade has again been thrown open, the whole of the factory, as we have already intimated, has once more become the scene of active operations, and preparations are being made now, in the shape of two 30 horse-power boilers which have just been delivered, new dynamos, &c., for a large increase in turn out. The period of enforced leisure which has just been terminated has, moreover, been utilised by the company for the perfecting and simplification of the process of manufacture, and, as most of our readers will be aware, they have succeeded in making a remarkably hard and dense form of carbon, which has also a higher specific resistance than any graphitoidal carbon hitherto produced. Telephone carbon buttons of this material, and with a wonderful surface, are now being supplied by the company. The most valuable feature in the filaments made of this material is that they do not require to be "flashed" in order to acquire uniformity of structure. Messrs. Woodhouse and Rawson maintain, and, as we think, with good reason, that (apart from questions of litigation) other things being equal an unflashed filament is better than a flashed filament. Flashing is a process devised to remedy the defects of non-uniformity in resistance and irregularity of structure in the original filament; and although this purpose is undoubtedly fulfilled by the flashing process in a quite remarkable degree, yet it is obvious that a filament so treated does not really become homogeneous throughout, nor is it likely to possess so long a life as a filament whose structure is strictly homogeneous from the first. Messrs. Woodhouse and Rawson have, we understand, entirely overcome the difficulty of making any single filament uniform throughout its length, and their attention is now being devoted to perfecting the method of standardising, so that any number of filaments successively produced may have exactly the same voltage and candle-power, so that special orders may be quickly filled. It is worthy of note that the filaments of these lamps have a highly polished surface, and are of ribbon shape and not circular in section. Each of these points is of considerable interest on the theoretical side, and we hope a little later to publish a Paper in which the question of surface and section of filaments will be discussed in the light of the experimental and practical results now attained.

Considerable attention has also been given to the process of exhaustion, and the pump now in use, which is the survival of many efforts to arrive at the fittest, is of a very unique design. Indeed, it is so far original that its chief features are not even to be found in the well-nigh exhaustive lectures on "Mercurial Air Pumps" by Prof. S. P. Thompson. The company has succeeded in rendering the various processes in the manufacture of lamps as automatic as can well be conceived possible, with the result that the number of hands employed is reduced to the smallest limit. Like other lamp makers, they have learnt by experience to adopt many little devices and precautions which might appear of trifling importance to the on-looker, but upon which commercial success has been found largely to depend. The Woodhouse and Rawson Company have expended some thousands of pounds in perfecting these details. Amongst the specialities introduced by them we may mention in passing the silvered lamps, which, under certain circumstances, are used with such good effect; and also a new kind of frosted bulb, which will shortly be placed on the market.

At the time of our visit the works were largely engaged upon the completion of an extensive order for "electric automatic shocking machines," and also were engaged on the manufacture of other automatic machines, which latter, although not electric, the company possesses every facility for producing. It is well known that these automatic machines have proved a very profitable speculation for every one concerned, and the company have done a large amount of experimental work in these, at one time having nearly 20 different varieties being manufactured at the same time. The electric apparatus consists of a small battery and induction coil, the latter having a movable core which is inserted further into the coil as the handle on the outside is turned. A stiff spring opposes the motion of the handle, and the latter is connected with the secondary coil.

On the ground floor of the principal building there is the usual collection of machine tools, such as planing, milling and drilling machines, together with a considerable number of hand and power presses used chiefly for stamping out sheet brass for lamp-holders, switches, &c.

Descending to the lowest floor we find a 20 horse-power Marshall engine, a couple of Roots blowers, and an air pump. These latter machines are employed in maintaining a service of compressed air and vacuum pipes, which are carried throughout the building, This service is, of course, chiefly useful in the lamp factory, where a large number of blow-pipes are employed, but it is also very useful in other parts of the building. In an adjacent room some 15 dynamos of all sorts and sizes are at work. Some of these machines deliver current to the testing room, others to the lamp department, some are used for lighting the shops, and others for charging or forming accumulators. A large alternator is at work supplying current for experimental purposes. On this floor also one or two of the heaviest machine tools are placed, and the general millwrights' work is carried on here. The secondary battery, plating and polishing departments are on the same floor. The small secondary batteries, of which Messrs. Woodhouse and Rawson have made a speciality, for surgical and theatrical work, are made here. A

Digitized by Google

number of accumulators of new types were also undergoing experimental tests.

Upon the first floor of the same block is the fitting shop. This is a fine room, measuring 100ft. by 30ft., and containing a large number of lathes and light tools. Some new models of automatic boxes were being made here, together with various descriptions of ammeters, voltmeters, automatic cut-outs, electric governors* and other instruments, such as Harcourt's pentane standard burners. At one end were being made the appliances to be used by the Institute of Medical Electricity at their new rooms. Our attention was also attracted by an ingenious appliance for stamping at any moment the date, hour, and minute, which Messrs. Woodhouse and Rawson are manufacturing for the inventors.

The top floor in this building is chiefly occupied by boys and girls engaged in making small and cheap switches, many hundreds weekly being made, and also the "Diamond" electric bell, which is sold at the retail price of half-a-crown. This low price for a good bell is made possible by the simplicity and ingenuity of the design, the fewness of the parts, and the employment of special tools and cheap labour in the manufacture. Here also is the department where coil-winding and lacquering is carried on, for which female labour is employed.

Crossing a bridge to the next block we come into the incandescent lamp department to which we have already alluded, and descending two flights of stairs, passing on the way the lamp tests rooms and photometer room, the latter fitted with all the latest appliances, we come to rooms where the new and interesting process of platinum plating is carried on under the patents of Prof. S. P. Thompson. The following is the method, as described by Prof. Thompson in his specification:—The metal or alloy is first brought to the state of chloride by known chemical processes. The chloride, after having been dried at a moderate temperature, preferably that of steam, is dissolved in distilled water or other soft water of adequate purity. To this solution is added a solution of a certain medium, also previously similarly dissolved, the weight of the medium taken being from 10 to 40 or 50 times as great as that of the metallic chloride. As mediums are employed phosphate of soda, or phosphate of soda mixed with borate of soda or carbonate of soda, or with tungstate of soda, or with any of these materials, or the corresponding salt of ammonia mixed with the soda salt. The mixed solutions of metallic salt and medium are then heated together, preferably to the boiling point; and to the liquor so produced is added one of the following brightening substances, namely, salammoniac, bromide of soda, carbonate of soda, bicarbonate of soda, carbonate of ammonia, hyposulphite of soda, hypochlorite of soda, chlorate of soda, or a mixture of two or more of them—for example, a mixture of salammoniac and carbonate of soda. Preferably such brightening substances are also similarly dissolved in a little water previously to being added to the solution. The mixture having then been preferably once more heated, it must be neutralised. If it is found alkaline, a few drops of hydrochloric acid or a solution of chlorine in water or other suitable substance are cautiously added. If it is found acid, carbonate or bicarbonate of soda is added. The bath so prepared should be warmed to a temperature of from 60° to 90° C. (140° to 194° F.), and is used in the ordinary well-known way, with a fairly strong electric current. The anode may be of carbon or of platinum; but in every case it will be found requisite in the daily use of the bath to add (preferably hot) further quantities of strong neutral metallic solution as the metal is withdrawn by deposition from the bath, and also from day to day to add small quantities of borate of soda or other medium, and also of carbonate of soda or of hydrochloric acid or chlorine water to correct the acidity or alkalinity of the bath.

There can be little doubt that this is an industry which has an important future before it. The cost of a platinum-plated article is but little higher than the best quality of silver plate, its appearance is almost identical, whilst it is far easier to keep clean, and for this reason it should last the longer.

On the same floor is a gas department, which was added to the establishment after they were stopped supplying lamps. Here was carried out all the early work on the well-known Wellsbach incandescent light; a new form of burner, called the "Schülke," is now undergoing test, and seems to promise successful results, 10 candle-power per cubic foot being obtained. On the floor below is the wood-working machinery, which is on a scale corresponding to the demands of the establishment. Other rooms on this floor are occupied by painters and polishers, and some alterations are being made with a view of adding several heavy machine tools.

On the ground floor is the primary battery department, and here may be seen the ingenious chlorine battery with which the name of Mr. Réné Upward* is associated. Power is supplied to this block by a second Marshall horizontal engine of 20 horse-power. The boilers and smithy are placed in a shed on the other side of a small yard, and special precautions are taken to carry the smoke away from the direction of the lamp factory. In this yard is the foundry, and beyond is the waste land already alluded to.

In the main court-yard is the testing room, under the charge of Mr. H. Davies, containing several ingenious instruments designed and manufactured on the premises, of which we shall perhaps give some account at a later date. Next to this is a room containing some special accumulators for testing purposes. One battery consists of a large number of small cells connected in series so as to give several hundred volts; there are also a number of very large Elwell-Parker cells, which can be connected either in series or in parallel, and in the latter case are able to deliver a current of upwards of 1,000 amperes.

With a glance at the stables and waggon house, &c., our tour of the establishment is completed.

In conversation with Mr. F. L. Rawson we have gathered that he attributes the success of the company largely to the fact that most of the hands have been with the firm since the commencement of the business, some six or seven years ago, thus having had a thorough training in and knowledge of the special features of the work. The firm have a considerable number of apprentices and a few pupils. The latter have the privilege not only of going through all the different departments of the works, but also of passing through the head offices in Queen Victoria-street and the other businesses with which the firm are connected. Many of those who had passed through the firm's hands are now employed by the P. and O. and other large shipping companies, who know the advantages of getting thoroughly well-trained youths. To give an idea of the spirit in which the business is carried on, we should add that one of the greatest difficulties the firm have had to contend with has been to keep the *employés* in good health, ill health from over-work having been very common. To counteract this we found on the notice board at the entrance to the works notices of various athletic sports, and we understand that the *employés* are well known for their proficiency in this respect. The interest taken by the heads of the company in these, together with the sick club and similar movements, has, no doubt, its influence on the men.

THE GRAY TELAUTOGRAPH.

For some time past Prof. Elisha Gray, the well-known inventor of the system of harmonic multiple telegraphy, has been at work on a new system of telegraphic transmission, the object of which is the *fac-simile* reproduction by telegraphy of the handwriting of the sender of a despatch. The idea of *fac-simile* telegraphy is, of course, not novel, and has been carried out in several ways, but the new system of Prof. Gray is based on an original method, and moreover it is able to do what no other writing telegraph has yet accomplished—that is, it permits the pen to be lifted and replaced on any part of the paper, so that any desired correction or erasure may be made, or any sketch or drawing, however elaborate, may be faithfully transcribed. As a consequence of this feature it is not necessary to write on a narrow strip of paper, ordinary letter

* For the Porte-Manville electric governor see *The Electrician*, Aug. 30, 884, p. 367.

* See *The Electrician*, July 2nd, 1886, p. 153; Sept. 17th, 1886, p. 385 and Feb. 25th, 1887, p. 349.

Digitized by Google

or foolscap paper may be used; moreover, the paper written on remains at rest, so that the movements of the pen are exactly those of ordinary writing, and the transcription at the receiving end faithfully reproduces the spacing of the original. In most of the previous instruments, owing to the movement of the paper, any irregularity in the speed of writing, or any momentary pause, is marked by an increased space in the transcript.

The system consists primarily of two instruments, a receiver and transmitter, each provided with a pen. The transmitting pen is connected to operate circuit making and breaking devices, termed "interrupters," located in two electric circuits and arranged to interrupt the currents passing over the respective circuits at short intervals, producing current pulsations as the pen is moved in two directions crosswise of each other in forming characters, the number of pulsations in the respective circuits being determined by the distance which the pen is moved in the respective directions. These two circuits pass through the receiver and include two pairs of "receiving magnets," the armatures of which act to impart a step-by-step movement to the receiving pen in two directions at right angles to each other, the number of steps in each direction being determined by the number of times the respective circuits are interrupted. By this means the movements of the transmitting pen in the two directions operate through the interruptions in the currents passing over the circuits to impart corresponding movements to the receiving pen, and thus reproduce the matter written by the operator.

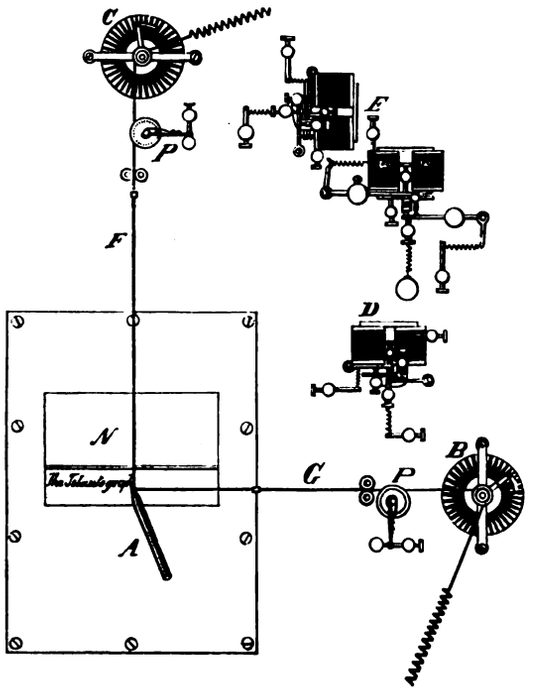

FIG. 1.

The method by which the receiving pen is made to follow the motions of the writer when he lifts his pen from the paper is extremely ingenious, although it is only attained by aid of a very delicate and complex piece of mechanism. In the American specification the full elucidation of the apparatus requires 26 figures, in which over 150 different index letters and numerals are referred to. Briefly, however, we may say that the lifting and replacing of the pen on the paper is controlled by mechanism which is primarily actuated by the pressure of the pen upon the paper at the transmitting station. The paper is placed on a frame supported by a very delicate spring. The pressure of the pen upon the paper is sufficient to close a contact in a local circuit which by means of a relay acting on a weighted lever transmits a signal to line. This signal consists of a certain number of makes and breaks transmitted in a certain pre-arranged order, and with pre-arranged, though very short-time intervals. This signal, arriving at the receiver, passes through a series of polarised and non-polarised relays, whose armatures are opened or closed in such order and in such fashion as finally to produce the required effect of lowering the pen upon the paper. The arrangement seems very complicated, but we have little doubt that a careful study of the conditions to be fulfilled would reveal the necessity for each link in the chain.

The shifting of the paper at the end of the line is, however, effected in a very simple fashion. At the receiving station the paper is in the form of a roll, which is weighted at the free end so that it would tend to travel over the table of its own accord if not prevented. The weight is, however, hindered from falling, when the instrument is in use, by a detent in connection with the armature of an electro-magnet. If the current in this circuit be stopped the weight descends over a space equal to the distance apart of the lines on the paper. The controlling magnet is energised by the current in each of the two main circuits, and its demagnetisation is effected from the transmitting end by opening both the circuits simultaneously. For this purpose a switch is provided, and the same movement shifts the paper to the same extent at the transmitting end.

The accompanying illustrations, Figs. 1 and 2, which, together with the following description, we take from the *Electrical World*, N.Y., show respectively a general plan of the transmitter and receiver, so far as relates to the motion of the pen in the plane of the paper. The transmitting pen A is connected at its point to two cords or other flexible connections F G, which extend horizontally at right angles to each other, and operate the two circuit making and breaking devices B C, termed the "interrupters," located in the two main circuits, connected to B and C. The arrangement is such that as the pen A is moved from left to right and *vice versâ* the circuit of B is made and broken repeatedly in quick succession, producing pulsations therein varying in number with the lineal extent of the movement of the pen, and varying in speed of succession with the rapidity of such movement; while, as the pen is moved up and down in forming the characters, the circuit of C is interrupted and pulsations produced therein in the same manner. The two interrupters B C are exactly similar in construction.

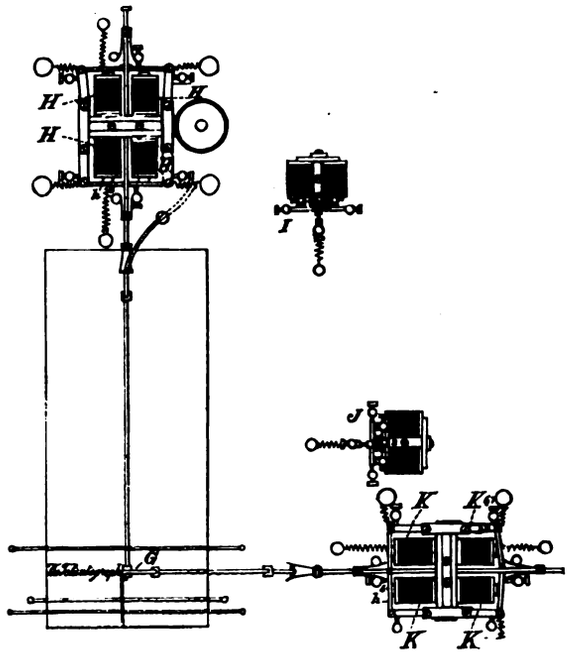

FIG. 2.

Each of the cords F G is wound upon a small drum upon a shaft to which one wire of the circuit is connected. The shaft is provided with an arm, the end of which carries a brush which sweeps in contact with the face of a metallic disc, to which the other wire of the circuit is connected. The face of the disc over which the brush sweeps is provided with insulating strips, so that as the brush sweeps over the face of the disc in either direction the current passing over the circuit in

Digitized by Google

which the brush and disc are located will be made and broken repeatedly in quick succession. Each of the shafts is also provided with a second cord, which is wound upon the shaft in the direction the reverse of the cords F G, and is connected to a spring which keeps the cords F and G taut at all times. Each of the cords passes between guides located between the pen and the shafts, and the cords are provided with stops which engage with the guides and arrest the cords and limit the movement given to the shafts and brushes.

The transmitting instrument is also provided with two local circuits which include local batteries and a pair of pole-changers D E, which are located, respectively, in the main circuits of B and C, and which act to automatically change the polarity of the currents passing over the respective circuits whenever the movement of the transmitting pen in either direction is reversed.

The pole-changers D E are connected to the two poles of the main batteries and to the two wires of the respective main circuits in the usual manner. For the purpose of operating the pole-changers the cords F G pass around pulleys P P mounted upon shafts which operate circuit makers and breakers included in the respective local circuits. For this purpose the shafts are provided with arms which are frictionally connected to the shafts and have a limited movement between fixed stops. The arms and one of the stops of each arm are included in the respective local circuits, so that the rocking of the arms between their stops operates to make and break the local circuits, and thus operate the pole-changers D E to change the polarity of the currents passing over the main circuits of B and C at each vibration of the arms.

It will now be readily understood that as the pen makes the down strokes in forming the characters the cord F will be unwound from the shaft of the interrupter C, revolving the shaft and moving the brush over the disc, and interrupting the current over that circuit repeatedly and in quick succession, the number and rapidity of the interruptions being determined by the speed and extent of the movement of the pen.

As the pen makes the upstrokes the spring will rewind the cord F and move the brush in the reverse direction, interrupting the current in the same manner.

It will also be understood that as the pen moves upward the cord passing around the pulley P will close the local circuit of the pole-changer E and send currents of one polarity over the line to C; and as the pen moves downward the pulley will open the circuit of the same pole-changer, so as to send currents of opposite polarity over the same line.

What has just been said with regard to the C circuit also applies to the circuit of B when the pen is moved from right to left, the pole-changer D being then operated by the lower pulley and arm B, so as to change the polarity of the current according as the motion is from left to right, or *vice versâ*.

We now come to the operation of the receiving instrument, which is shown in Fig. 2. This consists of a pen connected by means of a tube with a supply of ink shown at the right adjoining the upper receiving magnets. The pen is connected to two rods which are placed at right angles to each other similar to the cords in the transmitter, and are jointed so to have a free movement sidewise. One of these rods passes through the frame carrying the magnets H H, which are included in the circuit of the interrupter C of the transmitter, and are provided with armatures which act upon the rod in such a manner as to impart a step-by-step movement to it in opposite directions, according as one or the other of the magnets is energised. The rod and the magnets H H and their armatures are so arranged that the rod passes between the adjacent ends of the two parts of each armature in such a manner that when the two parts of either armature are moved towards each other they will act first to grip the rod between them, and being then moved toward the magnet they will carry the rod with them and impart a corresponding movement to the pen G.

In connection with the magnets H H there is a polarised relay, I, which is so arranged that when its armature is on one contact, due to a current coming over the line in a certain direction, it sends that current into the lower magnets H H; but when a current of opposite polarity comes over the line it is carried to the other stop, and the current is sent into the upper magnets, the lower magnets being then short-circuited.

Now, it will be readily seen that when the pen A at the transmitting station is upward it sends current pulsations of one direction over the line. These are received by the relay I and sent into the lower magnets H H, which act as described above to grip and raise the rod to correspond exactly with the number of pulsations, which, of course, are determined by the amount of movement given to the transmitting pen A. When the latter is moved downward the current impulses are sent in similar way into the upper magnets, which grip and lower the rod in an analogous manner at each pulsation. The identical action also takes place with the current transmitted over the main line connected to the interrupter B, the current passing into the relay I and magnets K K, which act upon the rod at right angles to the first to move the pen sidewise in either direction.

From this it follows that any movement of the transmitting pen in any direction oblique to the line or intermediate between these two directions will cause the receiving pen to move in a corresponding direction, but with a compound movement made up of a number of steps taken at right angles to or crosswise of each other, the relative number of steps in each direction depending upon the obliquity of the direction in which the transmitting pen is moved. By this means the receiving pen is caused to substantially follow any movement of the transmitting pen, and thus reproduce a *fac-simile* of whatever is written or traced by the latter.

The irregular or wavy character of the oblique lines made by the receiving pen is said not to detract materially from the appearance of the writing, and is not sufficiently marked to prevent the handwriting of the person at the transmitting instrument from being readily recognised. The length of the steps with which the receiving pen is moved may be varied considerably; but the receiver is so adjusted that the pen takes from seventy-five to one hundred steps to the inch.

REPORT OF THE COMMISSIONERS OF THE PRIX VOLTA.

The following is a translation of the full text of the report made by the Commissioners in awarding the Prix Volta to M. Gramme, omitting only the preamble:—"In the year 1832, a few months after Faraday's discovery that electric currents were generated by the relative movement of a magnet and a conductor, Pixii constructed, under Ampère's directions, a machine intended to utilise the rotation of a magnet to generate continuous currents in this way, obtaining from mechanical work the electrical energy which, from the time of Volta, had been obtained chemically. This was the starting point of a great number of attempts to increase the utility and efficiency of these so-called magneto-electric machines. A supreme difficulty, however, remained for long an obstacle to the industrial application of these machines. The distance between armature coils and field-magnets necessarily changes periodically. They approach and recede alternately, and consequently give rise to alternating currents, which are of no use at all in many of the industrial applications of electricity. From the first it was sought to correct these currents by using a commutator which alternately presented the two extremities of the external circuit to those of the dynamo circuit. As soon, however, as these machines were made on a commercial scale the sparking at the commutator quickly destroyed it. It was reserved for M. Gramme to get over this difficulty, and to invent a commercial electromotor which has been the starting point of the marvellous development of electrical industries which we are at present witnessing. Giving up the idea of such an unsatisfactory form of commutator, electricians now set to work to make as much as possible of alternating currents for lighting purposes, &c., where rapid alternations were not an obstacle. It was possible even in these days to see the germ of the present growth of commercial electricity. Thirty years ago the Société l'Alliance was working the patents of M. Nollet for dynamo-machines with permanent magnets. The workshops of this company were in charge of one Joseph Van Malderen, a Belgian by birth, a man of considerable merit, and to whom several of the improvements made in the 'Alliance' machine were due. In 1860, Van Malderen employed M. Lénobe Gramme, a countryman of his, whom he had met at Brussels, but who was then working as a carpenter in Paris. Endowed with great reflective powers, M. Gramme tried to master the strange machine which he helped to construct. Two years

Digitized by Google

later he was employed by Ruhmkorff to put finishing touches to the woodwork of influence machines, and here also M. Gramme found much to think about. Hardly knowing how to read or write he was but poorly prepared to understand the discussions and explanations which went on around him, so he endeavoured to form his own ideas about the mysterious force whose extraordinary effects he daily witnessed. To check the results of his meditations he purchased an elementary treatise on physics, which he perused painfully word by word by the help of a French dictionary. M. Gramme was greatly elated to find that the leaders of the scientific world were not much more certain of their ground than he was, and were reduced to much the same hypotheses. He had already tried his hand with but little success at several mechanical inventions, and he now hoped to be more fortunate in the field of discovery which lay open before him. His library consisted of two books—a treatise on physics and a dictionary; his laboratory was a modest kitchen, and contained a sheet of gutta percha, two magnets, and a few pounds of copper.

"In a patent dated 26th February, 1867, for improvements in the construction of alternate-current machines, M. Gramme described an electric pinion consisting of coils wound on the projecting teeth of an iron ring; he also pointed out the principles governing the excitation of the field-magnets by means of a current from the armature itself. But ill-luck pursued him. His want of money had delayed the application for a patent for over six months since the idea occurred to him, and in January, 1867, Wheatstone had communicated a Paper to the Royal Society upon the 'Self-Excitation of Dynamo Machines.' In the following year, while on a short visit to London, M. Gramme constructed his first continuous-current machine. The E.M.F. of this machine was to have been over 3,000 volts, but difficulties of insulation caused M. Gramme for the moment to give up the idea of a high-tension machine. In 1869 he constructed a new machine, with a magnet weighing 10 kilograms and a ring armature wound with 1 mm. wire. Satisfied with the results he obtained, M. Gramme now tried to get financial support in order to work out his idea. He addressed himself to Bréguet, whose standing and generosity were generally admitted. This eminent man was, however, ill-inspired on this occasion. He received the inventor with his habitual kindness, but showed him clearly that he had no illusions about the inanity of the dream. However, true to his generous instincts, Bréguet gave M. Gramme the 100fr. which were nccessary to enable him to take out a patent. We are inclined to doubt if the invention received much additional encouragement. The essential part of the Gramme machine is simply a soft iron ring, wound with a continuous wire and turning in a magnetic field. The currents induced in the two halves of the wire have, as starting and stopping points, two points, which are fixed in relation to space, but which are movable in regard to the ring itself. It is therefore only necessary that the two ends of the external circuit should terminate in two fixed bars, successively coming in contact with the armature coils, in order that the circuit should be traversed by a continuous current. This is the essential feature of the Gramme machine. Simple as it seems to us now it was nevertheless quite different then; it was quite unthought of, and it is easy to understand how little was anticipated from so simple a device.

"It ought to be mentioned that this principle was not absolutely new, and equity demands that the merit of first discovering it should be accorded to M. Pacinotti. In a note inserted in the *Nuovo Cimento* of June, 1864, M. Pacinotti described a little electro-magnetic machine, the principal feature of which was a ring similar to that of M. Gramme. It was a motor driven by a battery, and its commercial efficiency was about 10 per cent. 'Although these results,' says the author, 'do not place this new machine much above other small electro-magnetic machines, still, they are by no means bad, considering the imperfect mechanical construction.' M. Pacinotti also showed that if the electro-magnets of the machine were replaced by permanent magnets it could be used as a dynamo. 'I think the value of this style of machine is considerably augmented by the fact that it can be easily turned into a continuous-current magnetic machine. The electro-magnetic machine which results has the advantage of yielding induced currents in one direction without there being any necessity to separate dissimilar currents or to combine similar currents.' The eminent professor of Pisa never dreamt that this laboratory apparatus could become a commercial machine, and no one seems to have thought any more about the matter, for the communication to which we have just called attention remained hidden. Contemporary scientific journals hardly noticed it, it was not mentioned in any text book, and it was, in short, ignored until the undoubted success of M. Gramme's machine directed attention to previous researches, and amongst them to those of M. Pacinotti. Least of all was M. Gramme the person to have known of them, and nobody has ever questioned his *bona fides* or his claim to being the first to make the machine a practical success. We have seen how great were M. Gramme's discouragements, his absence of resources, and the incredulity of all competent men. Since 1869 M. Gramme has described and designed four different machines. In one of them the armature coils are under the influence of the magnetic field from both sides. In another there were two armatures and six poles. The third is the type of machine turned out by the Bréguet workshops for the last fifteen years. Finally, in 1871 the Académie des Sciences was shown a four-pole machine, and the very many scientists who visited the factory of MM. Mignon and Rouart on that occasion saw with astonishment a continuous-current dynamo which did not absorb more than four horse-power, and which was capable of transforming a 10-metre copper wire into a garland of fire. At this date the inventor had studied minutely the *rôle* played by the different parts of his machine. He was in possession of empirical formulæ, which enabled him to reduce weight to a minimum, to arrange the proper distribution of iron and copper, to calculate the diameter of the wire, the number of turns, and the necessary speed, so as to obtain in every case the greatest efficiency compatible with safety and durability. His capabilities were soon put to a severe test. From the year 1854 MM. Christofle had tried with but little success to replace the cumbersome and noisome batteries then employed in electro-plating by magneto-electric machines. Struck by M. Gramme's success, MM. Christofle set him the following problem to solve:—'Construct a machine which will deposit 600 grammes of silver per hour on a given surface, in four baths arranged in parallel; the machine to run at 300 revolutions per minute.' In spite of the progress made in recent years in the determination of the correct values of the different electrical units and the properties of iron, what *savant* of to-day would be able to solve this problem without the aid of the empirical formulæ of the workshop? Three months later M. Gramme handed over to MM. Christofle a machine constructed as specified, which from the very first deposited 600 grammes of silver per hour, and ran at 300 revolutions a minute. This was a genuine triumph, and was the signal for a revolution in the electro-plating trade. Two years after the inventor built for M. Wohlwell, of Hamburg, a machine which yielded 3,000 amperes at 8 volts, and deposited 800 kilogrammes of refined copper in 24 hours. From this date batteries disappeared from electro-metallurgical works.

"Success was now assured, but M. Gramme had not the gifts necessary to turn his inventions to the best account. He was fortunate enough to discover an eminent engineer willing to be his pupil, to collect his ideas, and to undertake the commercial part of the business. Legitimate success was soon attained, and the inventor obtained an unlooked-for fortune. M. Gramme's colleague administered his affairs himself, and saved his partner all the worry of financial operations. As for M. Gramme, he has ever remained a simple workman, completely immersed in the congenial task of improving the details of his machines, and creating every year new types for lighting factories, ships, lighthouses, and open spaces. M. Gramme has also paid attention to such accessories as the regulation of arc lamps and the regulation of the speed of motors in transmission of power of installations, evincing in every direction an ingenious and practical mind. M. Gramme works entirely by himself. He sketches, elaborates, and realises his plans without any assistance other than that afforded by two men, once entire strangers to both electricity and mechanics, namely, a stonecutter and a bookbinder. He does not care to appear in public, and avoids all occasions where his modesty may be troubled by praises. So obstinately does he adhere to his solitary workman's life, that an eminent foreign scientist, who had vainly tried to get sight of him, professed to disbelieve in his existence.

"Since the date of M. Gramme's invention, commercial development of electricity has gone on at a great pace. A large army of inventors have followed in his steps, and almost all, if not quite all, of the innumerable types of machines in the market which furnish continuous currents are of the Gramme-ring pattern. Science has benefited the most. Thanks to the dynamo, physicists have at their disposal currents which it would have been impossible to obtain in the days of the voltaic cell. M. Gramme certainly cannot be placed side by side with men of genius like Ampère and Faraday. Neither can M. Gramme's work be compared in importance to that of Graham Bell, the inventor of the telephone. Still, according to the words of the Institut, 'it forms a memorable epoch in the history of electricity,' and it is well included in the scope of the Ministerial decree of the 10th November, 1882. Volta's discovery remained a laboratory one; its commercial applications were very few, in spite of the many attempts and hopes which Faraday's discoveries gave rise to. Since M. Gramme's time, however, electricity has taken its place by the side of steam, and its part becomes daily more important. In awarding the Volta prize to M. Gramme, the committee thought that it was fulfilling the ideas of the founder, and that it was following the lines laid down by the Institut. It is confident that its decision will obtain the cordial assent of all *savants*, practical men, and those interested in the progress of science and industry."

The Electrician.

Published every Friday. Price Fourpence; Post Free, Fourpence Halfpenny.
Editorial and Publishing Offices
No. 1, SALISBURY COURT, FLEET STREET, LONDON, E.C.
Telephone No. 2714.

All Communications to be addressed to "THE ELECTRICIAN," 1, Salisbury-court, Fleet-street, London, E.C. Cheques and Money Orders should be made payable to "THE ELECTRICIAN."

All letters intended for insertion in "THE ELECTRICIAN," or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.

"THE ELECTRICIAN" is published every Friday morning, in time for the morning mails. Subscribers should receive their copies by the first post on Friday morning.

"THE ELECTRICIAN" is on sale at the railway bookstalls throughout the United Kingdom on Friday morning, and can be obtained at all Booksellers and Newsvendors; or direct from the office as above.

SPECIAL NOTICE.

Owing to the increase in the number of pages of "THE ELECTRICIAN," in order to partly cover the increased postage, we have been compelled to revise the rates for Foreign Subscriptions, which are now as follows:—

	3 months.	6 months.	12 months.
For Foreign Parts and Colonies:—	s. d.	s. d.	s. d.
Within Postal Union	6 6	... 12 6	... 24 0
„ Aden, Borneo, Ceylon, China, India, Japan, Java, Labuan, Mozambique, New Caledonia, Persia, Philippine Islands, Siam, Transvaal, and Zanzibar	7 6	... 14 6	... 28 0
The rates for the United Kingdom remain as follows:—	5 0	... 10 0	... 19 6

TO ADVERTISERS.

"THE ELECTRICIAN" offers exceptional advantages to Advertisers. **It has the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application to this office.

Advertisements intended for the current issue must be handed in not later than 4 p.m. on Thursday.

TECHNICAL PRINTING.

"THE ELECTRICIAN" PRINTING AND PUBLISHING COMPANY (LIMITED) *beg to inform Electricians and Electric Light Engineers that they make a specialty of Technical Printing, and have a Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electrical Catalogues and Electro-Technical Literature generally.*

The Electricians' Directory.

Royal 8vo. Cloth Boards, 3s. 6d. Boards, 3s.

At the end of December in each year is issued THE ELECTRICIANS' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and has now attained considerable proportions. Every care is taken to make the names and addresses of all persons engaged in the Electrical Industries absolutely accurate. Useful Tables and Electrical Formulæ are given, together with popularly-written Biographical Notices of the leading Electricians, accompanied in many cases by Portraits.*

THE DIRECTORY FOR 1889 IS IN PREPARATION.

"THE ELECTRICAL WORLD" IN THE UNITED KINGDOM.

Arrangements have been made by which "THE ELECTRICAL WORLD" OF NEW YORK can be obtained from "THE ELECTRICIAN" Office, 1, Salisbury-court, Fleet-street, London, E.C.

The Rate of Subscription (payable in advance), including postage, is **£1. 1s. 0d.** *per annum to this Country and Abroad.*

Single Copies of "THE ELECTRICAL WORLD" can also be obtained, **price 6d. each.**

The Rates for Advertisements in "THE ELECTRICAL WORLD" OF NEW YORK can be obtained on application to "THE ELECTRICIAN" PRINTING AND PUBLISHING COMPANY, LIMITED, as above.

"THE ELECTRICIAN" IN THE UNITED STATES.

Similarly, "THE ELECTRICIAN" can be obtained in America at the Offices of "THE ELECTRICAL WORLD," 168 to 177, Potter-building, New York.

"THE ELECTRICIAN" can also be obtained from D. VAN NOSTRAND, *23, Murray-street, and 27, Warren-street, New York.*

The Rate of Subscription for American Subscribers (payable in advance) is $6 per annum.

PHYSICS IN PUBLIC SCHOOLS.

IN an American review for the present month, and bearing the above title, there appears an article which might have been penned by an Englishman, and may certainly be read with advantage by everybody interested in the teaching of science in our English schools. Possibly the conclusions arrived at by the writer, Mr. C. J. H. WOODBURY, are not altogether those which we should ourselves endorse; but the facts disclosed are pretty much what are common experience with us, and being stated in sober seriousness, not as facetiæ extracted from an examiner's note-book, we are able to comment upon them with the same useful purpose which the writer had in view. The circumstances under which he has written arose as follows:—There was a High School to be started, and at least one prospective vacancy to be filled in the classical High School, besides several similar ones in the Grammar Schools. The positions were such that the head teachers, it was considered, ought to possess some knowledge of modern science, if only as a test of general intelligence and for guiding the miscellaneous reading of scholars upon technical subjects "even though not included strictly in the prescribed course of studies." Accordingly a teachers' examination was held, the series of questions including a few upon physics and chemistry. Only one related to electricity, and ran as follows:—"Explain the principle of the Bell Telephone." The notoriety of this invention and the prominence given to it in the newspapers induced the examiners to think, not unreasonably, that the answers given by the candidates would fur-

Digitized by Google

nish evidence of their habits of observation and of general reading, to say nothing of their scientific training.

Now, that the candidates had received some scientific training, or, rather, had acquired a considerable smattering of scientific phraseology, is plain to be seen from their answers both to this and the other questions in physics and chemistry; but as to their habits of careful observation and exact thought with which this training had endowed them we may leave our readers to judge for themselves. It should be mentioned that the candidates were of the gentler sex; but any allowance to be made on this account is rather discounted by the fact that they were women of proved superiority, being graduates of High Schools of excellent repute, or of the leading academies in New England. The answers, therefore, were not those of school children, either girls or boys, but, as the writer says, of "ladies who had received the benefits of the best public school instruction given in the oldest of our New England States." This being premised, we may now proceed to analyse the ideas these highly educated persons had formed, first with regard to the Bell Telephone.

Only ten of the number attempted any answer at all, and about half of these appear to have had no conception that the telephone was an application of electricity, or that it was other than a superior kind of speaking tube. Number 1 essays that the telephone is based "on the principle that sound may be transmitted a great distance along a wire." Number 2 confines herself to the safer assertion that "sound, having a medium to carry it, will travel." Numbers 9 and 10 are fuller and far more ambitious in their use of scientific terms, though not a whit nearer the mark than the other two. "By means of the telephone communication can be carried on by articulation." So far Number 9 is on sure ground; and hardly less so when she specifically describes the Bell Telephone as "a small wooden arrangement attached to a wall." After this, her memory of what she has evidently seen, but not understood, is lamentably at fault, for she speaks of an "opening for the mouth, and also a small piece connected to the instrument by a cord to hold it to the ear." With these appliances "sounds are transmitted in waves along the wire, and coming in contact with the air strike the ear drum and are transmitted through the chain of bones to the openings on the inside, and thence by the optic nerves to the brain." This young lady plainly does not mean to let her scientific vocabulary grow rusty for want of airing. Number 10, who is equally profuse in this respect, after a preliminary flourish of generalities, makes a dash at exact description as follows: "It" [a platinum disc] "vibrates against a magnet to which are connected two magnets which wind around two screw cups, and then pass through the instrument to the distant station." A few of the answers betray a certain suspicion that electricity plays some part in the business; but nowhere is there the remotest attempt at defining it. "It is," says one, "carried on by that mighty power electricity." This is a good beginning; but she immediately relapses into fatuity: 'We ring an electric bell. When we speak we hold a cup or handle to our mouth"—and so forth. Number 4 succinctly avers that "the principle of the Bell Telephone is based first upon electricity." But she stops at that, and, perhaps wisely; for the lady following her explains that as a membrane with a tube could only be employed for short distances, "electricity was applied to make them [the sounds] stronger, and iron plates were used instead of membranes." Another candidate speaks of the voice causing "waves of condensation and rarefaction to undulate through the wires;" while the next one spoils a promising beginning by a similar blunder; and the eighth finishes up with "two posts connected with the permanent magnet, one going into the ground and the other all connected with the receiver at the distant station."

The answers to the questions in physics need not detain us long. With definitions of well-known terms the candidates could not go very far astray; but here again we find the same hesitation, the same vagueness, or the same audacity of ignorance repeating the disjointed phraseology of the text-books, and often giving right answers, but unfortunately to the wrong questions—a trick of memory with which every examiner is only too familiar. "Force," we are told, "is a push and a pull;" "force is the attraction which one body has for another;" "inertia is the rate of motion;" "inertia is that force by which a body may be moved from one place to another;" unit of heat is defined as "a regulation made by which to reckon a decrease or an increase;" and, as "an amount of heat required to heat a certain body." Mr. WOODBURY assures us that the questions were framed on the text-books of physics actually used by the majority of the applicants; and he is careful to state that the subjects were accurately and clearly treated of in those books. For our part we need no such assurances, the answers in no way surprising us. Briefly, our comment on this part of the case is that where a true answer can be given only by an effort of memory, and not from experience and observation, the chances are about equal that the candidate will stumble on the wrong answer.

These New England candidates were from different institutions, but all alike exhibited the same failings, and Mr. WOODBURY attributes this to some radical fault in the methods of instruction. The radical fault, it seems to us, of all such methods of instruction, both in America and here, is that it attempts to substitute book learning for that training of the active faculties without which all learning by rote is mere waste of time and brain power. Had their eyes and understandings been properly disciplined these very learned ladies would have grasped the principle of the Bell Telephone without the aid of the newspapers; and as regards elementary physics, they might have been saved from their worst blunders by a few illustrative experiments. Instead of this, memory alone is cultivated, and in most instances with results which are a snare to the teachers and a mockery to the examiners. Mr. WOODBURY observes that in chemistry the lady candidates show greater proficiency, "because excellence in that study is the result of memory" rather than of the exercise of the other faculties. So far as the examination is concerned this may well be the fact; but for all useful purposes thereafter what is true of physics is true also of chemistry, viz., that laboratory and workshop practice should be given in all cases concurrently with the study of books.

ELECTRIC TRACTION ON THE INNER CIRCLE.

BY S. EVERSHED.

(Continued from page 441.)

It need hardly be observed that the estimate made in the last article of the maximum power required by a train is a very liberal one, and serves only to guide us in our choice of motors. Thus, four motors may be used, one on each car, capable of developing 75 horse-power each, without undue strain or excessive heating during twenty to thirty seconds. As the stationary plant must be able to meet the maximum demand from the whole line, we will, before going on, consider the conditions of maximum traffic during the Exhibition

Digitized by Google

season, for example. For one or two hours in the morning the City-bound trains are fully or even over-loaded, and the Kensington trains are at the same time often from one-half to two-thirds filled, the trains between Kensington and Edgware-road being comparatively empty. Thus, there may be about twenty trains of 100 tons, an equal number half-loaded, which may be put at 85 tons, and the light trains at 75 tons, the average weight being 87 tons. For the present the average weight of a train during times of heavy traffic will be taken as 90 tons.

The average power required per train will be nearly independent of gradient, except where gradients occur at starting and stopping places, in which case work is done in starting trains up, which is not recovered by the trains running down the gradient. Let us allow for a gradient of ·5 per cent. during starting, therefore, and the total work done on a 90-ton train during the run from a station to the point at which power is cut off works out at 5,290,000 foot-pounds; of this amount nearly 2,200,000 foot-pounds are done in the first 20 seconds and the remaining 3,100,000 foot-pounds in 100 seconds, *corresponding to rates of* 200 W.H.P.* and 56·5 W.H.P.; and if the motors are assumed to work at an average efficiency of ·6 during starting and ·85 at full speed, and the gearing is supposed to absorb 15 per cent. of the power, we require 393 E.H.P. and 78 E.H.P. respectively at the motor terminals.

To keep the output of the power stations as constant as possible an arrangement must be made to prevent more than a certain proportion of trains from starting at once. If we imagine the stations at exactly equal distances, it is clear that in order to do this the time interval between the trains must be greater or less than that from station to station. Let the former be 20 seconds greater than the latter, so that there will be a train every 170 seconds. We still require some system by which an even distribution of trains may be secured; the writer suggests that a train while starting from a station should cut off the power from the conductors at the next station in the rear until it has passed over the space required for reaching full speed. This compels the trains to run with the right time interval, and also works as an automatic block system. It is obvious that on a circular line worked in this manner the number of trains must be at least one less than the number of stations, otherwise every train on the circle might be blocked by a train in front. As we have already increased the time interval to 170 seconds, there can only be about 50 trains on the circle, or 25 trains on each rail, and as there are 27 stations there will be at least two trains free to start.

The method of leading the current from the mains to the motors will not be discussed in the present article; it is generally agreed that there would be no great difficulty in applying either the "centre," "side" or "overhead" conductor system to the Underground Railway. The writer, however, doubts whether it would be advisable to use the rails as a return circuit in a case where the working potential difference will necessarily be high, and possibly dangerously so, and will therefore allow for double mains. What is the highest potential difference which can be employed consistently with public safety and ease of working? Five hundred volts is used in some instances, with perfect freedom from accident so far; a sense of the fitness of things suggests 1,000 volts as perhaps the limit beyond which it would be unwise to go. For the present purpose it will be convenient to put the E.M.F. at the motor terminals at 746 volts, not because of any peculiar virtue in this happy medium, but because amperes and horse-power become synonymous. The number of power stations depends to a great extent on the spaces available as sites; probably suitable positions could be found at or near Gloucester-road, Edgware-road, King's Cross, Aldgate, and Victoria. Each of these five stations would operate ten trains on about 2·8 miles of line, the mains thus extending not more than 1·4 mile on either side of the station. It will probably be found convenient to divide the feeding mains into two sets: first, a heavy main to feed those sections in running over which the motors are working at maximum power (we shall call this the *starting* main); second, lighter mains, sufficient for those parts of the line where only average power is required (these will be referred to as *ordinary* mains). The contact conductors should also be divided into corresponding starting and ordinary sections. The writer does not feel called upon to solve "the most economical main" problem; the mathematical solutions usually arrived at in similar cases have no practical significance whatever, as mathematical mains are destitute of insulation and cost nothing to lay down, while the capitalist is assumed to be a philosopher who carefully balances waste of power against interest of money. As a matter of convenience, however, it will be advisable to proportion the ordinary mains so that the working potential difference is fairly uniform and the loss moderate; they may, for example, be calculated on the basis of a maximum waste of 15 per cent. Taking as a unit the 1·4 mile of line forming one-half the circuit of each station, we see that it may be necessary to maintain all the trains on this section at full speed; in other words, the mains must be able to supply five trains at 78 E.H.P. each. The longest circuit will require a main 2·8 miles in length to carry 78×2 amperes with a drop of 132 volts; the resistance is therefore $\frac{132}{156} = \cdot 85\omega$ nearly, the sectional area being ·146 square inches, and weight 8,300lb. The next circuit will be 1·8 mile in length. It will carry the same current with the same drop, and its resistance is therefore ·85ω, area ·093, and weight 3,440lb. The shortest main is ·8 miles in in length, area ·042, and weight 680lb. Thus, the total weight of ordinary mains for 1·4 mile of line will be 12,420lb., or, say six tons, which allows for mains from power stations a short distance from the line.

Now for the starting mains. Since the time occupied in starting is 20 seconds, and the whole cycle takes 150 seconds, not more than $\frac{20}{150}$, or let us say one-seventh of the total number of trains can start at once, and as there are only five trains on the section under consideration, it is obvious that the starting main will never be required to supply more than one train, but that train may be at any point on the 1·4 mile. There being only one train dependent on it, uniform potential difference is not of much consequence, and its area may be calculated on the basis of a train starting 1·4 mile from the power station, and with a loss of 15 per cent. at full speed, as in the ordinary mains. If the speed of a train increases at a uniform rate, the average back E.M.F. of the motors during starting will be about half the maximum, the average current being therefore about half that necessary with maximum E.M.F., or the current must equal $393 \times 2 = 786$ amperes, unless provision is made for putting the motors 4 in series for the first 5 seconds or so, then in two parallels of 2 in series for 5 seconds more, and all in parallel for the remaining 10 seconds, when by moderate variations in the motor fields (an automatic variation with series-wound machines) the average E.M.F. may be kept as high as ·75 of the maximum, needing an average current at 525 amperes to give the average power required. Now as the dynamo at the power station must run at 878 volts in order to supply the motors when they reach full speed, and 132 volts are to be wasted when the motors are taking 746 volts and 393 amperes, we have $\frac{132}{393} = \cdot 336\omega$ as the resistance of the 2·8 miles of starting main; but at half-speed, assuming the means of regulation indicated above to be dispensed with, the drop in volts will be 505, while the current at this time is 786 amperes, so that the resistance should then be ·65ω nearly; in short, either the motors must be regulated, or the dynamos used to supply the starting main must be quite independent of those feeding the ordinary mains, so that some at least of the enormous waste in starting may be avoided. Gearing which permitted the motors to start at full speed and full power at once, while only gradually increasing the train speed, would, of course, solve the problem in the most perfect manner.

However, taking the lower resistance given above, viz., ·336ω, the sectional area would be ·367 square inches, and weight 21,000lb, or, say, 10 tons. If the highest estimate of maximum power be taken, namely, 300 W.H.P., the starting main would weigh 15 tons, but as, so far as the writer can learn,

* The letters W.H.P. will here be used to signify horse-power *delivered to the wheels.*

Digitized by Google

the maximum gradient is under 1·5 per cent., and the places where trains will require more than 200 W.H.P. very few, 12 tons of copper per section will be ample for the starting mains.

The size of the contact conductors may be arrived at by considering the average power required per train during the time current is supplied from the power stations. As 5,290,000 foot-pounds are done between two stations, and the current is on for two minutes, the average power is about 80 W.H.P., or, roughly, 125 E.H.P. As the loss in the conductors will depend to some extent on the nature of the moving contact it will be useless to allow for any specified loss, and we will therefore put the sectional area at ·125 square inches. There would probably be a separate pair of conductors for each road, so that $1·4 \times 4 = 5·6$ miles will be required in a section, and the weight will be 14,200lb., or say 6·4 tons. It is not unlikely that copper would prove unsuitable when used for contact conductors, but the above weight may as well be included in the total, which now amounts to:—

Ordinary mains = 6 tons.
Starting main = 12 „
Conductors = 6·4 „

Total weight of copper per section = 24·4 tons.

As there are five power stations operating two sections each the total weight of copper for the whole circle will be 244 tons. It will be seen that this estimate assumes the conductors to run over the whole line, inclusive of stopping places. It is not without interest to remark that the sum of the areas of the conductors at any point on the line will be nearly constant, since on gradients the increased size of conductors on the up road is nearly compensated for by the diminished area of those serving the down road. Again, corresponding with each starting section, where the conductors are, of course, very heavy, is a section on the opposite road where they will be light; these differences do not neutralise one another exactly, and if the motors are used as dynamos while stopping, heavy conductors will be required on both roads at each end of a station.

We will now ascertain the total amount of generating plant required. Here it will be best to take one train as the unit. As each train uses power at the average rate of 125 E.H.P. for two minutes, and then no power for half a minute, it is clear that the generating plant need only supply $125 \frac{2}{2·5} = 100$ E.H.P. to the motors; the loss in the mains we have put at 15 per cent., so that the generating plant must have an output of 117·5 E.H.P. per train, or allowing for spare machines, &c., 120 E.H.P.; giving a total, for fifty trains, of 6,000 E.H.P., divided into five stations of 1,200 E.H.P. each. The efficiency of the dynamos may be safely assumed to be ·9; the loss in engine and other friction ought not to exceed 15 per cent., giving a combined efficiency between indicated and electrical horse-power of $·9 \times ·85 = ·765$, and the engine must, therefore, be capable of indicating 7,850 horse-power—that is, 1,580 I.H.P. at each power station.

The efficiency between indicated horse-power and power delivered to the wheels is about 45 per cent., but would very probably not exceed 40 per cent., and if we take the coal consumption of the engines at 2lb. per I.H.P. hour we have 5lb. per W.H.P. hour, and therefore $5 \times 64/12 = 26·7$lb. per train mile, a quantity which appeals to railway men, but which has not much meaning apart from the weight of the trains moved. We may note, however, that from 25lb. to 30lb. of coal per train mile is a very usual consumption for such trains as those under consideration.

Having thus roughly outlined a complete scheme for working the Inner Circle electrically, we are in a better position to foresee and discuss the difficulties which would certainly occur than if they had been noted as they arose. There remains to be considered the brake question, which is really of the first importance, and some remarks should also be made with respect to automatic blocking and other matters incidental to railway working. It may be well to point out here that, although the service of circle trains has been assumed to work quite independently of the extension trains, no very material change would be made in the amount of plant required should it be decided to adhere to the present system of working. It might, for example, be possible to dispense with one power station, either that at Edgware-road or Gloucester-road; but it would be preferable to use the possible surplus power from these two stations, consequent on the infrequency of trains between them, to work the traffic electrically over a portion of the branches.

(To be concluded.)

THE BARCELONA EXHIBITION.

(FROM OUR CORRESPONDENT.)

August 18th, 1888.

Although it is now some thirteen weeks after the official opening of the Exhibition, I regret to say that the electric lighting is still in a somewhat unfledged state. The greater portion of the main building is as yet only fitted with lamps and leads, the evening shades being left in undisturbed possession as soon as the sun sets; indeed, it is only within the last four or five weeks that any part of the Exhibition has been regularly lighted. An International Exhibition left in darkness every evening is a decided novelty in these days, and it is certainly to be regretted that the first Exhibition of the kind ever held in Spain should distinguish itself in this unhappy way. It is only fair to mention, however, that circumstances certainly do not warrant any great extravagance. The average daily attendance is only some seven or eight thousand, and, except on saints' days and Sundays, only a few dozen individuals are to be seen in the grounds after nightfall; and there seems but little hope of the number of visitors being swelled to any great extent unless we have a rush of foreign tourists within the next few weeks. I will now give a detailed account of the electric lighting plant and the electrical exhibits of interest to be seen at the Exhibition.

The lighting of the buildings and grounds is divided between four firms, each of different nationality, so that the Exhibition is thoroughly international in this respect at any rate. The Compania Espanola de Electricidad, the only electrical engineering enterprise of importance in Spain, has 10 dynamos at work, all of native manufacture, supplying at present 120 arc lamps of 2,500 candle-power, and lighting the Gardens, the Fine Art gallery, the Science section, and the large restaurant. This is a tolerably stiff piece of work, owing to the scattered nature of the installation and the distances to be traversed by the wires. Later on this company will operate 3,400 16 candle-power incandescent lamps, though when I cannot say. The dynamos are driven by two powerful engines of 200 horse-power each, which also drive the machinery in the Exhibition. These engines have 23ft. fly-wheels, whose mammoth proportions greatly impress the Catalonian peasants. The Compania Espanola de Electricidad was formed in 1881, with a capital of £80,000, and has been a most successful venture. At the present moment this enterprising concern has a central lighting station at Barcelona, which supplies 80 2,500 candle-power arcs and 500 incandescents for public lighting, and 70 arcs and 500 incandescents to private consumers. Messrs. Ganz and Co., of Budapest, have a few large and small dynamos at work, but all detailed information is refused by the superintendent in charge. The Compagnie Continentale Edison makes, in my opinion, the best show of any. Their plant comprises two 200 horse-power boilers, two 150 horse-power compound condensing engines, running at 170 revolutions a minute, and two Weyher-Richemond dynamos having an output of 800 amperes and 125 volts at 350 revolutions a minute. These two machines are probably the largest in Spain. This company has contracted to light 75 750 candle-power arc lamps and 750 20 candle-power incandescent lamps. It would be difficult to surpass these lights in brilliancy and steadiness.

The Anglo-American Brush Corporation light the orna-

Digitized by Google

mental fountains. Their plant comprises three high-pressure boilers, of 200 total horse-power; a high-pressure compound vertical Browett and Lindley engine, working at 225 revolutions, and driving a couple of 40-unit "Victoria" dynamos. An underground passage, 95 metres long, runs from the engine house to a room under the fountain, where the coloured lights are operated. The arc lamps are of special design, and are each of 4,000 candle-power. They are arranged in multiple series. The Anglo-American Brush Electric Light Corporation obtained the contract for this fountain in March, and notwithstanding the numerous difficulties which were encountered in cutting out the foundations and building the basin, the whole was put successfully to work on the evening of June 14th. The general features of the fountain are similar to those of the first example of this interesting exhibition, which was constructed under the personal superintendence of the late Sir Francis Bolton, at South Kensington. Advantage has been taken of the experience there gained, and many improvements have been introduced, which greatly enhance the effect. From the centre a jet mounts to an enormous height, estimated by eye-witnesses to be 120ft. Six jets around this rise to about 80ft., and eight outer jets to 40ft. These, with the sprays which surround them, are fed by very powerful steam pumps, and are illuminated by 15 projectors, throwing vertical and concentrically inclined rays of white and coloured lights. The fountain has made a great sensation in Barcelona, and has been greatly praised, on account of its exceptional beauty, by members of the Exhibition Committee, who, previous to its installation, inspected some two or three similar fountains which were at work in England last year. The power employed to produce the above results is about 100 horse-power for the electric light, and from 150 to 200 horse-power in the pumps.

Messrs. R. E. Crompton and Co. (Limited) exhibit two of their well-known dynamos, only the smaller of which is at work. Messrs. Julius G. Neville and Co., of Liverpool, show a No. 10 "Castle" dynamo, driven by a Davey-Paxman engine. This machine supplies five arc lamps and 20 incandescent lamps, the light being remarkably steady. Messrs. Schuckert, of Nürnberg, have a mixed installation, 45 incandescent lamps and several arc lamps being run off the same machine. This dynamo, I may mention, is driven by an "Otto" gas engine; in fact, gas engines are very prominent in the Exhibition, and are as plentiful as blackberries.

C. Conradty, of Nürnberg, exhibits a great variety of carbons for electrical purposes; they are of all sizes and shapes, from long rods as thick as walking sticks to almost invisible filaments. The Société Anonyme de Barcelona shows some beautifully-finished incandescent lamp globes. Malagrida y Casellas, of Barcelona, exhibit a few electric light cables, but it is a poor display, more remarkable for the difficulty of obtaining information than anything novel or practical. The India-Rubber, Gutta Percha, and Telegraph Works Company have a fine and unique selection of their well-known goods; while the firm of Felten and Guilleaume, of Mülheim, make a similar and equally creditable display. The Electrotechnische Fabrik, of Leipzig; the Société Générale des Téléphones, and MM. Ch. Mildé, Fils et Cie., of Paris, have exhaustive exhibits of all things appertaining to telephonic work. The Spanish official section is of great historic interest; everything relating to telegraphic and telephonic enterprise in the Peninsula from the earliest days of their introduction being carefully exhibited. The Barcelona Institute sends several noteworthy exhibits, amongst which I noticed a monster pile of Leyden jars of all shapes and sizes. A varied display of electro-medical apparatus is made by Messrs Meyer and Metzer, of London. Messrs. J. E. Spagnoletti and Crookes have, at present, a very incomplete stall; they only show what they call an electrical fire-announcer, about which mysterious exhibit no information is to be obtained. Finally, three large electric organs are to be seen in the Fine Art Gallery; they are made by Señor Aquilluo Amerzna, of Barcelona, and are a very praiseworthy piece of work.

These are the chief electrical exhibits at Barcelona, and I must say, considering all things, the display is by no means unworthy of the first international fair which has ever been held on Spanish soil.

REVIEWS.

Eclairage a l'Electricite: Renseignments Pratiques. By HIPPOLYTE FONTAINE. Second Edition. (Paris: Baudry et Cie., 1888.)

Although this is nominally a "second edition," yet when we mention that the work made its first appearance in 1879, and that in the 688 pages of the volume now before us the whole subject of electric lighting is, with some few exceptions, brought well up to date, enough has been said to show that the author has practically given us a new work under an old name. There is no existing book in the English language which covers quite the same ground as this of M. Fontaine. Of elementary text-books and introductory treatises, in which the leading facts and principles of electrical science are more or less cursorily traversed, we have enough and to spare; books on electric lighting well adapted for amateur or "popular" audiences we also possess in sufficient number for our present need; nor do we even lack thoroughly technical treatises on particular branches of electrical engineering. But we have not at the present time any comprehensive work in which the subject of electric lighting is systematically treated, and which may be consulted with a reasonable probability of discovering the fact or the description of which we may be in search. This, however, is a position which for the French reader is very fairly well occupied by the work of M. Fontaine.

The introductory chapters have been greatly enlarged from the first edition; they are well and clearly written, whilst avoiding all but the most necessary and elementary mathematics. Nearly all the diagrams in these chapters have been specially drawn, and although some old friends are met with there is on the whole a refreshing novelty in the illustrations throughout the book. The chapter on the mechanical generation of the electric current is well conceived and explicit, and the sectional diagrams of the various types of field-magnets are convenient for reference, and are somewhat more numerous than can be met with elsewhere. The subject is not, however, viewed from the modern stand-point of the magnetic circuit, which indeed the French electricians seem very slow to adopt. The two chapters on arc and incandescent lamps in this section are full of interest, and much of the information here given is gathered together for the first time. This remark also applies to the succeeding chapter on photometry, which is full and accurate. We find, for instance, a summary of Mr. Dibdin's very able report* on the pentane standard.

The second part of the volume is devoted to a descriptive and historical account of dynamo machinery, arc and incandescent lamps, and methods and apparatus of distribution. In the first chapter, on continuous-current dynamos, the author affords considerable space to the early history of M. Gramme's invention, and some eight or nine different types of machines designed by M. Gramme at different dates are illustrated and described. All the best known machines made in this country are referred to; but the selection of American machines for description does not strike us as being the best that might have been made. M. Fontaine illustrates, amongst others, the Clarke dynamo, which for our own part we regard as a monstrosity, and of which he mildly and more politely remarks that it is "a little complicated, and possesses nothing extraordinary in the way of efficiency." The machine is, however, in use in the United States. M. Fontaine does not, in fact, cumber his pages with many actually obsolete types, although amongst this class we must distinguish the Elphinstone Vincent and the Bürgin, both of which are here illustrated. The numerous tables in this part of the book are evidently taken bodily from the price lists issued by the makers, and in fact the prices of machines of various sizes are in many cases quoted. We may add that the cheapest machine we have ever come across is one supplied by a Belgian firm for 45fr. The output is put down as 8 amperes at 70 volts; but we fancy the price quoted must be a misprint.

We have already said that the author does not consider the dynamo machine from the modern point of view, and conse-

* See *The Electrician*, Aug. 12th, p. 287, and 19th, p. 309, 1887.

Digitized by Google

quently we find no data for establishing a definite comparison between the performances of any of the machines described.

The chapter on arc lamps is particularly good; we think it, in fact, the most valuable in the whole volume. No fewer than fifty-seven arc lamps, besides "candles" and "semi-incandescents," are here described, and the chapter contains sixty-six drawings and diagrams relating to about forty different lamps. The illustrations here, as all through, are beautifully clear, and the author spares no pains to make every detail of the mechanism perfectly intelligible. Very many of the lamps described as being in use on the Continent are little known in this country; such, for instance, as the Cance, the de Mersanne, and the Mondos in France; the Jaspar in Belgium; the Poege and the Kremensky in Germany. The de Mersanne is a very singular lamp; the carbons are placed horizontally, and are fed forward by grip wheels. The mechanism is somewhat complicated, but is said to work with great regularity. The lamp may be seen in action in the Plâce du Carrousel, in Paris. The classification adopted in this chapter, in which the author divides the lamps under the titles of the countries in which they are used, is distinctly misleading. Under the head of "Lamps used in England," we find only three names—Crompton, Lever, and Rogers. This last is a lamp which has hitherto escaped our observation. As for other lamps well known in this country, we have to look for them under the title of the country in which they originated: the Brush and the Thomson-Houston under the United States; the Siemens, Pilsen, and Gülcher under Germany, and so on. The Brockie lamp is relegated to a final section under the heading of *Appareils Divers*. We would suggest for the author's consideration, in view of later editions, the propriety of adopting a principle of classification for arc lamps based upon the leading principles of their construction. It would not be difficult to select a small number of leading types, to one or other of which, with a few exceptions, all lamps might be shown to conform. The attempt would, at least, be instructive. This chapter ends with a chronological table giving the dates of the principal inventions or improvements in arc lights, from the Foucault lamp of 1844 down to the Gramme lamp of 1861. From some reason or other the name of Duboscq has been omitted from the list.

The chapter on conductors contains a good deal of information on the Edison, Siemens, and Berthoud-Borel systems of laying and jointing underground wires. The three-wire system is briefly considered, and some attention is given to Prof. Elihu Thomson's ingenious method of carrying out the principle by means of single dynamo, the E.M.F. in the two halves of the circuit being automatically balanced by means of a motor-generator.* We notice, by the bye, that M. Fontaine repeats the common statement that the three-wire system effects an economy of 25 per cent. in the total weight of copper. In a Paper published in *The Electrician*, March 28th, 1885, p. 412, it was shown by the present editor of this journal that if the system be properly carried out the saving amounts to nearly 40 per cent., even when the third lead is of the same size as the other two.

In the chapter on transformers both alternate and continuous-current apparatus is dealt with. On the first-named subject the information is tolerably complete, considering the rapid rate at which the subject is still growing.

M. Fontaine is, we believe, in error in ascribing to Mr. Gordon the first use of an impedance coil for replacing an extinguished lamp on an alternating circuit. The idea is only of practical utility in connection with transformers worked in series, and it seems to have originated with Messrs. Sharp and Kent. What Mr. Gordon did was to place an impedance coil in series with an arc lamp so as to prevent a sudden rush of current if the arc failed to be struck.

Part III. is entitled "Prix de Revient," and although somewhat unconventional is one of the most interesting sections of the work. The author first considers the question of the efficiency of dynamos, conductors, and lamps, and calls attention to the progressive increase in the efficiency of dynamos up to the year 1886, since which period little has remained to be done in this direction. M. Fontaine has himself carried out some valuable experiments on the efficiency of arc lamps, and he finds that with a continuous current the mean intensity may be taken as approximately equal to double the horizontal intensity. The results of the Philadelphia tests on arc lamps, and the Munich tests on incandescents, are also summarised. In the next chapter the "cost of an installation" is considered. Twenty years ago a dynamo machine with an output of 2,500 watts cost about 4fr. per watt; in 1881 the price ranged from 0·5fr. up to 2fr. per watt; while to day the Gramme dynamos of the "type supérieur" cost only 0·28fr. per watt. In England, we may add, a machine of this size would probably cost at the present time rather less than £10 per unit, or, say, 0·25fr. per watt. We are next furnished with a table showing the price of 28 different types of arc lamps. Unfortunately, the current which each lamp is designed to take is not given. The prices quoted vary from 300fr. down to 125fr., the average being about 190fr. Average prices are then quoted for incandescent lamps, switches, fuses, conductors, ammeters, and voltmeters, &c. The author next gives the cost in detail of some actual installations carried out in France at various dates.

The cost of arc lighting in France at the present time for an installation of 30 lamps of 1,500 candle-power is taken at 500fr. per lamp, or 33fr. per candle-power, but this is for the electrical plant alone. Some very detailed estimates, from recent practice in incandescent lighting, are furnished, the results coming out as follows:—

No. of 16 candle-power lamps.	Total cost of electric plant per lamp.
30	61·87fr.
60	54fr.
120	51·29fr.
250	47·56fr.

The style of fittings allowed for may be gathered from the fact that 6fr. per lamp is allowed for brackets, &c. Somewhat lower figures are quoted for "industrial" installations. Roughly speaking, the actual cost may be about doubled when engines and boilers are taken into account. In Paris, however, where the Popp system of distributing motive power by compressed air is so widely extended, probably not more than about 60 or 70 per cent. would be added to the first cost for motive power. The chapter ends with a very short paragraph on accumulators, which commences with the significant words: —"We do not look upon the accumulator as an industrial apparatus. . . . ."

The chapter following deals with working cost. The value of a (French) horse-power hour is quoted as follows:—

0·01fr. to 0·03fr. for water.
0·03fr. to 0·15fr. for steam.
0·35fr. to 0·60fr. for gas.

In Paris the average value may be taken at 0·1fr. for steam with engines of from 25 to 100 horse-power, and 0·5fr. for gas engines of from 4 to 25 horse-power. M. Popp's tariff is not quoted.

After dealing with the cost of carbons and renewal of incandescent lamps M. Fontaine works out the average running cost as follows:—

For an installation of 20 arcs, each of 1,250 candle-power, burning 2,000 hours per annum, and assuming that the electric plant cost 500fr. per lamp, and that the mechanical plant amounts to the same total, and taking interest and depreciation at 10 per cent., the annual cost would be 16,800fr., or 0·42fr. per lamp hour. The consumption of carbon is taken at the rather large rate of 80mm. (3·15in.) per hour; this, however, includes the ends wasted in the holders.

For an installation of 200 incandescent lamps of 16 candles, working 1,500 hours per annum, driven by steam, and valuing the electric plant at 42·82fr. per lamp the cost would be 11,034fr. per annum, or ·0366fr. per lamp-hour. These figures, as might be expected, agree very fairly with average English practice, and for that reason we think it the more useful to quote them. It may be added that the cost of engine plant in the last case is taken at 17,500fr., which would perhaps be a little high for this country.

Passing over some highly interesting and detailed descriptions of theatre lighting, we come to the important subject of

* See *Electrician*, May 13th, 1887, p. 9.

Digitized by Google

Central Stations, to which, however, only some 38 pages are devoted. The author's remarks on the causes for the comparative failure of central station lighting in Europe, as compared with the remarkable success achieved in the United States, are of a highly judicious character. He points out the fact, which is often overlooked, that light for light a central station must necessarily cost more to install than a private installation (except when the latter is of the smallest dimensions). Not only is the cost of distributing plant entirely disproportionate, but the ratio of total plant to mean-plant-in-use (if we may be allowed the phrase) is far higher. To this has to be added rent of buildings, expenses of management, &c., so that while central station distribution is, of course, an enormous convenience, and brings the electric light within reach of hundreds of people who would never dream of laying down a private installation, yet, as a rule, electric lighting companies will not be able to supply current at a cheaper rate than that at which in fairly large buildings it can be generated on the spot. We also find ourselves in emphatic agreement with M. Fontaine when he says that the attempt to compete in price with gas is a fallacious and a mistaken policy. The electric light is essentially a luxury, and as soon as that fact is fully realised it must and will be paid for as other luxuries are paid for, without demur. To talk about reducing the cost to that of gas is simply to defer the time when people will be willing to accept it at its proper valuation. People do not hesitate to burn wax candles because they cost more than tallow. Just so it will be eventually with the electric light; the only especial and inherent difficulty which arises in the latter case is that at present, while the taste is still being developed, it is not always easy to find a sufficiently large number of people by whom it has already been acquired, and who happen to live in sufficient proximity to justify the commencement of operations at a really remunerative tariff.

We fear that M. Fontaine is justified in complaining that many of the central stations which already exist in Europe leave much to be desired in several important respects; the *matériel* is not used to the best advantage, the organisation is often defective, the expenses are unnecessarily high, and the record of breaks-down is by no means a creditable one.

The author does not furnish anything like an exhaustive account of any existing central station. Some details are given respecting the two Edison stations at New York, which are now supplying a total of 13,000 lamps, and employing a staff of 31 persons. We learn that for the year 1886 the total working expenses amounted to 397,482fr., or 30·57fr. per lamp of 16 candle-power; but this does not include interest or depreciation charges. The arc lighting at Detroit and Minneapolis is also briefly dealt with.

Returning to Europe, the author describes the lighting of the harbour at Havre and the Edison station at St. Etienne at some length; he also discusses the various attempts which have been made to establish central stations in Paris on a permanent basis. Only two of these are in existence at the present moment, namely, that of the Cité Bergère, which is now supplying some 1,400 lamps in the neighbourhood of the Boulevard Montmartre, and that of the Plâce du Carrousel, where a small number of arcs are to be seen. The rest of the chapter contains a general survey of the state of things in the French provinces, in Germany and in Italy; but although the information given is instructive and interesting, we fail to find anything of special value with which the readers of this journal have not already had an opportunity of becoming acquainted. Singularly enough, no mention whatever is made of central lighting stations in this country.

The remaining pages deal with the application of electricity in navigation, and with the use of primary batteries for "domestic lighting."

Here we must take our leave of this important work, and although the limit of our space has hindered us from dealing with the volume as fully as its merits deserve, yet we trust that what has been said will have been sufficient to show that from beginning to end it is crammed with information of value to the electrical engineer. The work is one which cannot fail to add to the already very high reputation of its author.

A REVIEW OF THE PRESENT CONDITION OF THE THEORY OF THE ELECTROLYSIS OF SOLUTIONS.*

BY F. KOHLRAUSCH.

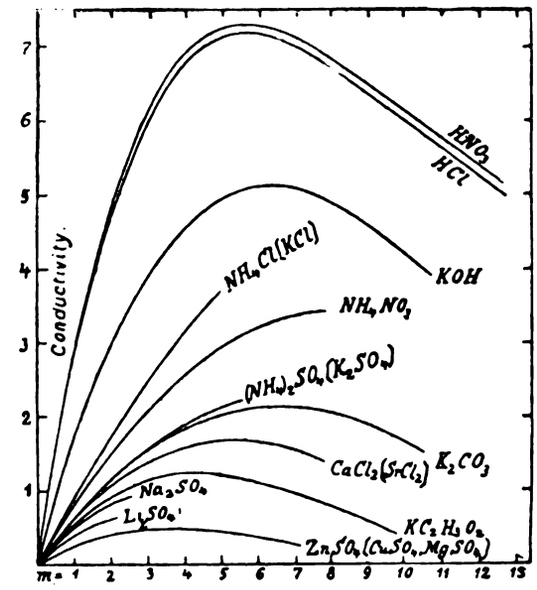
(Concluded from page 467.)

10. *General Facts Relative to Conductivity.*—If water be added to an electrolyte the conductivity at first increases with the strength of the solution. As a necessary consequence, however, of the general law that pure fluids are bad conductors, the conductivity must reach a maximum when a certain definite strength has been attained, after which the addition of more of the electrolyte will diminish the conductivity, and this is found to be the case with all sufficiently soluble bodies. In connection with this, it is always found that from the beginning of solution the conductivity increases less rapidly than the strength of the solution.

11. *Examples.*—Fig. 2 shows the curves obtained for a number of substances where the molecular strength m of the solution is taken as abscissa, and the corresponding conductivity as ordinate.

These curves, although representing the conductivity of very different substances, are clearly of the same general character. (These curves are for the most part taken from a Paper by the author in Wiedemann's *Annalen*, Vol. VI., p. 148, and Tables I. and II., 1879. They are drawn for a temperature of 18°, and each millimetre of the ordinates represents a millionth of the conductivity of mercury. The best conducting electrolytes have, at ordinary temperatures, a conductivity equal to about $\frac{1}{14000}$ of that of mercury.)

Fig. 2.



The principal point brought out by the diagram is that similarity of chemical constitution carries with it a similarity in the march of the conductivity. (If the strengths of the solutions be given in terms of percentage composition instead of in terms of the chemical equivalents, this general similarity in the curves will disappear, they will cut each other frequently, and there will no longer be an agreement between the curves corresponding to bodies of similar chemical constitution, thus giving an additional proof of the fact that the chemical equivalent is the natural unit of measurement in electrolytic actions.)

Salts of ammonium and of potassium behave so nearly alike that, on the scale of the diagram, their curves cannot be distinguished. The sulphates of magnesium, zinc, and copper are also represented by the same curve. The mono-basic mineral acids, hydrochloric, hydrobromic, hydriodic, and nitric, almost coincide. There is very little difference also between the behaviour of the salts which these acids form with the same metal.*

12. *Influence of Temperature.*—Electrolytes differ from metals—firstly, in that their conductivity increases instead of diminishing with increase of temperature, and, secondly, in that the effect of temperature is much greater in their case, the conductivity at 40deg. being on an average double that at 0deg. The increase is generally fairly regular. The relations described in §11 are not

* *See* F. Kohlrausch and Grotrian, Poggendorff's *Annalen*, Vol. CLIV., p. 236, 1875; F. Kohlrausch, *ib.*, Vol. CLIX., p. 268, 1876; Wiedemann's *Annalen*, Vol. VI., p. 148, 1879.

Digitized by Google

altered by change of temperature, as it is found that substances which behave in nearly the same way at any one temperature undergo similar changes when the temperature varies, so that if the curves coincide at one temperature they will continue to do so when the temperature is changed.

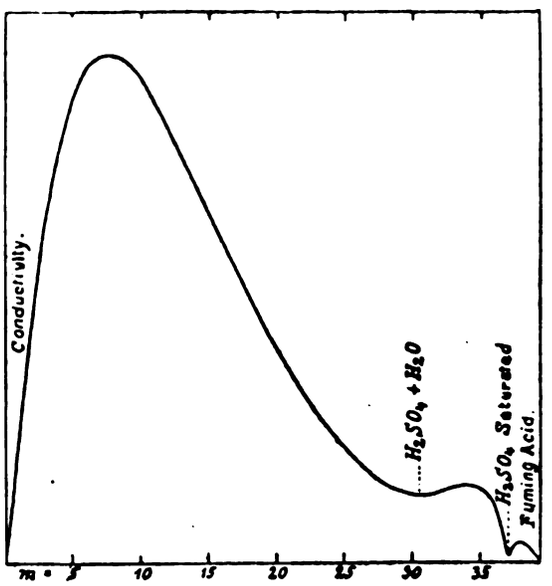
All dilute solutions exhibit about the same change in conductivity with change of temperature, in general about $\frac{1}{38}$ to $\frac{1}{46}$ per degree, but the hydrogen compounds, alkaline hydrates, acids, and acid salts vary to a somewhat less amount, about $\frac{1}{70}$ to $\frac{1}{100}$.

A remarkable general law, deduced from these investigations, is that the conductivities tend toward equality as the temperature increases.*

13. *Sulphuric Acid.*—The behaviour of sulphuric acid (Fig. 3) is instructive in several ways. The conductivity, as in the case of other substances, increases at first less rapidly than the degree of concentration until a maximum is reached, when the solution contains about 30 per cent. of H_2SO_4 or $m=8$. From this point the conductivity diminishes, and attains its lowest value with the concentrated acid, fuming H_2SO_4; but the decrease is not regular, but reaches a minimum when the solution contains about 85 per cent. of H_2SO_4; it then undergoes a slight increase, after which it decreases more rapidly than before, until the solution consists of concentrated H_2SO_4.

The minimum value occurs when the relative proportions of acid and water are those which form the crystallisable chemical compound $H_2O+H_2SO_4$, confirming our former conclusion that the conductivity is less for a chemical compound than for a mixture.

Fig. 3.



The conductivity is much less again for the more stable compound H_2SO_4. If anhydrous sulphurous acid (SO_3) be now added to the concentrated H_2SO_4 the conductivity will again increase slightly, and finally fall almost to zero.

The two minima corresponding to $H_2O+H_2SO_4$ and H_2SO_4 being no less than the values observed is in agreement with the known fact that these compounds are not very stable even at ordinary temperatures, and that hence, through dissociation, they contain separated water.

The curve for sulphuric acid does not coincide with those for nitric acid and hydrochloric acid, which fact affords a confirmation of the chemical theory which assigns to the former (dibasic) acid a different constitution from that of the other two. In the case of extremely dilute solutions, however, the curves show a much greater similarity, from which it would appear that when sulphuric acid is largely diluted with water it tends towards the constitution of a monobasic acid.

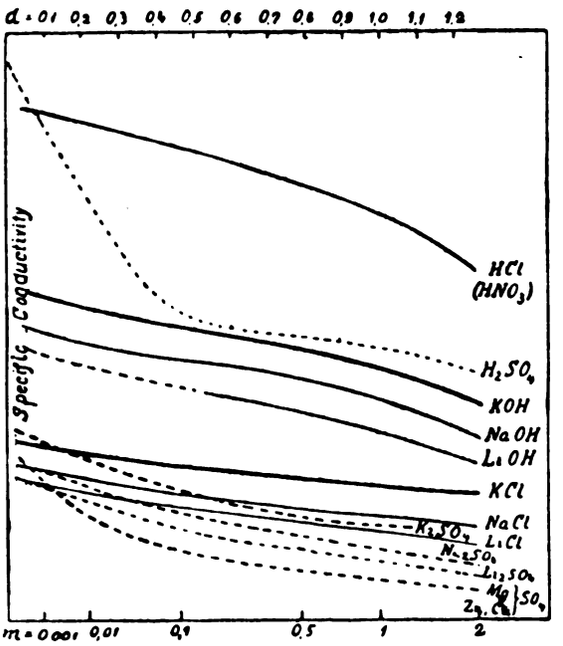
14. *Influence of Viscosity on Internal Friction.*—There is indisputably a connection between the electrical resistance and the mechanical viscosity of solutions. In the first place, namely, a series of salts arranged in order of conductivity agrees in general with the series arranged in order of fluidity.†

The maximum value of the conductivity is also generally attained sooner in the case of electrolytes of greater viscosity than in the case of those of less, and again we find, for example, that the minimum conductivity of sulphuric acid (§ 13) corresponds to a maximum value of the viscosity. Lastly, there is found to be a remarkable agreement between the effects of decrease of temperature on the viscosity and on the electrical resistance. Both of these are, in the first place, of the same order of magnitude, and secondly, different electrolytes, arranged according to the two effects, give approximately the same series.*

As is well known, endeavours have been made to determine the absolute magnitude of molecules from various optical, thermal and mechanical properties of bodies. According to these investigations, for example, a milligramme of water contains from 10 to 20 millions of molecules. Now the moving force due to the difference of potential in a circuit may be expressed in mechanical measure. Making the assumption that the electrolytic friction is of the same order of magnitude as the mechanical friction, the requisite thickness of a single layer of molecules in order to give the resistance actually observed can be calculated, and the order of magnitude of a molecule determined in this way agrees with the results obtained by methods.†

A number of instances are known in which substances continue to conduct electrolytically, even when they become solid. In reference to this, it is noteworthy that if a solution be solidified by the addition of gelatine, very little effect is produced on the conductivity.‡

Fig 4.



This result does not tend in any way to disprove the existence of a relation between viscosity and electrical resistance, for mechanical rigidity and viscosity are by no means identical properties, and moreover gelatinous bodies are not homogeneous.

15. *Specific Conductivity, Linear Molecular Density.*—If the conductivity were proportional to the number of electrolytic constituents in a given volume the curves of Fig. 2 would necessarily be straight lines. The curvature of these lines shows that the molecules introduced later do not increase the conductivity in the same extent as those introduced earlier. These relations may be shown most clearly by the following modification of our former method of representation.

In the first place, instead of taking the values of the conductivity k, we will take the values of the ratio of the conductivity to the number of electrolytic molecules m in unit volume of the solution—viz., the specific conductivity of the electrolyte in the solution. This quantity k/m may clearly be regarded as the rate of

* F. Kohlrausch, Wiedemann's *Annalen*, Vol. VI., pp. 191 and 196, 1879.

Experiments which have been carried out at my suggestion by Herr Kreichgaller on a number of similar solutions ($m=$) give almost identical series in order of viscosity and of electrical resistance respectively. This result has been confirmed by Arrhenius, British Association Report, 1886, p. 387.

migration of the electrolytic constituents. Secondly, instead of expressing the strength of the solution in terms of the number, m, of electrolytic molecules in units of volume, we will measure it by the linear density, d, of these molecules—viz., by the number of molecules intersected by a line of unit length in the solution.*

This linear density, therefore, will be taken as abscissa in Fig. 4, and the specific conductivity k/m as the ordinate.

The approach of the curves towards the axis of abscissæ, like the curvature in Fig. 2, shows that the rate of migration k/m decreases as the density increases. The present method of representation shows that in the case of many electrolytes this decrease is very nearly proportional to the linear density. An approximate expression for the conductivity k as a function of m, the strength of the solution, is therefore, in the case of these substances, given by the formula

$$\frac{k}{m} = a - b m^{\frac{1}{4}}.$$

In the case of sulphates, especially those of magnesium, zinc, and copper, the decrease is greater when the solution is very dilute than later. Sulphuric acid itself behaves quite abnormally, its curve apparently consisting of two distinct portions.†

16. *Relation between the Conductivity and the Migration Coefficients.*—If we compare the conductivities as represented in Fig. 4, confining our attention for the moment to the positive ions, we see that the best conductors are the hydrogen compounds or acids. The conductivities of salts are considerably less, and in descending magnitude; they are throughout in the order K or NH_4, Na, Li. This order also holds good for the hydrates. Referring now to Fig. 1, and considering the group of chlorine compounds, we see that the velocity of the hydrogen is relatively much greater than that of the chlorine; after hydrogen comes potassium, then sodium, and lastly lithium. Other compounds containing these elements behave in the same manner; for example, the nitrates and sulphates. The three hydrates, KOH, NaOH, LiOH, also occur in the same order.

If we now turn our attention to the negative constituents, we see that for salts of a given metal those formed with OH are the best conductors, then the chlorine salts, and so on, the acetates coming much lower down, as shown in Fig. 2 in the case of $KC_2H_3O_2$. Fig. 1 shows clearly that the length of path traversed by the negative constituent, measured in the figure from the lower boundary, has the greatest value for OH, is less for chlorine, &c., and least for $C_2H_3O_2$.

We may sum up these facts in the statement that hydrogen is the element which travels with the greatest facility, then follows K, then Na, and lastly Li. Of the negative constituents, the rate of motion of OH is the greatest, then follows Cl, &c., and lastly comes $C_2H_3O_2$.

The conductivity is obtained by adding together the separate speeds of the ions.

17. *Definite Speeds of Ions in Dilute Solutions.*—In the case of dilute solutions of electrolytes with monovalent acids, these results admit of a simple quantitative expression, viz., every constituent possesses a certain definite speed of its own, whatever be the compound in which it occurs.‡

The numerical values of some of these ionic speeds are given below, for a concentration for which $m = 0{\cdot}1$, this value being taken since very few of the numbers have been determined for more dilute solutions. This value of m corresponds to from 1¼ to 2 per cent. by weight of salt, according to its equivalent weight.

K	NH_4	Na	Li	Ag	H	Ba	Mg	Ln
+51	50	33	25	42	272	31	25	24

Cl	I	NO_3	ClO_3	$C_2H_3O_2$	OH
−54	54	48	43	27	146

Adding the speeds of the two constituents of a salt, we obtain its specific conductivity for $m = 0{\cdot}1$; for example

KCl	51+54=105
$AgNO_3$	42+48= 90
$NaC_2H_3O_2$	33+25= 58
HCl	272+54=326

The relative distances traversed by the ions are obtained by division; for example

$K/Cl = 51/54$; $Ag/NO_3 = 42/48$; $K/C_2H_3O_2 = 51/27$; $H/Cl = 272/54$.

The numbers thus obtained are found to be in close agreement with those determined by experiment. Thus Ostwald* has experimented upon a large number of acids and salts, and has confirmed the law of definite speeds. According to his researches the speeds of compound acid radicals are in general smaller. For example, he finds for the radicals of the fatty acids:—

Formic Acid.	Acetic Acid.	Propionic Acid.
CHO_2	$C_2H_3O_2$	$C_3H_5O_2$
−37	−27	−23

Butyric Acid.	Valerianic Acid.
$C_4H_7O_2$	$C_5H_9O_2$
−20	−18

Multivalent acids and their salts cannot at present be included in this system. When more extended observations have been made on extremely dilute solutions this restriction may possibly be removed.

18. *Absolute Velocity of the Ions.*—By means of the above numbers, which represent 107 times the specific conductivities referred to mercury units, the absolute velocities of the ions for a given slope of potential may be determined when we know the electrochemical equivalent, and the ratio of the ohm, to the Siemens, or mercury unit. For example, let the slope of potential be 1 volt per millimetre, then the absolute velocities of the ions in the direction of the current will be obtained in millimetre-seconds by dividing the tabular numbers by 900.† Doing this we get for hydrogen 0·3, for potassium or chlorine 0·06, and for lithium 0·028 millimetre-seconds. These numbers are of course for $m = 0{\cdot}1$, and for very dilute solutions they would be some 10 to 20 per cent. greater.

It is evident that the electrolytic movements cannot be regarded as of such a nature that all the constituents should have identical velocities at any given moment. There may be only one, or more probably a very limited number moving at any one time in the direction of the current. Their velocities, too, will by no means be all equal, and may not be at any time in the direction of the fall of potential, since there are other molecular motions to be considered. The above numbers, therefore, represent merely the mean values of the velocity components, in the direction of the current, of all the constituent molecules. This, however, is all that can be determined or that has to be considered in reference to the total strength of current.‡

Recently, the theory has been broached that in the case of extremely dilute solutions all aqueous solutions of the same molecular strength conduct equally well, and that, therefore, the velocities of both the ions must be equal.§ This simple relation is, however, by no means proved; indeed, all the known facts are strongly opposed to it. A point worthy of special attention is that some substances, such as sulphates and sulphuric acid, which in the case of strong solutions are bad conductors, become more like other substances when greatly diluted.‖

Before the true significance of this fact can be understood, we must know more about the part played by water in dilute solutions.

19. *Conductivity and Diffusion.*—Electrolysis depends on the differences in the motion of the constituent molecules. The dispersion of entire molecules through a liquid is known by the name of diffusion, a phenomenon which is really caused by the molecular motions due to heat. It is well known that different substances have very different diffusibility in water, and it is an interesting fact that electrolytes which are good conductors are for the most part substances which diffuse rapidly; and the converse also holds. It follows that those substances which allow great freedom of motion to the constituent molecules are in general those in which the entire molecules move most freely.¶

20. *Conductors of a Lower Order.*—A large number of hydrogen compounds, both acids and bases, exhibit an incomparably lower conductivity than those hitherto considered; for example, on the one hand, sulphide of hydrogen, prussic acid, boracic acid, carbonic acid, and acetic acid; on the other, ammonia and many organic substances of both classes. Aqueous solutions of these bodies conduct in general so many times less than the others that no comparison can be made between them; for example, the best conducting solutions of acetic acid or ammonia have a conductivity some 500 times less than that of the mineral acids and alkaline

hydrates. With one another, however, these acids and bases give salts, acetate of ammonia, for example, whose conductivity is not inferior to that of the salts previously considered.

In connection with this the following facts have been observed, which may lead to an explanation of the phenomenon.

In the first place this great difference disappears in the case of very dilute solutions.* A trace of acetic acid or ammonia dissolved in water gives a conductivity of the same order of magnitude as an equivalent quantity of a good conductor. A numerical investigation of this important phenomenon is difficult, owing to the impossibility of obtaining perfectly pure water.

21. *Conductivity and Rapidity of Chemical Reaction.*—In the second place, an interesting relation is found to exist between the conductivity and the chemical activity of these substances. Acids are called strong acids when they act rapidly ; for example, hydrochloric acid, sulphuric acid, nitric acid, &c. The action of acetic acid is much less rapid. This rapidity of reaction can be determined by observing the time taken to cause conversion of cane sugar or some other similar slow operation. Observations have shown that the conductivity of acids and bases is closely related to the rapidity of their chemical reactions.†

22. *Dissociation. Active Molecules.*—A theory to account for the simultaneous increase of the rapidity of chemical reaction and of the conductivity may be deduced from a hypothesis proposed some time back by Clausius.‡ The forces of chemical affinity are, without doubt, of great strength. Suppose, then, that an electrolyte is composed of molecules firmly bound together by chemical affinity, then we should expect that electro-chemical decomposition could only begin when the electrical separating force attained a certain value. On the other hand, this deduction seems to be disproved by the fact that Ohm's law is obeyed by electrolytes, and that decomposition begins with any E.M.F., no matter how small (compare §9). Clausius assumes, therefore, that an electrolyte is not in such a condition of stable equilibrium, but that of the dissolved molecules a certain number are dissociated, probably by the action of the water, and that these free molecules are the first which are acted on by the electrical forces, and that the decomposition then extends by interchanges to the others.

In this case the degree of dissociation, measured by the number of free molecules, would be of the greatest importance relatively to the conductivity. If we now make the further assumption that the chemical action also of an acid, &c., starts, not from the molecules in combination, but from the dissociated molecules, which would therefore be the really "active molecules," then the relation between conductivity and rapidity of chemical reaction at once become explicable.§

The scientific goal of the theory of electrolysis is the explanation of electro-chemical phenomena by means of mechanical actions, and their reduction to mechanical or electro-mechanical laws.

In the foregoing Paper a number of data have been given by means of which we may endeavour to reach this goal. Its attainment would be of even more importance in relation to molecular physics and chemistry than for its own sake simply.

The true nature of solution is still shrouded in darkness, nor do we know any more about the ultimate nature of chemical forces. There can be no doubt that there exists a close connection between these forces and electricity.

Electrolysis is one of the simplest and most powerful means which we possess for learning more about the nature of matter. The borderland of chemistry and physics now offers a field of research which promises to be fruitful in results of the greatest importance.

The India-Rubber Trade of Upper Burmah.—Mr. Warry, of the British Consular Service in China, and at present political officer at Bhamo, has made an interesting report on the india-rubber trade of the Mogung district. Rubber was first exported from Upper Burmah in 1870, and until 1873 the trade was free to all. Since then the forests have been worked by five Chinese firms, who employ the Kachins in tapping the trees. In the present year the sale of the right to work the forests produced a lakh of rupees. In spite of plentiful blackmailing and transit difficulties, the trade is a very paying one to the *concessionnaires*.

LETTERS FOR LEARNERS AND UN-PROFESSIONAL READERS.

BY H. D. WILKINSON.

CHAPTER IX.—*Magnetic Fields.*

(Continued from page 476.)

125. *The Moment of a Magnet Measured by its Field.*—The two methods, due to Gauss, by which the moment of a magnet may be determined can now be easily understood. By the first method the magnet is placed so that its normal line (para. 121) is in the same magnetic meridian as the magnetometer needle, the distance between the centres of the needle and magnet being known. In Fig 96, let the circle represent the magnetometer in plan, properly mounted and adjusted. A wooden table, A, is placed close to the magnetometer board, its surface being marked out in cross lines indicating distances in centimetres from the centre of the suspended needle, and its height such that magnets placed on it are in the same horizontal plane as the needle. The line drawn longitudinally along the centre of the table must lie in the magnetic meridian, and be the continuation of the line joining the zero points on the scale (the line *m m*, Fig. 94) ; the suspended needle will then lie in the same line before any magnet is placed on the table.

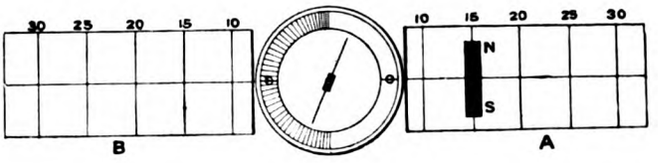

FIG 96.

Now let a magnet, N S (Fig. 96), whose moment is to be determined be placed on the table, so that its polar line agrees with one of the cross lines at a certain distance from the needle, and its normal line coincides with the central line along the table. The magnetometer needle is then deflected, and the natural tangent of the angle of deflection is the scale reading divided by 100 (para. 123). Now, in the region of the needle we have two fields (H of the earth and f of the magnet) superposed at right angles to each other, and by para. 119 the ratio of f to H is the tangent of the angle a between H and the resultant field. That is,

$$f = \mathrm{H} \tan a \text{ (in C.-G.-S. units),}$$

the angle a being that moved through by the magnetometer needle from its position of rest in the field H. Also the intensity of field on the normal line of a magnet at a point r centimetres from either pole has been shown to be the moment of the magnet divided by r^3 (para. 120) ; that is—

$$f = \frac{\mathrm{M}}{r^3} \text{ (in C.-G.-S units).}$$

From these two values for f we obtain the relation

$$\frac{\mathrm{M}}{r^3} = \mathrm{H} \tan a ;$$

whence

$$\mathrm{M} = r^3 \mathrm{H} \tan a.$$

The only observations to be made, then, are the tangent of the angle of deflection and the distance r. Knowing the distance d of the magnet from the needle, we have (para. 120)

$$r^2 = d^2 + \left(\frac{l}{2}\right)^2 ;$$

whence

$$r^3 = \left[d^2 + \left(\frac{l}{2}\right)^2 \right]^{\frac{3}{2}},$$

where l is the length of the magnet.

In order to eliminate error in placing the magnet, or in observing the deflection, another observation is taken with the magnet reversed on table A giving the deflection on the opposite side of zero. Again, the table is moved to the other side B, where two similar readings are taken. It is better to have two

Digitized by Google

tables, carefully adjusted and fastened down in position so that a number of observations may be taken of different magnets without altering that adjustment. All screws or clamps used in the making of the tables or securing them in position must be of brass, not of iron.

The sum of the four readings so taken divided by four gives the mean deflection, which is then used in the calculation.

Example.—(1) Determination of the moment of a galvanometer controlling-magnet. (Fig. 65.) Mean of four observations, 60 divisions on the tangent scale, distance between centres 30 centimetres. Whence tan $a = \cdot 6$,

$$r^3 = (30^2 + 7\cdot5^2)^{\frac{3}{2}} = (956\cdot25)^{\frac{3}{2}},$$

and H being ·18 C.-G.-S. units, we have

$$\text{Moment} = (956\cdot25)^{\frac{3}{2}} \times \cdot18 \times \cdot6.$$

This is most readily worked by logarithms thus:—

$$\log (956\cdot25)^{\frac{3}{2}} = \frac{2\cdot9806 \times 3}{2} = 4\cdot4709$$

$$\log \cdot18 = \bar{1}\cdot2553$$

$$\log \cdot6 = \bar{1}\cdot7782$$

$$3\cdot5044 = \log 3194$$

The required moment is therefore 3,194 dyne-centimetres, and the distance between the poles of this magnet being 15 centimetres, the strength of each pole is

$$\frac{M}{l} = \frac{3194}{15} = 213 \text{ C.-G.-S. units.}$$

(2) A compound horseshoe magnet (Fig. 62), consisting of 8 separate magnets and measuring 8·8 centimetres between the centres of its poles, gave a mean of 131 divisions. Distance between centres 35 centimetres. Its moment was therefore—

$$(35^2 + 4\cdot4^2)^{\frac{3}{2}} \times \cdot18 \times 1\cdot31 = 10{,}351 \text{ dyne-centimetres}$$

and strength of pole $= \frac{10351}{8\cdot8} = 117\cdot6$ C.-G.-S. units.

(3) A powerful steel bar magnet 1 foot in length (30·48 centimetres), gave a mean of 87·5 divisions. Distance between centres 45 centimetres.

Its moment was therefore

$$(45^2 + 15\cdot24^2)^{\frac{3}{2}} \times \cdot18 \times \cdot875 = 16{,}890 \text{ dyne-centimetres,}$$

and strength of pole

$$\frac{16890}{30\cdot48} = 554 \text{ C.-G.-S. units.}$$

(4) A similar sized magnet under the same conditions gave a mean of 83·25 divisions. Hence its moment (by comparison with the preceding) was—

$$16890 \times \frac{\cdot8325}{\cdot875} = 16{,}070 \text{ dyne-centimetres,}$$

and strength of pole

$$= \frac{16070}{30\cdot48} = 527 \text{ C.-G.-S. units.}$$

By the second method of Gauss the magnet is placed so that its polar line passes through the centre of the magnetometer needle at right angles to the meridian, the distance between the centres of the needle and magnet being known.

The table must therefore be placed at right angles to its former position, as in Fig. 97, in which the magnetometer needle is shown deflected by a magnet. One reading is taken with the magnet placed as shown, a second reading with the magnet reversed, and two similar readings with the table placed on the other side of the magnetometer, the mean of the four being finally taken.

Now, in para. 120 it was shown that the intensity of field f at a point on the polar line of a magnet situated d centimetres from its centre was expressed by

$$f = \frac{2M}{d^3\left(1 - \frac{l^2}{4d^2}\right)^2},$$

and in para. 119 the ratio of two magnetic fields of intensity f and H superposed at right angles to each other was shown to be equal to the tangent of the angle a between H and the resultant; that is—

$$f = H \tan a;$$

whence, equating these two values of f,

$$\text{magnetic moment (M)} = H\frac{\tan a}{2} d^3 \left(1 - \frac{l^2}{4d^2}\right)^2.$$

Example.—(1.) A small bar magnet, 10·3 centimetres long, gave a mean deflection of 105·5 divisions, the distance between centres being 20 centimetres. Its moment was therefore

$$\cdot18 \times \frac{1\cdot055}{2} \times 8000\left(1 - \frac{106\cdot09}{1600}\right)^2$$

$$= \cdot18 \times \cdot5275 \times 6978\cdot8$$

$$= 662\cdot6 \text{ dyne-centimetres.}$$

(2). The same magnet was placed with its centre at 30 centimetres distance from the centre of needle. The mean deflection was then 29 divisions; the moment was therefore

$$\cdot18 \times \frac{\cdot29}{2} \times 27000\left(1 - \frac{106\cdot09}{3600}\right)^2$$

$$= \cdot18 \times \cdot145 \times 27000 \times \cdot9419$$

$$= 663\cdot7 \text{ dyne-centimetres.}$$

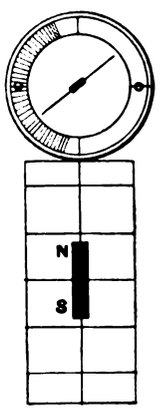

FIG. 97.

This last was taken to check the former reading, the mean of the two results being 663 dyne-centimetres, and

$$\text{strength of pole } \frac{663}{10\cdot3} = 64\cdot3 \text{ C.-G.-S. units.}$$

Tapping the Telegraph.—The Austrian War Office is very much perturbed by the somewhat late discovery that in time of war telegrams can be easily read by the enemy by means of the simple device of running a short length of wire parallel to the telegraph line and inserting a telephone in it. Herr Heinrich Discher proposes to get over the difficulty by duplexing the lines, one station sending the actual message, the other an agreed upon despatch, so that the listener at the telephone would only hear a confused *pot-pourri* of sound. We should have thought a good cipher would have been more to the point.

THE RECHNIEWSKI ALTERNATE-CURRENT MOTOR.

We illustrate herewith a motor designed by M. W. C. Rechniewski to work with alternating currents, and constructed by Messrs. Goolden and Co. at their Halifax works. The motor does not differ from the ordinary continuous-current type, except that the field is of laminated iron. The armature is of the drum type with Paccinotti teeth. For the sake of economy in the manufacture both the armature and field-magnet cores are stamped out of one sheet. Fig. 2 is a section of the iron cores.

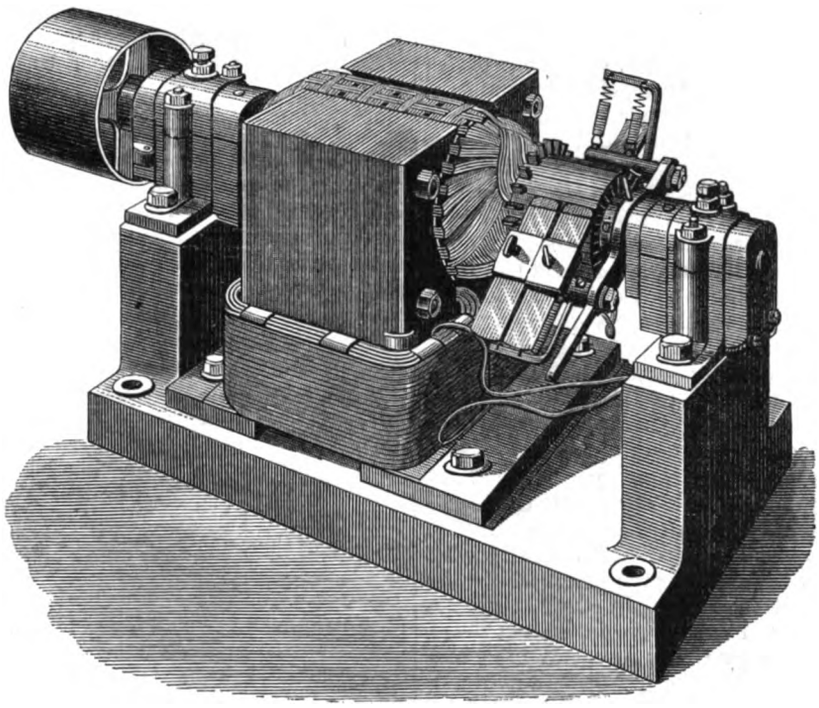

FIG. 1.—The Rechniewski Alternate-Current Motor.

The following figures relating to a machine of fifteen horse-power have been furnished us :—

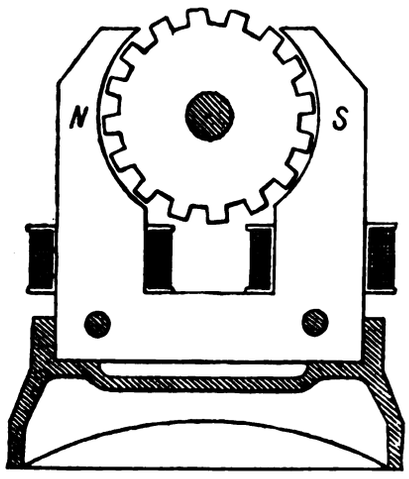

FIG. 2.

Volts at terminals, 115.
Current, 100 amperes.
Revolutions per minute, 1,400.
Diameter of armature, 8in.
Peripheral velocity in feet per minute, 2,800.
Weight of iron in field, 440lb.
Weight of iron in armature, 108lb.
Section of iron in field, 42·5 sq. in.
Section of iron in armature, 33·5 sq. in.
Induction in armature, 3,700,000 lines.

This motor is not, of course, self-regulating.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *August 11th*, 1888.

This city was visited last Saturday by a very severe thunderstorm, which inflicted damage for many miles around, and made itself specially felt in the various electric offices and plants. The 300 or 400 night operators in the Western Union building were treated to a brilliant display of dancing fires, and work on the telephone lines, cables, &c., was temporarily suspended. As forty or fifty places were struck in New York and the neighbourhood, it is not surprising that the electric light stations, too, should have been among the number. One large station visited was that of the United States Company uptown. It is not quite known whether the stroke came directly or from one of the circuits ; but at any rate there was a very lively fire, and the result was that a number of machines were left in bad shape. At Mount Vernon, also, near this city, the dynamos in the electric light stations were burnt out, and I heard of one or two other places where armatures were injured. Altogether the experience went to show that electric light stations are not sufficiently protected against incursions of this kind, and, timely enough, the subject was taken up at the meeting of the Edison Association this week, as mentioned below.

The meeting of the Edison Association, which is composed of local electric light companies operating under license from the parent company, or on the cash basis, took place this week at Boston, at a large hotel on one of the fine beaches which abound near the Hub. Although the convention was thus called for an extreme corner of the New England States, the attendance appears to have been large, there being about seventy-five members and visitors in attendance, many coming from remote parts of the country. What has been said in various ways with regard to the serious competition brought to bear against the continuous current for incandescent lighting might reasonably have led to the belief that the convention would meet under somewhat depressing circumstances ; but, on the contrary, the tenor of feeling was very cheerful, and Mr. E. H. Johnson, president of the parent company, was able to report, as indicating the confidence of capital, that a few days previous to the meeting he had organised a new company in the city of

Digitized by Google

Minneapolis, with a capital of half a million dollars, the plant to be running as soon as possible. As you may be aware, the Edison Convention, unlike the meeting of the National Electric Light Association, is held with closed doors. Of course, where there is so much of the private relations between the parent and sub-companies to be discussed, this practice is natural, but at the same time there is undoubtedly much else that would be of general interest, and much that the Association would do well to give the general public the opportunity of learning with some degree of fulness. It may be mentioned that among the subjects discussed was the use of the current generated in Edison stations, not only for lighting but for motive purposes, and the supply of the current was also advocated for telegraph offices, various successful attempts having already been made in this line. One of the evenings was given up to a very interesting Paper by Mr. W. J. Jenks, one of the most capable men in the electric light business in this country, on the subject of lightning and the methods by which electric light companies might be protected from it. The frequency with which stations have been struck or visited has at last become noticeable, and while provision is made in not a few stations, it is safe to say that in the vast majority the precautions taken are altogether inadequate. Mr. Jenks, I understand, suggested various remedies as to arresters and lightning rods, and in view of the fact that a good deal of contumely has been heaped of late on the rod in some quarters, it is significant to see that it has still its position as an effective protector. But the most striking part of Mr. Jenks's Paper, aside from, and in addition to, its practical bearing, was his reference to the divining rod. He remarked that one theory which had been entertained of late years was that subterranean watercourses were points or lines of attraction representing the earth's electrified condition. That being the case, Mr. Jenks has undertaken to see whether the peculiar property which has been attributed to the divining rod could not be utilised in determining the places where the lightning would be most likely to strike. In company with a divining rod operator, he visited several places, and in every instance was able to determine by the lines marked out and indicated by the bending of the rod, the spots where lightning had actually struck. All the determinations were verified by subsequent inquiries, and received in some cases most startling verification. One case was that at Amesbury, in Massachusetts. Certain residents of that place were very sceptical as to this method of indication, so they took the experimenters out on a long stretch of broad highway, and then ironically invited them to tell where the lightning had struck. It did not seem at all a likely place, but in a short time three lines were marked out, and where they intersected was said to be the point of greatest danger. This declaration silenced the sceptics, who themselves then produced an old history of the place wherein it was recorded that in 1802, right on that very spot, a man with two yoke of cattle had been struck, and with his four animals instantly killed. The divining rod, I might add, though perhaps the fact is pretty well known, is generally a stout forked twig of apple, peach or hazel bent over in the hands of the operator, and thus under a strain. It is most singular in this connection, that should the operator put on rubber boots or goloshes his power to obtain indications at once leaves him. All this is undoubtedly very interesting. Mr. Jenks made his experiments very cautiously, and is known to be a thoroughly careful and experienced experimenter, so that every reliance may be placed on his statements. It is to be hoped, however, that he will follow up this line of inquiry, as he may have something even more interesting to tell us about it later. It will be rather funny if, after all, we have to enrol the divining rod man among our electrical experts.

The subject of the supply of current to telegraph offices occupied the attention of the convention as noted above. Its importance may be gauged by the fact that both the Western Union Company and the Postal Telegraph Company in New York are now using dynamo current for a very large part of their work. The *Electrical World* illustrates this week a plant which Mr. F. W. Jones, the electrician and assistant general manager of the Postal Company, has just put in to replace several thousand batteries. This plant consists of a group of eight special Edison machines, run by two 10 horse-power engines. The steam for the engines is taken from the steam mains in the street, but the company has also its own battery of boilers, and has taken a further precaution against the interruption of the service by putting in an electric motor to take current from the street, with which to drive the generators in case both steam supplies should give out. A pretty little piece of work consists in the use of Edison lamps as resistances. These lamp resistances are adjusted to two ohms to every volt, so as to prevent any damage by overheating should the wires get crossed or grounded at or beyond the main switchboard. The glowing of the lamp detects instantly such trouble, which heretofore has been made known by the ordinary relay tests. Altogether the plant is said to be extremely successful, and it yields even better results than were expected.

A statement was made by Mr. T. D. Lockwood, in a recent number of the *Western Electrician*, to the effect that only one exchange in the world, that in New York, had as many as 7,000 subscribers. A correspondent of that paper writes to it challenging the statement, stating that there are 10,000 subscribers in the Berlin Exchange, which is operated by the German Government. But the point that Mr. Lockwood was making was with regard to the number of wires brought directly to one exchange, meaning thereby one switch-board or operating-room, and in that view of the case Mr. Lockwood is, as usual, correct in his statements. It may be questioned whether there is any exchange in the world which approaches the New York one by some thousands, and when the big board here is in full operation it will certainly be one of the greatest electrical sights in this country. Work on the board is still going on, but I believe that it is not expected that everything will be in thorough readiness for at least two or three months.

CORRESPONDENCE.

ALTERNATING-CURRENT ELECTROLYSIS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: It does not appear to be known to the readers of *The Electrician* that electrolysis has already been performed by the means of the alternating current, and described by Jamin in *Comptes Rendus* about six years ago.

Recently the experiment was repeated in this laboratory under the direction of the chief electrician, Mr. John F. Kelley, with good results. The current from a transformer working at about 6,000 alternations per minute was passed through a resistance, a copper mercury arc, and an Ayrton and Perry magnet ammeter; so long as the copper rod made actual contact with the basin of mercury no deflection was observed on the ammeter, but as soon as an arc was struck a permanent deflection to one side was observed which proved capable of reversal by changing the wires in the ammeter. Afterwards a copper depositing cell was connected in shunt with the resistance, and immediately copper was torn from the anode and deposited on the cathode; finally the electromotive force at the ends of the resistance was measured by a tangent galvanometer, and found to be equal and opposite to that at the terminals of the arc, while around both no deflection could be observed though the Cardew voltmeter at the same points indicated the full electromotive force of about 100 volts. This actual rectification of the alternate current seems to be due to the arc being a seat of electromotive force acting internally in one direction and externally in the opposite, precisely as a battery does; whether the action is a thermo-electric effect or something of the nature of electrolysis we have not yet been able to determine, all experiments having so far proved negative in character, though those of Jamin point to a thermo-electric explanation, as he says that the same effect may be observed with an arc between any materials provided only there is a considerable difference in their size.

However, I hope to repeat these experiments at an early

Digitized by Google

date, and to continue them in connection with actual measurements of the phenomena, in hopes of arriving at some conclusion which I may send you.—Yours, &c,

FREDERIC A. C. PERRINE, Sc.D.,
Assistant Electrician United States Electric Lighting Company.

29, Plane-street, Newark, N.J., August 9, 1888.

TELEPHONIC COMMUNICATION WITH SHIPS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your No. 526, Vol. XXI., appears an interesting communication from the Postmaster-General of South Australia respecting the above subject. Perhaps it may be of interest to your readers to hear that telephonic communication with ships has been in constant use here since February, 1884, viz., with the Messageries Maritimes (and for some time with the Clan line and Arab line of steamers, until they discontinued running here).

The system varies slightly from that in use at Adelaide. The cable is shorter, but we are compelled to place the buoy almost in mid-channel, so that ships anchor on both sides of it, thus making the task more difficult. The ships are in direct communication with the "Exchange," and the telephone is in frequent requisition from exchange subscribers as well as the agents.

When two ships are connected at the same time a switch is placed on board one of them, with an extension bell in circuit, and a cable run out to the other, thus saving a second main cable and aerial wire.—Yours, &e.,

HENRY GOODWIN, Electrician and Manager.

Oriental Telephone Company (Limited),
Port Louis, Mauritius, July 25th, 1888.

UNIPOLAR INDUCTION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I referred your correspondent, Mr. Snowdon, to the experiments of Exner and Czermak described in the *fourth* paragraph of Art. III., page 203. Mr. Snowdon's reply is an assault upon some experiments of Fessel's, which are incidentally stated, in the *third* paragraph of the article referred to, to have been confirmed by Exner and Czermak. Mr. Snowdon, however, admits that induction may be produced by the aid of sliding contacts in a circuit which remains fixed in an invariable field, due to a revolving magnet, which is exactly the point denied by the advocates of the theory that the lines of force of a magnet remain fixed as the magnet revolves.

Mr. Snowdon's statement that it is an incontestable fact that the one condition necessary for a current to be induced is not that the number of lines within the circuit should vary—in other words, that Faraday's law of electro-magnetic induction given in italics on page 203 is untrue—is hardly one that requires any comment. It is of course necessary that the E.M.F's at the different parts of the circuit should not balance, for if they did the total E.M.F. round the circuit would be zero. Faraday's law states the conditions under which an E.M.F. round a circuit can be produced, but it would hardly be profitable for me to take up your space and my own time in setting forth the evidence on which it is based, as this can be found in almost any elementary text-book; at any rate until something of more weight than Mr. Snowdon's bare assertion is brought against it.—Yours, &c., G. W. DE TUNZELMANN.

ELECTRICALLY-FORMED COPPER PIPES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your issue of August 10th, p. 431, you have a notice of the new method of making electro-deposited copper steam pipes by the agate-burnisher process.

I recently had the opportunity of passing ten days at Mr. Elmore's Mill at Cockermouth, and witnessed the whole *modus operandi* of this interesting and valuable invention. The first impression one gets is the complete absence of the noise and dirt which necessarily accompany the usual method of making copper pipes. One finds no smelting or refining furnaces with their sulphurous fumes loading the atmosphere and destroying vegetation all around. At Cockermouth beautiful roses climb the walls of the mill in which the tubes are manufactured, a picturesque watercourse runs through the mill grounds (which cover six acres), trout and other fish may be seen in the clear, pure water, and beautiful flowering shrubs afford a haunt for nearly every kind of English song-bird in full enjoyment of its natural element.

This is a marked and pleasant contrast to the copper works of Swansea, where miles and miles of country are completely destitute of vegetation.

Even the hum of the dynamo machine is absent in the tank rooms, only a silent transfer of copper from the anodes to the rotating mandrel in the tank, and one looks through the clear blue solution at a copper tube being built up molecule by molecule under one's very eyes.

Ordinary electro-deposition is always a beautiful process, but in this case Art steps in to assist Nature, and seems to say, "Please let us have these molecules of copper pressed closer than has ever yet been done." And so a copper pipe is built up *automatically* and *directly* from the impure and crude copper in the operation of refining the latter, and this merely by the passage of a current of electricity and an astonishingly small amount of manual labour.

As to the question of cost to which you refer, we know that 6040·8 amperes passing for 144 hours will deposit 1 ton of copper, and if we multiply this by ·5 volt, which is a very liberal allowance to overcome the resistance of the bath, we get 3020·4 watts, which is equal to 4·04 horse-power. One horse-power is produced by the combustion of 3lb. of coal per hour, and therefore $144 \times 3 \times 4{\cdot}04 = 1745{\cdot}28$lb. of coal, which equals ·779 ton. Add for loss of power in dynamo, engine, slipping of belt, &c., the large allowance of 50 per cent. = ·389 ton, we get 1·168 ton of coal consumed to deposit one ton of copper. Then, taking the cost of coal in a manufacturing district such as Birmingham or Cockermouth at 6s. per ton, we have, say, 7s. as the cost of fuel expended in the production of one ton of tubes.

It is difficult in the face of these considerations to see how the ordinary mechanical processes of drawing in which a large amount of manual labour is involved can possibly compete with this new process.

We may fairly look for an enormous development of electrolytic operations of this kind, in which the burnishing method can be used to give the marvellous strength and homogeneity indicated by Mr. Parker's independent tests, especially when it is borne in mind that it is just as easy by this process to make a 9ft. diameter calico-drying cylinder or a paper-maker's cylinder or a brewer's or distiller's boiling pan, with the bottom all in one piece.—Yours, &c.,

CHAS. J. SIMMONS.

18, Southampton-buildings, London, W.C., Aug. 22, 1888.

DETERMINING PERCENTAGE OF COPPER IN A CYANIDE SOLUTION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In reply to the inquiry of Mr. D. Corrie in your last issue it may be suggested that the best way of determining the percentage of copper in a cyanide depositing solution would be first to deposit the whole of the copper by a strong and long-continued current upon a platinum cathode with a platinum or iron anode. The purity of the deposit could then be tested by ordinary chemical analysis. After this the amount of potassic cyanide present might be found by means of a standard solution of nitrate of silver in the usual manner. But if the solution is very impure the process will, no doubt, be found troublesome.—Yours, &c., ELECTROLYSIS.

PATENT RECORD.

RECENT APPLICATIONS FOR PATENTS.

NOTE.—*The undermentioned applications are not open to public inspection until after the acceptance of the complete specification. The names within parentheses are those of communicators of inventions.*

11,312. J. HAMER. Halifax. Certain improvements in scoring boards used by billiard players and others, and in means for operating the indicating devices by electricity. August 4, 1888.

11,328. W. BOGGETT. London. Improvements in obtaining electricity for electric lighting motive power and other like purposes. August 4, 1888.

11,338. L. KELNER. London. Improvements in telephone line circuits. August 4, 1888.

11,352. J. SCHOLEFIELD. Leeds. An improved electric pen or pen and holder, specially applicable for stippling and similar purposes. August 7, 1888.

11,376. G. DRAPER and W. H. ASH. London. Improvements in syphon recorder telegraph instruments. August 7, 1888.

11,388. J. L. E. DANIEL. London. A system of and means or apparatus for automatically and electrically indicating the breaking of a train, or for actuating signals on railways. August 7, 1888.

11,403. H. H. LAKE. London. Improvements in apparatus for the propulsion of vehicles by electricity (F. J. Weis, United States). August 7, 1888.

11,411. A. W. MESTON. London. Improvements in armatures for dynamo-electric machines. August 7, 1888.

11,441. H. A. GALLIERS and F. KLAERR. London. A combined shade and globe or chimney for oil lamps, chandeliers, gaseliers, electric lamps, and the like. August 8, 1888.

11,475. C. BLANKE. Manchester. An improved electric stop-motion for automatically arresting the operations of apparatus for folding envelopes and similar articles of paper. August 9, 1888.

11,479. T. PARKER and A. E. ROBINSON. Manchester. Improvements in the manufacture of iodine and iodoform by electrolysis. August 9, 1888.

11,490. A. E. COCKBURN. London. Improvements in lock switches for electric circuits. August 9, 1888.

11,491. D. NICHOLL. London. Improvements in the insulation of electric conductors and for the preparation of wires to prevent vibratory sound when used for telephonic and other electrical purposes. August 9, 1888.

11,495. J. J. MANN and J. CUTLAN. Improvements in the arrangement and construction of telephonic exchange systems. August 9, 1888.

11,503. L. S. M. PYKE and H. S. BARNETT. London. Improvements in electric generators. August 9, 1888.

11,511. J. L. E. DANIEL. London. An improved system of automatic electric signalling for railways and means or apparatus for use therewith. August 9, 1888.

11,514. S. R. DOUSE. London. Electrically controlled apparatus for checking, extinguishing, and preventing the spread of fire, and for simultaneously giving the alarm. August 9, 1888.

11,529. W. TOWLE, London, and W. E. LANGDON, Derby. Improvements in electric lighting. August 10, 1888.

11,544. J. G. CUMMING. Edinburgh. Improvements in electrical coin freed machines. August 10, 1888.

11,568. W. SHEDLOCK. London. Improvements in electric batteries. August 10, 1888.

11,569. H. PIEPER. London. Improvements in secondary and other electric batteries. August 10, 1888.

11,570. H. PIEPER. London. Improvements in electric arc lamps. August 10, 1888.

11,573. H. HEAD and L. SAUNDERSON. London. Improvements in electric lamps. August 10, 1888.

11,582. F. H. VARLEY. London. Improvements in apparatus for the electro-deposition of metals and for the separation of chemical compounds or bases therefrom. August 11, 1888.

11,681. E. LIEBERT and S. A. ROSENTHAL. London. Improvements relating to electric batteries and to exciting liquids or compounds therefor. August 13, 1888.

11,703. E. CROWE. Middlesborough-on-Tees. Improvements in electric dynamos and motors. August 14, 1888.

11,705. W. P. THOMPSON. Liverpool. Improvements in apparatus for measuring electric currents and recording the amount of electric energy consumed in a given circuit (the Westinghouse Electric Co., United States). August 14, 1888.

11,718. J. GOZO. London. An induction apparatus—a substitute for dynamo-electric machinery—for the generation of electricity without converting the energy of mechanical motion into the energy of electric currents, *i.e.*, without moving coils of wire past magnets or magnets past coils of wire. August 14, 1888.

11,737. G. BINSWANGER. London. Improvements in electric bell pushes.

11,749. J. S. SELLON. London. Improvements in the manufacture of carbons for electric lamps. August 15, 1888.

COMPLETE SPECIFICATIONS ACCEPTED.

August 11, 1888.

10,611. R. P. MILBURN. Newcastle-upon-Tyne. Improvements in electric batteries. August 2, 1887.

10,833. F. R. BOARDMAN. London. Improvements relating to electric lamps. August 6, 1887.

10,838. F. L. RAWSON and W. WHITE. London. Improvements in electrical switches. August 6, 1887.

10,952. L. ANSPACH and L. GERARD. London. Improvements in or connected with dynamo-electric machines and electro-motors. August 10, 1887.

11,802. A. SHIPPEY. London. Improvements in and relating to the manufacture of incandescent lamps, and the methods adopted for converting old lamps into new, materials used therefor and in combination therewith. Aug. 31, 1887.

12,203. T. L. HEMMING. Birmingham. Improvements in dynamo-electric machines. September 9, 1887.

13,320 J. G. STATTER and S. L. BRUNTON. London. Improvements in electric regulators. October 1, 1887.

13,558. P. EVERITT and P. R. ALLEN. London. Improvements in or relating to casings for electrical conductors and apparatus. October 6, 1887.

13,567. A. M. CLARK. LONDON. Improved automatic electrical firing mechanism for naval ordnance (P. Oriolle, France). October 6, 1887.

14,024. N. DE BENARDOS. London. Improvements in secondary batteries or electrical accumulators. October 15, 1887.

14,029. F. C. ALLSOP, Bexley. Improvements in electrical tramways and railways. October 15, 1887.

5,681. C. S. SNELL. Saltash. Improvements in switches used for electrical purposes. April 17, 1888.

August 18, 1888.

13,720. A. DE KHOTINSKY. London. Apparatus for effecting electrical measurements and contacts. October 10, 1887.

12,247. W. PARKINSON. Manchester. Improvements in dynamometers (J. Wallace, India). October 20, 1887.

15,455. W. S. ROGERS. London. Apparatus for connecting a number of separate electrical conductors to one main conductor. November 11, 1887.

713. T. COAD. Forest Gate. Improvements in voltaic or galvanic batteries. January 17, 1888.

7,619. G. J. WEIR. Glasgow. Primary electric battery. May 24, 1888.

PATENTS SEALED.

August 10, 1888.

7,865. F. GEORGE. Gloucestershire. Improvements in dynamo-electric and electro-dynamic machines. March 31, 1887.

9,191. G. A. SCOTT. London. Improvements in type printing telegraphs. June 28, 1887.

9,843. W. T. GOOLDEN and S. EVERSHED. London. Compensating electric measuring instruments for temperature. July 13, 1887.

10,519. J. B. PETTER. Yeovil. Improvements in posts, such as fencing, telegraph, direction, lamp and other similar posts. July 28, 1887.

10,606. L. GERARD. Brussels. Improvements relating to the distribution, storage and regulation of electric currents. July 30, 1887.

10,748. A. SCHANSCHIEFF. Gipsy Hill. Improvements in portable batteries for the production of electric light. August 4, 1887.

13,005. F. VILLIERS STEAD and E. R. HEDGMAN and J. SPRATT. London. Electrical automatic boxes for the delivery of small articles. September 26, 1887.

13,954. W. E. IRISH. United States. Improvements in or appertaining to electrical railways. October 14, 1887.

1,406. M. TURTON and S. TURTON. Tipton. Portable combined electric and mechanical clock alarum. January 31, 1888.

1,851A. J. Y. JOHNSON. London. A sound-conveying tube for telephones, graphophones and like instruments (The Volta Graphophone Company, United States). February 7, 1888.

4,524. W. J. S. BARBER-STARKEY. Shropshire. Improvements in portable galvanic batteries. March 24, 1888.

6,237. A. MILLAR. Glasgow. Improvements in jars or cells for primary or secondary electric batteries. April 27, 1888.

6,481. H. H. LAKE. London. Improvements relating to the electrical transmission of power and to apparatus therefor (N. Tesla, United States). May 1, 1888.

6,502. H. H. LAKE. London. Improvements relating to the generation and distribution of electric currents and to apparatus therefor (N. Tesla, United States). May 1, 1888.

August 17, 1888.

8,240. J. R. HARD and T. WILSON. United States. Improvements in galvanic batteries. June 8, 1887.

8,500. R. S. WARING. United States. Improvements in conduits for electric wires or cables. June 13, 1887.

8,701. J. ROSS. Dundee. Improvements in and relating to the production and application of electric energy for lighting or other purposes. June 16, 1887.

THE "STEAM CYLINDER LUBRICATOR."

The introduction of sight-feed lubricators for steam-engine cylinders is of quite recent date, and they constitute a very great improvement over the clumsy and wasteful oil and tallow cups which engineers were long in the habit of fixing to their engines. They enable the engineman to give a regular and visible supply of oil to the cylinder, which is of great importance for economy in working.

Notwithstanding their advantages over the old-fashioned tallow cup, the sight-feed lubricators, as generally constructed, have several defects, which impair their usefulness. They depend for their working on the displacement principle, whereby the condensed steam from the condenser displaces a certain quantity of lubricant, according to the degree of condensation taking place.

If anything should occur to prevent condensation of the steam they fail to act, and the engineman has to resort to the tallow cup, to supply the engine with lubricant.

This want of certainty in their action is a serious drawback, and most enginemen provide for the defect by retaining the old tallow cups in case of emergency. With displacement lubricators, also, the quantity of oil which can pass through them depends on the efficiency of the condenser, while it is often necessary to give a steam cylinder a flush of oil—as, for instance, in case of priming—which cannot be done by an ordinary sight-feed lubricator.

The lubricator shown in Fig. 1, which has lately been introduced by the Steam Cylinder Lubricator Company of Manchester, has been designed to overcome these defects, and to provide an apparatus which is automatic in its action, supplying a regular and visible feed to the cylinder, and perfectly under control. The oil is displaced, not by the accumulation of condensed steam, but by the direct pressure of the live steam acting on the underside of a piston, whose surfaces are of unequal areas. The action of the lubricator is thus positive in its nature, not liable to derangement;

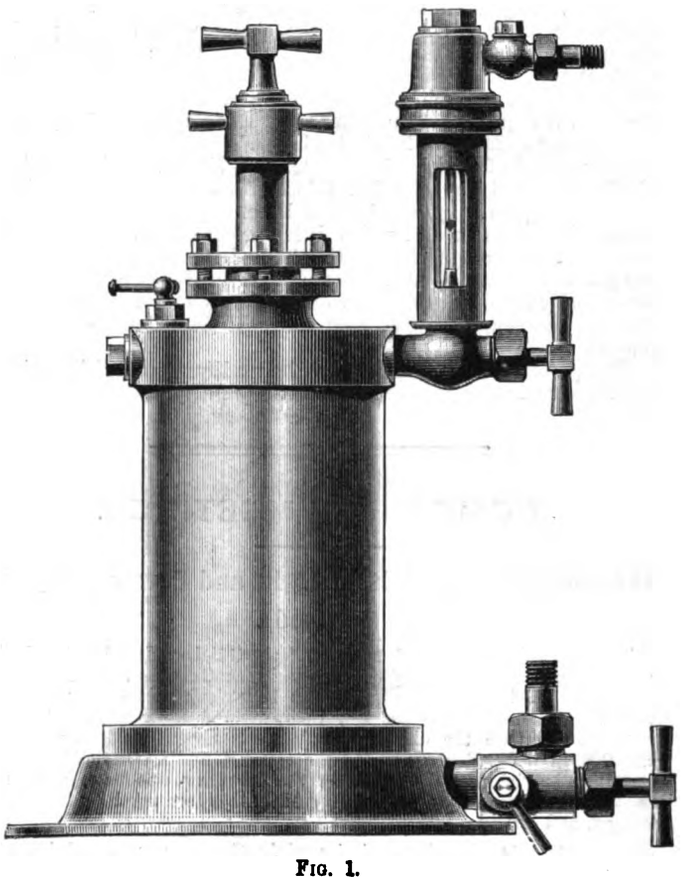

Fig. 1.

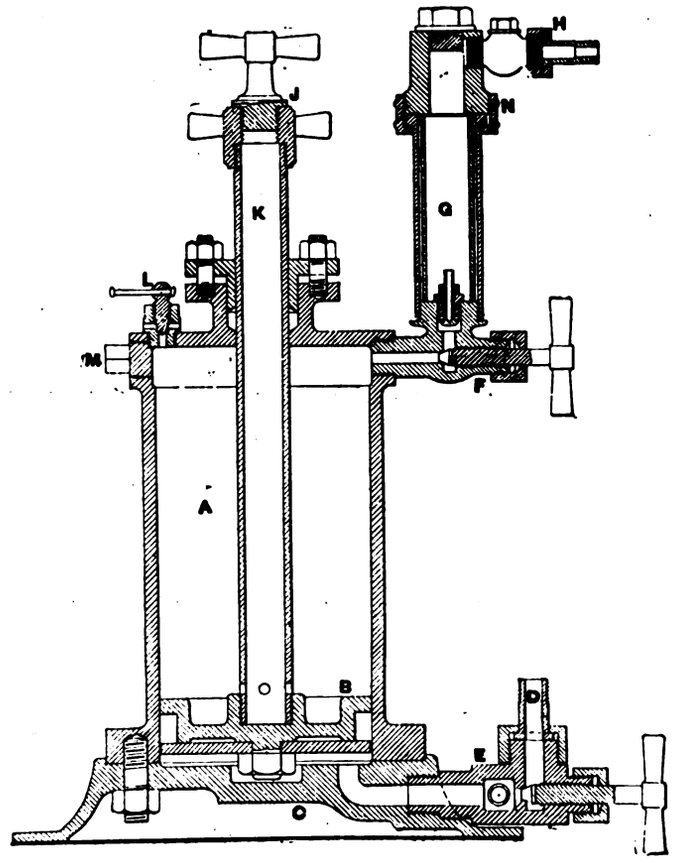

Fig. 2.

and an important feature is, that the piston-rod acts as a tell-tale, indicating the gradual consumption of the oil, and showing when it requires to be replenished.

Digitized by Google

In Fig. 2 A is the oil chamber, in which works a steam-tight piston, B, which is asbestos packed, having screwed into its top side a hollow steel piston rod, K, which works through a stuffing box. This piston rod also serves as an indicator showing the level of the oil. At the top end of the rod is a filling plug, J, through which the oil is delivered into the chamber A, the oil passing through the small holes at the bottom of the tube; D is the steam inlet, H the connection to the cylinder, G the sight feed, L an air valve, M a plug which can be unscrewed and the sight-feed G inserted, if required, at the other side, E is a run-off valve, and C is the base to which the lubricator is fixed.

The method of working is as follows:—When the piston B is at the bottom, and the chamber filled with oil, steam is admitted through the pipe D by opening the lower valve to the underside of the piston, the area of which is larger than the top side by the amount of the area of the rod K. This difference of area causes the piston to be raised within the cylinder, and so displaces the oil above, which finds its way out to the engine steam pipe or chest through the upper valve F, past the sight-feed G and connecting pipe H.

The quantity of oil displaced can be readily regulated by adjusting the outlet valve to give any desired quantity.

COMPANIES' MEETINGS.

The Gulcher New Electric Light and Power Company (Limited).

The first ordinary general meeting of the Gülcher New Electric Light and Power Company (Limited) was held at Cannon-street Hotel, on Thursday, the 9th of August, 1888, at 12 o'clock when the Chairman reported the formation of the new Company and the conditional agreement to purchase the old Company's assets for £16,000 in cash and £20,000 in deferred shares. On the conclusion of the ordinary general meeting a special general meeting of the Company was held, when the following resolution was proposed by Mr. Lloyd, seconded by Mr. Binswanger, and carried:—

"*That the Articles of Association of the Company be amended as follows:*

"*Article 7, by omitting all words after the words 'Ordinary Shares,' and in place thereof inserting, 'The Preference Shares shall be entitled to receive out of the net profits of each year a preferential dividend of £10 per centum. After provision has been made for such preferential dividend, the surplus net profits or so much thereof as shall be sanctioned at the annual meeting of the Company shall be distributed upon all the shares, both Preference and Ordinary, rateably in proportion to the amount paid up, or credited as paid up, thereon respectively. In the event of a winding up of the Company, the surplus assets shall be applied, first, in repayment to the holders of Preference Shares of the amounts paid or credited as paid thereon; then in repaying to the holders of Ordinary Shares the amounts paid or credited as paid thereon; and the residue shall be divided as to one-third part amongst the holders of the Debenture Stock of the Company, as to one-third part amongst the holders of Preference Shares, and as to the remaining third part amongst the holders of Ordinary Shares.'*

"*Article 12, by inserting after the word 'registration' the words 'and shall have been duly registered as a shareholder in the books of the Company, whereof the production of a share certificate in his name shall be sufficient evidence.'*

"*Article 46, by striking out the words '31st December,' and in lieu thereof inserting '30th day of June.'*

"*Article 60, by inserting after the word 'member' the words 'who shall be registered as a holder of a preference share or shares.' By inserting after the word 'each' the word 'such.' By adding at the end of the article the words 'And every member who shall be registered as a holder of an ordinary share or shares, shall have one vote for each such share up to five shares, and one vote for every additional five shares beyond the first five shares held by him up to fifty shares, and an additional vote for every ten shares held by him beyond fifty shares.'*

"*Article 75, Sub-section (c), by inserting after the words 'Acts of Parliament' the words 'Provisional Orders.' Sub-section (j), by inserting after the word 'debentures' the words 'or debenture stock.'*"

The Pilsen-Joel and General Electric Light Company (Limited).

An extraordinary general meeting of the shareholders of this Company was held at the Cannon-street Hotel on Friday, the 10th inst., Sir Rawson W. Rawson, K.C.B., the Chairman, presiding.

A circular had previously been sent to the shareholders, signed by the Chairman and the other two Directors, and two members of the committee appointed at the last meeting of the Company, held on June 27th, in which it was stated that no tenders had been received for the patents, plant, stock and goodwill of the Company's business in response to advertisements which had been issued in several papers. Mr. Gwynne, a member of the committee, however, had made an offer for the purchase of the entire undertaking of the Company, taking over all assets and liabilities as they stood on July 26th, for £4,550. Mr. Gwynne's intention according to the circular, was to provide forthwith considerable further capital (£10,000 or more), and then to continue the business by the formation of a new company, with a small body of shareholders. He was prepared, should his proposal be favourably entertained, to at once buy any partly paid shares at 4s. per share, and any fully paid shares at 18s. per share, and would afford holders of not less than 100 shares an opportunity of joining him in his new company. The alternatives, other than the sale to Mr. Gwynne, appeared to be that the remainder of the Company's capital would be called up for the extension and development of the business on the Company's own account, or that voluntary liquidation should be entered upon for realisation of the assets and distribution thereof amongst the shareholders, after satisfying the liabilities. In this latter alternative the risk of the uncalled capital being called up in the liquidation, though eventually returned, was to be borne in mind. The opinion of the Directors was that the proposal of Mr. Gwynne should be accepted, as no better course presented itself. Of the members of the committee Mr. Fyfe dissented, Mr. D. Parrish was absent from England, and Mr. Phillips was in agreement with the Directors; the fourth member of the committee was Mr. Gwynne himself.

The notice convening the meeting having been read,

The CHAIRMAN said: I have no doubt you have all received the circular which explains the circumstances under which we meet to-day and the view that the Directors take of our present position, and of the only offer that has been made to us, that of Mr. Gwynne. At the last meeting a committee was appointed and instructed to consider the best means of disposing of the property of the Company, and as an alternative to consider the advisability of continuing the business. Accordingly the Directors have met those members of the committee, and the result is communicated in the circular. We issued advertisements for tenders in accordance with the desire of the shareholders, and the result has been that there has not been a single offer and only four applications to become acquainted with the nature and value of our business. Under these circumstances, Mr. Gwynne, a member of the committee, whose attention, it appears, has been called to this matter for some considerable time, has made an offer, and this the Directors now submit to the shareholders for their consideration with their recommendation that it should be accepted upon the ground that it makes an offer to those who do not desire to invest any more money in this Company, and at the same time offers to those shareholders who have confidence in the future of electric lighting and who are prepared to pay the balance of calls, amounting to 12s. per share an opportunity of joining Mr. Gwynne in the future management of the business, sharing equally with him in the advantages and profits, whatever they may prove to be. I wish to say that I am aware that a circular has been issued to the shareholders by Mr. Fyfe since the appearance of this circular; he has not thought it necessary to send me or my co-Directors a copy of it, but I am perfectly aware of its existence, and there is one point in it which contains an error which I desire to correct. It states that the balance of assets which Mr. Gwynne will obtain possession of when this contract is carried out amounts to £1,500. I wish to say that that is entirely an error; it does not amount to a third of that sum. That is a mistake, and on the whole the Directors are of opinion that inasmuch as this offer gives nearly as much as the market value of the shares at the present moment, as it imposes upon Mr. Gwynne all the responsibility of finding the capital for carrying on and extending the work, which it is admitted by all parties is absolutely necessary, and inasmuch as Mr. Gwynne encourages all those to join him who hold such an interest in the Company that he can secure their acting with him for the benefit of the Company and for no other purpose, we consider that it is an offer which it is to the interest of the shareholders to accept. There are but two alternatives. We presume that the shareholders are not prepared to adopt one of them. The alternatives are, first, to carry on the business, calling up the 12s. a share remaining due, or to dispose of the business. The shareholders at previous meetings have declared their opposition to paying further calls. The Directors have endeavoured to obtain an offer for the business, and to dispose of it on the best terms that they can, and it will rest with you to-day to decide whether this offer shall be accepted or declined. There is one thing which I must point out, that under any circumstances, whether Mr. Gwynne's offer or anybody else's offer be accepted, the only way of carrying out the object which we all have in view is by voluntary liquidation, by means of which the Company, when reconstituted, will start clear, with only a liability for the capital invested in it, and will get rid of that which has been the difficulty of the Directors and will be the difficulty of the Company if carried on by paying up the further calls, namely, the nominal value of the patents and goodwill, which stands at £25,000. Until that is arranged in some way you cannot divide profits. I do not think I have anything more to say. I wish to avoid all points likely to lead to unnecessary discussion or recrimination, and therefore I put the question before you as a mere matter of business to accept this offer or not to accept it. I propose this resolution:—

"*That the undertaking of the Company be sold to Mr. Gwynne, he taking over all assets and liabilities as they stood on July 26th, 1888, at the price of £4,550, and upon such other terms as may be arranged between the Directors or the liquidators of the Company and Mr. Gwynne.*"

That latter clause has reference to the arrangement which Mr. Gwynne has proposed, and by which he is prepared to abide, but which our lawyers have found very difficult to put into black and white.

Mr. WHATELY seconded the resolution, explaining in more detail than the chairman had done the terms of the offer made by Mr. Gwynne and the conditions upon which he was willing to admit other large shareholders to participation in the future conduct of the business. He re-

Digitized by Google

marked that there were suggestions that if they waited a little while they would get a better offer, but he could only say that this question of the sale of the Company's plant and business had been before the world a very long time, and they had received absolutely no offer at all but that of Mr. Gwynne. With regard to the absence of Mr. Parrish's signature to the circular, that gentleman was aware of the offer, and had sent in his proxies to vote for it. Mr. Gwynne, he might say, did not confine his offer of participation to those who already held 100 shares; anyone having less than 100 shares who liked to buy more to make up that number would be equally welcome.

After a somewhat prolonged discussion, Mr. GWYNNE complained of the unfair way in which he had been treated and attacked by Mr. Fyfe, and said he declined to keep his offer open. It must be either accepted or rejected at that meeting. As the result of a desultory discussion, he was prepared to increase his offer to £6,000, provided the condition as to other large shareholders having the option of joining him were omitted. He concluded his remarks by saying that at the last meeting he was one of the men who led an attack upon the Directors. In consequence of the statements made to him by Mr. Fyfe, he entered into the inquiry thoroughly saturated with prejudice against the Directors, believing them to be the essence of all that was bad. He had now gone thoroughly into the matter, had been to the works dozens upon dozens of times, and he was bound as an Englishman and a gentleman to confess that he had been deceived. Instead of finding a gang of men doing all they possibly could to rob the shareholders, he found a body of gentlemen who were prepared to do the best they possibly could for the interests of the shareholders. He had not the pleasure of a personal acquaintance with the chairman, but by his courteous, honourable, and straightforward conduct he had not only removed the prejudice he had previously felt against him, but had brought him to feel that he should be delighted to be associated with Sir Rawson Rawson in any business with which he was connected. He placed implicit confidence in him, in the other Directors, and in the officers of the company. He could only openly apologise for the gross mis-statements he had made respecting them.

Mr. F. L. RAWSON said, that on behalf of Woodhouse and Rawson (Limited), he had looked into the business and had made the Pilsen Company an offer, which, however, was not accepted. He considered that Mr. Gwynne's offer ought to be accepted, as it gave those possessing over 100 shares a right to become part purchasers of the business upon the same terms as Mr. Gwynne himself.

Mr. FYFE, replying to some remarks at an earlier stage by Mr. Gwynne, said that he had never intended that that gentleman should get the business for less than it was worth, and he thought it was worth more than was now offered for it.

Mr. ROPER said he preferred the offer of £6,000 made by Mr. Gwynne, and he moved as an amendment that that offer should be accepted, with the view of testing the views of the meeting. He had implicit confidence in the Board. He believed that, badly as the affair had turned out, they were in no way in fault.

Mr. LAYTON seconded the amendment.

Mr. F. L. RAWSON thought if the shareholders accepted that offer they would make a great mistake. In his opinion, with good management, such as he believed that Company would have and had had, considerably more might be made of it.

After further conversation, Mr. Roper withdrew his amendment, and the original motion was put to the meeting, with the result that 13 voted for it and 12 against. A poll was demanded and taken, the voting being 6,352 for and 1,424 against. The resolution was therefore carried.

Mr. GWYNNE said the shareholders had behaved badly in robbing the Directors of their fees, but it was his intention that they should be paid.

The CHAIRMAN moved that the Company be wound up voluntarily.

Mr. WHATELY seconded, and the motion was carried, as was a further resolution appointing Mr. W. H. Trentham, the secretary, liquidator of the Company.

A vote of thanks to the Chairman terminated the proceedings.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended August 17th, 1888, amounted to £4,596.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended August 17th, 1888, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company, were £3,813.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The traffic receipts of this company for the half month ended 15th August, 1888, were £2,533, as compared with £2,048 in 1887.

WEST COAST OF AMERICA TELEGRAPH COMPANY.—At the usual meeting of the directors of this company, Mr. Frederick Walters, of 12, Tokenhouse-yard, E.C., and partner of Messrs. Huth and Co., in Valparaiso, was elected to a seat at the board.

Offices—**WINCHESTER HOUSE, OLD BROAD STREET, LONDON, E.C.**

The principal objects of the Corporation are:—

1. Performing the duties of Trustee, Executor and Administrator.
2. The Insurance of Bonds, Shares and all other Securities lodged with the Corporation against risks of all kinds.
3. The Issue of Warrants and Certificates against Securities deposited, and making and procuring advances on such Warrants.

The Office of Trustee or Executor is to private persons usually a thankless post, involving much anxiety, time and money, and frequently leads to serious actual loss; whilst death, illness and change of residence necessitate frequent fresh appointments, and consequent expense to the parties interested. The Corporation undertakes all the duties of Executor, Trustee or Administrator for reasonable remuneration proportioned to the work and responsibility in each case.

The Corporation insures existing Trustees and Executors against all risks attending those positions, where the business is conducted by the Solicitors to their Trusts under the supervision of the Corporation, it not being the desire of the Corporation to interfere in any way with the duties of the family solicitor.

The Corporation acts as Trustees for the Debenture Holders in Public Companies.

For terms, &c., application should be made to the General Manager at the Company's Office.

GEORGE PEARSON *General Manager and Secretary*

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL SCIENCE, INDUSTRY AND ENGINEERING.

No. 537.—Vol. XXI. FRIDAY, AUGUST 31, 1888. Price 4d.

NOTES.

The failure of the Westinghouse Company to sustain the Gaulard-Gibbs patent in the United States comes to us with considerable surprise. It is generally known that the American patent was drawn up very differently from the English specification, and that the principal claims were made to rest upon the feature of the closed *metallic* circuit upon which the dynamo is worked. Notwithstanding the ingenuity of this construction, the American Courts have gone behind the specification and have invalidated the monopoly upon the ground that the first published description of Messrs. Gaulard and Gibbs' invention referred solely to the use of transformers in series, and that parallel working is presumably of later date. If this decision is supported on appeal, it is evident that the Westinghouse Company will be dethroned from the position of supremacy which they have hitherto occupied in the United States. Whether the decision will have any effect upon their contemplated raid on British territory remains to be seen.

In an interesting letter on "Flashed Filaments and Lamp Voltages," a correspondent suggests that if the makers of transformers were to wind the secondaries to give slightly different E.M.F.'s from the normal 100 volts now generally adopted, they would probably be able before long to buy better lamps at a cheaper rate. Our correspondent's views are based upon the idea that in the process of making unflashed filaments there will always be a certain number which deviate slightly on either side of the standard voltage, and that the makers will be unable to get rid of these lamps under ordinary conditions. It seems to us, however, that our correspondent addresses his appeal in the wrong quarter. If the lamp makers were from time to time to advertise the sale of so many thousand lamps of 98 or 102 volts at a reduced price, no doubt they would very soon find plenty of purchasers. Meanwhile, it is perhaps more important to insist on the desirability of using lamps of lower voltages in connection with transformers. We hope that the 100-volt lamp on transformer circuits will soon become a thing of the past.

The resuscitation of the British Electric Light Company is an event of some importance, though as to its wisdom we hesitate to express an opinion upon the evidence before us. A winding-up order was made by Mr. Justice Kay in February, 1886, and the proceedings were still pending when (according to the terms of the circular recently issued) it was discovered that "there are good grounds for believing that the interest of the company under two licenses—one from the Edison Electric Light Co. (Limited), and one from the Manchester and District Edison Electric Light Co. (Limited)—is now of considerable value, and that the licenses may be operated with at a profit, and that it will be beneficial to the creditors of the company, both secured and unsecured, as well as to the shareholders, that an arrangement should be made between the company and its creditors, both secured and unsecured, for the satisfaction of the company's debts, with a view to the resuscitation of the company as a going concern for the purpose of working under these licenses." The creditors and debenture-holders having been jointly and severally induced to adopt this view, the process of resuscitation is now in an advanced stage. We are at present quite in the dark as to the nature of the licenses alluded to. If they are for the manufacture of lamps they may possibly be of some value, but we are unable to imagine that any other license which it is in the power of the Edison Companies to grant can be of any value whatever.

The report of the meeting of the shareholders of the Pilsen-Joel Electric Light Company, which we published last week, was inaccurate in one particular, the resolution to accept Mr. Gwynne's offer having, as a matter of fact, received the approval of a majority of the shareholders present. Since then, however, Mr. Fyfe, who is strenuously opposed to the policy of the directors, has obtained an injunction from the Court of Chancery restraining the Board from effecting the sale. The company is now to be wound up voluntarily.

In the number just issued of the *Proceedings* of the Royal Society Dr. J. Hopkinson has a Paper "On the Magnetic Properties of an Impure Nickel," in which twenty-one curves are drawn, showing the relation between the magnetising force and the induction for various temperatures—a subject on which a good deal was written in the earlier part of the last volume of this journal. When Dr. Hopkinson commenced the investigation he was under the impression that the nickel was fairly pure; a subsequent analysis showed, however, that only 95·15 per cent. of that metal was actually present, cobalt, copper, iron, and carbon all being represented in comparatively large quantities. It is, nevertheless, interesting to note that Dr. Hopkinson's experiments confirm the results arrived at by earlier observers as to the temperature at which the magnetic permeability of nickel suddenly and rapidly falls off. In *The*

Digitized by Google

Electrician of January 20th, 1888, will be found a set of curves obtained by M. LEDEBOER, in which the temporary and permanent magnetisations are distinguished, with the curious result that the temporary magnetisation *increases* continuously up to about 270° C., and then falls with great rapidity, whilst the temporary magnetisation slowly falls off almost from the commencement of the heating; both magnetisations arrive simultaneously at minimum values at a temperature of about 320° C. Dr. HOPKINSON's methods did not permit him to distinguish between the permanent and the temporary inductions, but on the other hand he has noted the effects of magnetising forces of different values—a point which M. LEDEBOER apparently neglected. The temperature at which the induction begins to diminish is not appreciably affected, however, by the value of the magnetising force within the limit of the experiments.

OUR readers will, no doubt, remember that last winter a good deal of interest was aroused by the suggestion that this property of nickel might be employed upon a commercial scale for the direct conversion of heat into electric energy. As usual, the suggestion arose in at least two independent quarters at or about the same time, though up to the present it has had no practical outcome. We do not know what Mr. EDISON is doing with his thermo-magnetic generator, but we are sorry to say that M. MENGES (whose designs seemed by far the more promising of the two) has for some time past been hindered from prosecuting his experiments. At the date when we last heard from him he had, however, by no means given up the idea, and hoped before long to be again at work.

FOLLOWING up its recent attacks on the management of the Metropolitan telephone system, the *Financial News* now publishes the report of a "technical expert" commissioned by that journal to inquire into and compare the electrical arrangements provided respectively under the National Telephone Company in Glasgow and district, the Lancashire and Cheshire Telephone Company in Manchester and its district, and the United Telephone Company in the metropolitan area. On the whole, the commissioner is justified in stating that as regards the latest and most valuable improvements in telephony, including wiring, switching, exchanges, and uninterrupted service, the two provincial companies named are far ahead of the parent company. Whereupon the *Financial News* falls foul of the United Company in what seems to us a very sweeping and inconsiderate fashion. That the oldest company is saddled with the oldest appliances is as natural as that the youngest has provided itself with the newest. The only serious doubt still remaining is whether the United Company is taking steps, as opportunity offers, to replace its old-fashioned and inefficient plant by newer and better; and as to this the report is rather encouraging than otherwise.

ON two other points the report is incidentally more dogmatic than the evidence it adduces would seem to warrant, namely, the relative efficiency of the systems, and their economy. We hear of the complaints in London, but it is rather too much to assume that there are none outside London because they do not reach us; and as regards economy of working it is no doubt true, as the reporter alleges, that it is cheaper in the end to adopt this and that improvement. It must also be remembered that some of the greatest difficulties with which telephone companies have to contend—difficulties both in the switch rooms and on the line routes—tend to increase almost in geometrical progression as the number of subscribers is extended; so that, under the best possible management, and with the most perfect appliances hitherto known, the difficulties of the telephone service are necessarily and enormously greater in an exchange such as that of London, with four or five thousand subscribers, compared with those of Manchester or Glasgow, with less than two thousand.

AT the same time we have no hesitation in expressing our unqualified admiration for the degree of perfection which has been attained in the telephone service, both in Manchester and in Glasgow, each of which exchanges we have ourselves visited. By a singular coincidence we commence this week the publication of a detailed description of the work of the National Telephone Company in the Glasgow district, from the pen of Mr. D. SINCLAIR, the electrician in charge.

DURING one of the recent balloon ascents made from Olympia by the late Mr. SIMMONS that ill-fated æronaut had a very narrow escape of being caught in a thundercloud which was engaged in active operations. By dint of clever manipulation he succeeded, however, in keeping beyond the limits of the actual discharge. We are aware of only one instance in which a balloon has remained within the zone of a thunderstorm; this occurred last summer during an ascent made from La Villette by M. LECOQ. This intrepid æronaut was brave or rash enough to court the terrors of the unknown, and appears to have purposely timed his ascent so as to get well within range of an approaching storm. At the height of 600 metres the balloon moved rapidly towards the storm-cloud, as if attracted by it. At 7:40 p.m., and at a height of 1,100 metres, it entered a mass of grey-green cloud, which was momentarily lit up by fitful lightning flashes, followed by immediate and deafening thunderclaps. The discharge appeared to take place between this cloud and another directly overhead, and the balloon was tossed to and fro between cloud and cloud, and set spinning round and round in a manner both bewildering and dangerous; and which reminds one of the well-known experiments in which pith-balls are placed between oppositely electrified plates. That these oscillations were due to electrical attraction and repulsion seems to be proved from the fact that a strong gale was blowing at the time, which could be felt in the car, and which the balloon therefore did not wholly obey. As a rule, an æronaut scarcely feels the wind, however strong, since the balloon is carried along at the same rate. Neither M. LECOQ nor his companion felt any ill effects beyond the usual sense of oppression which accompanies such atmospheric conditions. There were no brush discharges visible upon the cordage of the car, but gusts of warm air were felt every now

Digitized by Google

and then, which expanded the gas and carried the balloon further aloft. In one of these upward movements the balloon rose to a height of 1,600 metres. At this altitude the storm attained its greatest intensity, constant discharges taking place between the cumulus in the middle of which the balloon was floating and a cirrus formation above it. "This ascent seems of interest," says M. LECOQ, in concluding his narration, "on account of our prolonged stay in the storm cloud, a circumstance of rare occurrence. I was particularly struck by the very violent agitation of the air, and by the ascending and descending whirls which existed in the heart of the cloud, as well as by the very strong attraction experienced by the balloon and light bodies floating in the air."

H.M.S. "Sanspareil."—The new armour-clad, the "Sanspareil," is to be fitted with three electric search lights.

The Price of Copper.—The price of copper was further advanced yesterday, £90 to £90. 10s. being the quotation for Chili bars.

The Telephone in China.—The Viceroy of the Two Kwang and the Governor of Canton have made arrangements to have their respective Yamens connected by telephone.

The Tesla Motor.—It is stated that the Westinghouse Company has purchased the Tesla alternate-current motor patents, and intends shortly to put some of these machines upon the market.

Arc Carbons.—The Brush Company of Cleveland has recently added to its electric light carbon plant, but orders have been so numerous that the company is said to be behindhand to the extent of 400,000 carbons.

Railway Telegraphs.—The coroner's jury in the Hampton Wick accident added a rider to their verdict that all signal-boxes ought to be in direct telegraphic or telephonic communication with the boxes on either side.

Versailles.—A company has just been formed at Versailles for the purpose of supplying that town with electric light. It is proposed to have the station at Marly, and to transmit high-tension currents from there to Versailles, a distance of over six miles.

Tynemouth.—At a meeting of the Tynemouth Town Council, to be held on Friday next, a recommendation from the Trade and Commerce Committee will be submitted to apply for a Provisional Order for lighting the public buildings and streets with the electric light.

The Telegraph in China.—M. Lemaire, the French Plenipotentiary at Pekin, is negotiating at the present moment with the Chinese Government with a view of obtaining a convention permitting the Tonkin telegraph system to be connected with that of China.

Cuban-Mexican Cable.—The *Madrid Gazette* of August 20th contains a Royal order granting permission to Don Augusto Ghirlanda y Hemandez to lay and work a submarine cable between the coast of the Island of Cuba and the Mexican peninsula of Yucatan.

Science and Art Scholarships.—Among the successful candidates in the competition for the Whitworth Scholarships and Exhibitions for 1888 we notice Benjamin Young, aged twenty-three, electrical engineer apprentice, of Belfast. The value of the scholarship in his case is £100 a year for three years.

A Reservoir Destroyed by Lightning.—A terrible thunderstorm occurred at Toulon on Saturday night. The lightning struck and burst open the aqueducts of the reservoirs at Saint Antoine, the water rushing down the hill and causing great damage to property.

Cable Laying.—Mr. Henry Stott, writing from ss. "Minia" at Halifax, N.S., on August 13th, says:—"Perhaps it might interest some of your readers to know that we used 44 knots of the Trott-Hamilton patent hemp cable on the repair of the Brest-St. Pierre cable, at a depth of 1,600 to 1,900 fathoms, with perfect success."

Madrid.—The Spanish Government has refused to alter the date fixed for the compulsory introduction of the electric light in the Madrid theatres, and no place of entertainment will be allowed to open this autumn unless lit by electricity. The majority of the theatrical managers have, however, already complied with the ministerial decree.

Glasgow.—The Anglo-American Brush Corporation have recently opened a new office at 123, Hope-street, Glasgow, which has been placed under the charge of Mr. W. Geipel, their Superintendent for Scotland. A room on these premises has been fitted up as a show room, and a large assortment of Benson's artistic fittings are on view.

An Electrical Society in Japan.—We are officially informed that an electrical society has been formed in Tokio, Japan, and that at the first meeting upwards of 800 members were announced. The president is Viscount Enomotto, Minister of the Department of Communication, and Mr. R. Shida, who represents the Society of Telegraph-Engineers in Japan, is chairman of the Council.

Electric Connection with Lightships.—According to the *Dover Chronicle*, a Mr. Goodman has been exhibiting at Dover and other places an invention of his for preventing electric cables attached to lightships becoming damaged by fouling the chains when the vessel rides round. We have no particulars of Mr. Goodman's appliance. Meanwhile we have reason to believe that the experiment at the Sunk Lightship under the direction of the Telegraph Construction and Maintenance Company is proving satisfactory.

A New Cable.—We understand that the new cable between Warnemönde and Gjedser will probably be finished next month, and Messrs. Felten and Guillaume have undertaken to have it laid by the middle of September. The laying of the cable will begin on the German side, and probably the large cable steamer of the Great Northern Telegraph, "H. C. Oersted," will be employed for the purpose. The cable will contain four wires, and have a length of 50 kilometres. The cost of laying will be borne by Germany and Denmark in common, and Denmark is to execute all necessary repairs.

The Western Counties Telephone Company at Swansea. The Western Counties and South Wales Telephone Company have with much thoughtfulness and liberality just attached the Swansea and Llanelly Hospitals with all the works, manufactories, and all places of business connected with their telephone system in the neighbourhood free of charge. This company stands alone, we believe, amongst telephone companies in giving free connection to the police station, chief fire brigade station and the general hospital or infirmary, as well as the important charitable institutions of all towns in which it has an exchange.

Swansea.—At a recent meeting of the Swansea Town Council the announcement of the gas company that they intended to raise the price of gas supplied to the public lamps was discussed. In the course of the discussion Mr. Burnie said it was time the Corporation should look round determinedly with the object of seeing if a new method of lighting—elec-

Digitized by Google

tricity, for instance—could not now be introduced. There were electric lighting companies who would guarantee the street lighting for a less sum than that now paid. There was ample margin in £3,770 a year to make it worth their while to consider the question of electricity.

The London Electric Supply Corporation.—The above company has made application to the Board of Trade for a license, under the Acts of 1882 and 1888, to supply electricity in the undermentioned localities, namely, the Greenwich District, the St. Olave District, the St. Saviour's District, the City of London, the Strand District, the parish of St. Martin-in-the-Fields, the parish of St. James's, Westminster, the combined parishes of St. Margaret and St. John, Westminster, the parish of St. George, Hanover-square, the parish of Chelsea, the parish of St. Mary Abbotts, Kensington, the parish of St. Marylebone, the St. Giles District (comprising the parishes of St. Giles-in-the-Fields and St. George, Bloomsbury), and the Holborn District, the districts above-mentioned being taken as defined in the Schedule B appended to the Metropolis Management Act, 1855.

The Telegraph and the Recent Manœuvres.—Sub-Lieutenant H. A. B. Shrubb, the officer in charge of the Intelligence Department on board the "Hercules" during the recent manœuvres, has submitted an interesting report to Sir George Tryon on the telegraphic information received by him as to the movements of the opposing fleets. It appears that 20 letters and 602 telegrams were received by the flagship during the time the B Squadron lay in Berehaven. These came principally from coastguard stations on the coast, signal stations established at Cahermore and Browhead, and from Lloyd's and other local sources. The character of the information received was most satisfactory, only 3 per cent. of the news sent being unimportant. This is highly creditable to the senders, as to most of them the work was entirely a new experience. The value of similar information in the case of war would, of course, be incalculable, but Mr. Shrubb points out that it would also be considerably increased if the various coastguard stations were connected with one another by electric telegraph. A hope is expressed that no time will be lost in carrying out this suggestion.

The Public Lighting at Fleetwood.—A meeting of the ratepayers of Fleetwood was held last week to consider the question of the price charged for gas in the town, and also the best means of improving the public lighting. Mr. T. Seed (chairman of the Improvement Commissioners) presided. The first resolution submitted was to the effect that the price of gas ought to be greatly reduced, which was carried unanimously. A committee was then formed to make inquiries as to the methods of lighting adopted in other places, and the cost thereof, and to report to a subsequent meeting. A communication was read from the Public Streets Lighting Company offering to light the whole of the streets of Fleetwood with petroleum oil lamps, as now in use at East Moulsey and elsewhere. A communication was also read from Messrs. Chamberlain and Hookam (Limited) with reference to the illumination by the electric light at Leamington, and inviting a deputation from Fleetwood to meet them at that place, and gather opinions as to this method of lighting both houses and streets. These communications were left to be dealt with by the committee.

Liverpool Electric Supply Company (Limited).—On Saturday the staff and workmen employed in this company journeyed by saloon and reserved carriages to Blackpool for their annual trip. On arrival various pleasures were indulged in for about three hours, after which the party proceeded to the Derby Hotel, where an excellent dinner awaited them. Dinner being concluded, the secretary, Mr. B. H. Collins, speaking on the continued success of the company's undertakings, said that the public of Liverpool would most probably witness a large extension of electric lighting in their city in a comparatively short period, and both the private and commercial community, he hoped would not be slow in still further adopting this light and source of power now that they are becoming more fully alive to its special advantages. "Success to the Firm and Messrs. Holmes and Vaudrey, the Managing Directors," was proposed by Mr. Collins, seconded by Mr. A. Clough, the foreman, and most heartily received. In the evening the party again met at the hotel, and after a concert arranged among the members was concluded, the company returned to Liverpool, thoroughly pleased with the day's excursion.

St. Thomas, Charterhouse, Boys' School.—The boys of the upper class of this school have again this year achieved some very brilliant results in connection with the recent Science and Art Examinations of South Kensington. The success of these boys is remarkable when it is borne in mind that they had to compete with candidates who, in the majority of cases, were double their age. Some fifty-five boys were presented for examination. Of this number all except one succeeded in passing in one or more subjects, while some of the best passed in eight subjects. Thirty-five first class certificates were obtained. In mathematics twenty nine passed. Forty-five passed in acoustics. The results in magnetism and electricity were equally good considering the difficulty of the questions; only eight failed, and five obtained Advanced Certificates, two of them being of the first class. We may add that recently Dr. Gladstone, F.R.S., in giving evidence before a special committee of the London School Board, submitted the following statement:—"Prof. Silvanus Thompson told me that the only elementary school in London from which the Finsbury College could draw youths qualified for the technical classes was that of St. Thomas, Charterhouse, where a good deal of scientific instruction is given, and the boys are encouraged to make their own apparatus."

Electric Side Lights for Ships.—An excellent practical suggestion arising out of the discussion on the disastrous collision between the two Danish steamers has been made by Mr. J. Kenward, who in *The Times* of Tuesday recommends the use of incandescent lamps of high-candle power for the port and starboard lights. The power of these lamps could be proportioned, as no oil lamps can be, to the penetrating power of the white light overhead; and by this means the red and green lamps would be visible at as great a distance as the topmost light. At present, the statutory range is five miles for the white light, and two miles and a-half for the coloured lights. But owing to the absorption of the coloured lenses, the green light rarely reaches the lowest of these ranges, and the red seldom exceeds it. If all the three triangular lights were of equallised long range, the risk of collision would be reduced by about one-half. As there is no imperative rule of the road at sea for steam vessels approaching each other, and, as their safety rests on the discretion of the commanders, obviously the great object should be to increase the distance at which all three lights can be seen, and consequently the time for exercising this discretion. We are glad to learn from Mr. Kenward that at least one steam line company of high distinction is now preparing to give this plan a trial.

Proposed Electric Lighting at Richmond.—At the meeting of the Richmond Select Vestry, on the 14th inst., the clerk

Digitized by Google

read a letter from the secretary of the Richmond Gas Company (Mr. E. B. Blott), acquainting the Vestry with the resolution come to by the company to reduce the charge for the public lamps from £3. 10s. to £3. 6s. 8d. per lamp per annum, as from the 24th of June last. Notwithstanding this concession, the Vestry on the same occasion referred to the Parliamentary Bills Committee an offer from Mr. R. F. Coles, on behalf of the proposed Richmond Electric Lighting Company (Limited), to the following effect:—"That in consideration of their transferring, or delegating to him, on behalf of the company, the Provisional Order and powers held by the Vestry from the Board of Trade for electric lighting within their area, and giving him any necessary assistance to have their order altered or substituted for similar powers under the new Act, and further guaranteeing him entire co-operation and support in the matter of electric lighting in their district, the company would either pay him a royalty of 1s. per light per annum (street lamps by special contract), or if preferred would undertake to give a fixed sum—say, £150 per annum—for consideration of the transfer. He undertook to satisfy the Vestry as to the *bona fides* of the undertaking; and mentioned that he had orders in hand for some 200 lights, and only desired the sanction of the Vestry before commencing the erection of a central station.

University College, London.—Gilchrist Engineering Scholarships.—An entrance scholarship will be offered at University College, London, in the present month. The value is £35 per annum, tenable during two years, and the competition is limited to those who have not previously been students of the College, and who will not complete their nineteenth year before October 1. Every candidate must declare his intention of taking, at least, the two first years of one of the engineering courses, and the second payments will depend upon his success during the first year and the arrangements he makes for the second year's study. The subject of the examination will be mathematics and any two or more of the following five subjects:—Mechanics, mechanical drawing, an essay on a given subject, French or German, and the use of tools. A senior scholarship of £80 will be awarded at the close of the session. Candidates must have attended college classes in the following subjects during the whole of the session; Applied Mathematics, Physics, Engineering, Engineering Drawing and Geology. The result of the class examinations will decide the obtainment of the scholarship, providing sufficient merit has been shown to justify the award. There are also entrance and other exhibitions and scholarships given at University College for Mathematics, Physics, Chemistry, Classics, German, French, Art, Greek, Hebrew, Jurisprudence and Political Economy, Philosophy of Mind and Logic, English Literature, Medicine, Surgery, Pathology and Physiology.

Lighting of Cowpen.—The action of the Cowpen Local Board in advertising for tenders for lighting the place by electricity does not meet with the approval of the *Blyth Examiner*, in which journal we find some rather interesting remarks, which we quote below. We may, however, first state that the population of Cowpen is a little over 10,000, that it consumes about 8,000,000 cubic feet of gas per annum, there are 130 street lamps, and 450 private consumers, and that the gas mains are 4½ miles in length. The *Blyth Examiner* says:—

"It certainly seems somewhat ridiculous that an unimportant place like Cowpen (part only of the town of Blyth) should place itself alongside of Barnet, Exeter, Southampton, and Taunton, and actually presume to teach all grades of corporations their duty as to electric lighting. If any electric lighting company contemplating tendering for the lighting of Cowpen district will first make a study of the facts and figures we have adduced, they will know more about the prospects of ultimate success with their speculation than they are likely to do from twenty interviews with that wonderful and loquacious individual, the 'Surveyor to the Board.' It is also interesting to notice how electric companies go about establishing themselves in a given locality. They are tolerably old birds now, and not likely to be caught with chaff. But Cowpen Local Board seem to think a company will come upon the ground, run all the risks incident to dealing with a fickle authority having no continuous policy, and forthwith transfer to the place a large amount of costly plant, without requiring a substantial guarantee that the speculation shall ultimately yield a profit to the company. They *may* do so, for nothing seems to be impossible; but if they do, all we can say is—their trifling with their shareholders' funds will be on a par with the Board's trifling with the funds of the ratepayers. We are much mistaken if it is not the general rule that electric companies have ceased to experimentalise merely with a view to payable business in the distant future. Their usual practice now is to require that a local company be formed on the spot. The electric company takes some shares, and the rest of the capital is subscribed locally. Cowpen Local Board has no power to invest in such shares, and we do not think 20 private individuals could be found to do so to any appreciable amount."

Municipal Lighting Statistics.—In a recent issue we gave a list of provincial towns in which the local authorities are at the present moment actively interested in electric lighting. The following tabular statement with regard to the population, ratable value and gas lighting in these places will be of interest to many of our readers:—

	Population.	Ratable Value. £	Gas Capital Invested. In £'s.	Gas consumed. In cubic feet.	Miles of Mains.	No. of Private Consumers.	Public Lamps.

THE SPRAGUE MOTORS AT RICHMOND, Va.

BY ALBION T. SNELL.

A Paper recently read before the American Institute of Electrical Engineers contained some interesting data of the Richmond motors. The undoubted success attained by the engineers of the Sprague Company justifies the writer in examining more closely the peculiarities attributed to these motors. Let it be clear, however, that it is not intended to criticise in a captious spirit what is really a very successful application of electricity to street-car driving. The object is rather by a close examination to see whether there be any marked difference between English and American practice in motor design, and further to appreciate the meaning of such differences if any be found.

Thanks to Mr. Sprague, we are enabled to see some of the points peculiar to the Richmond machines. This gentleman gave in his Paper a series of curves, which purport to illustrate their chief characteristics. These curves are reproduced with a few additions by the writer.

On first examining them the writer asked himself why they were ever published in their present form? As they stand, with the exception of the curve O A, they are purely theoretical. They refer to an imaginary motor of 3·65 ohms running at a constant potential of 400 volts, and having no losses other than that due to ohmic resistance with 10 per cent. increase allowed for heating. Such an assumption can make no proper allowance for material friction, hysteresis, or self-induction. The former cause of loss of energy might perhaps be included by a percentage. But the latter are variable, being both of them small at low outputs, and increasing somewhat irregularly with the load. It is the writer's experience that the losses resulting from hysteresis and self-induction are too large to be neglected, and, moreover, they vary so in different machines and with various loads, that the extent of the error can only be estimated by a brake test. If curves E D C, O F C, and O D G had been plotted from a series of brake tests, the writer believes that very different results would have been obtained.

It probably is Mr. Sprague's opinion that the effects of hysteresis, &c., are included in the curve O A. Let us examine this curve more closely. O A is the external characteristic of the machine, run as a series dynamo on a variable external resistance, at 856 revolutions per minute. This consequently includes the dynamo reactions of the armature, and also the effects of hysteresis; and the characteristic of the machine, run as a motor at the same speed and currents, would probably approximate closely to it. But its significance is lost in the deduced curves III., IV., and V., owing to the uncertainty attached to curve B C. This latter is assumed to be a linear function of the current, and is plotted from $e = E - C R$. This equation is, on the above assumption, only true if the value of R be constant. Since R is necessarily a variable, owing to induction and hysteresis being included in it (in Sprague calculations), an error creeps in, the magnitude of which is uncertain. Now, if brake tests had been made to determine the curves here deduced from I. and II., which are really the fundamental ones, this uncertainty of internal resistance would have been of no moment for practical purposes. Mr. Sprague, however, proceeds to combine I. and II., and thus plots the speed curve of the motor for different currents at a constant potential of 400 volts.

The work curve IV. is next obtained by multiplying the several currents by the corresponding value of e, and dividing by 746. It expresses the work as a function of the current. It will be noted that the effective horse-power of the motor is assumed to be $\frac{Ce}{746}$, and that the curve is quite symmetrical. If brake tests had been made to plot IV., the writer suspects that the dotted curve would more nearly approximate to the actual readings; in fact, the effective horse-power would not only be generally less than that shown, but the divergence from theory would be the more marked as the load increased. Also the maximum work would be given by a current considerably less than that determined by the condition $C = \frac{E}{2R}$, where E is the E.M.F. of supply.

The next important curve, V., expresses the work as a function of the speed. This should also have been plotted from brake tests. Its real form would then be somewhat like the dotted curve 5, in which the values of the ordinates (speed) are less for a given current than in the published curve. This is principally due to a certain quantity of energy being absorbed by hysteresis in the armature, and also by induction in both armature and field. The chief effect is seen in the increase of current required for a given output over that determined by the calculations used in the Sprague curves.

The remaining curves need no special reference. They are based on the effective horse-power being equal to $\frac{Ce}{746}$, and hence stand or fall by the others. The tractive effort expressed as a function of the speed in curve K L and in terms of the current in O H is instructive, and subject to the corrections indicated is of considerable use. The so-called car curves serve to give a rough idea of the efficiency of the motor at different speeds. The value of a (constant for each part of the work and speed curve) diminishes in value as the efficiency increases. The current required at each point can be read direct from the abscissæ by reference to the speed and current curve when the value of n is determined. There is one curve omitted. That is the efficiency curve or ratio of B.H.P. to E.H.P. The theoretical efficiency $\frac{Ce}{CE}$ can, of course, be obtained by inspection from the published curves.* But it would be more satisfactory to see a curve plotted from brake tests. It would be found to be somewhat as shown by the dotted lines in curve 6. The efficiency would be zero till a value of c was reached sufficiently large to overcome the static friction of the motor it would increase rapidly with the load, and attain a maximum somewhere about 25 amperes, and not with zero current as shown in the Sprague curve.

It is more convenient, however, to refer the efficiency to the speed of the motor. Brake tests are taken, and speeds plotted as abscissæ, and E.H.P. as ordinates. Curve E E then gives E.H.P. as a function of the speed. Taking B.H.P for ordinates, and using the same abscissæ, O e is traced. This expresses B.H.P. in terms of speed. The ordinates of O e are then divided by ordinates of E E, and plotted to any convenient scale. The resulting curve O F F gives us $\frac{\text{B.H.P.}}{\text{E.H.P.}}$ as the true commercial efficiency. It must be noted that the maximum of the B.H.P. curve and the efficiency curve do not coincide with the same speed. They do so, however, if the horse-power be taken as C e. Mr. Sprague has done this. Hence his output is a maximum with 50 per cent. efficiency, while really the output for 50 per cent. efficiency is less.

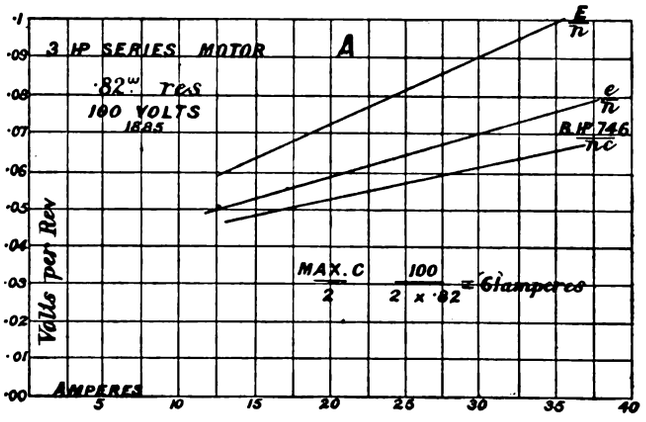
The following curves based on brake tests of various series-wound motors will serve to show some reasons for the writer's criticisms, and will support his objections to Mr. Sprague's treatment of the subject.

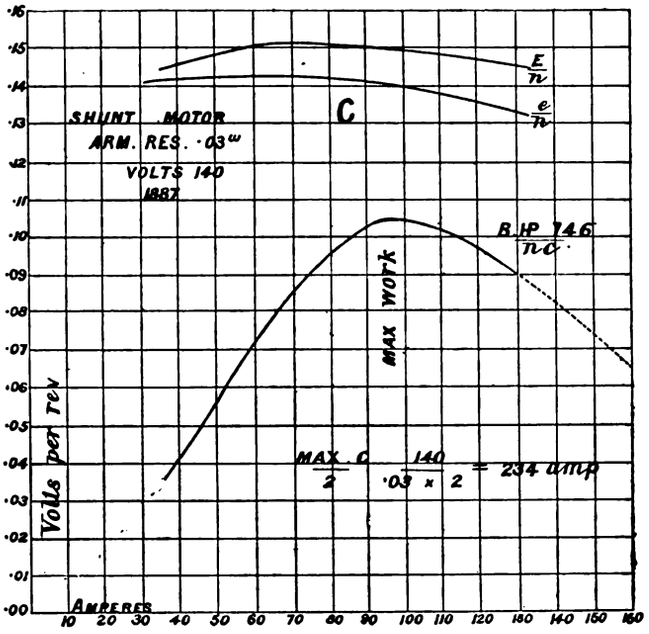
It will be noted that each diagram contains three curves, severally denoted by $\frac{E}{n}$, $\frac{e}{n}$ and $\frac{\text{B.H.P.}\ 746}{nc}$. In all of them the symbols have the same meaning. E = the terminal E.M.F.; e = the theoretical back E.M.F. found from equation $e = E - CR$, where R is the ohmic resistance of the motor measured hot; n = the number of revolutions per minute; and C = the current in amperes. The two first speak for themselves; they severally represent the number of volts required to perform certain work during one revolution. The last quantity $\frac{\text{B.H.P.}\ 746}{nc}$ is of the same order—viz., a definite number of volts absorbed per revolution in actual work on the brake. Note that the measured B.H.P. multiplied by 746 gives the available useful horse-power in watts—that is, a quantity that can be

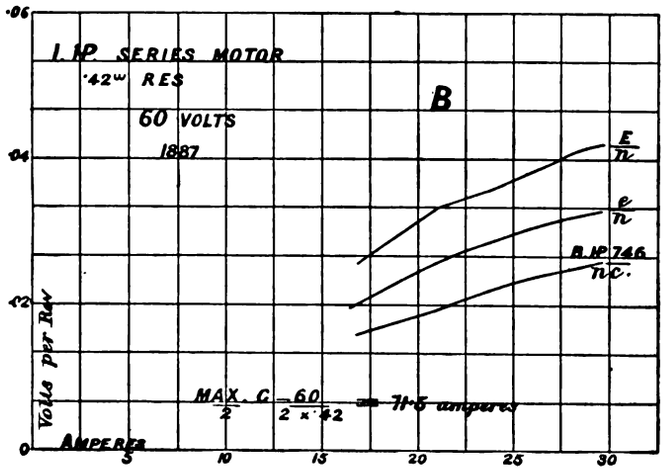
* If the ordinates of II. be divided by four, the theoretical efficiency $\frac{e}{E}$ is given as a percentage for corresponding currents.

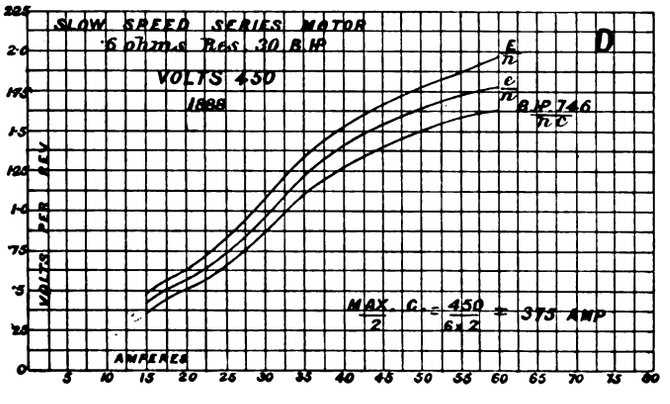
Digitized by Google

Diagrams A, B, C and D are traced from brake tests of motors by three of the principal English manufacturers. They show graphically the large amount of energy lost by causes other than simple ohmic resistance. And, further, it will be noticed that this *extra* loss increases with the load. This is shown by $\frac{e}{n}$ and $\frac{\text{B.H.-P.}\ 746}{nc}$ not being parallel. The motors have not been selected on account of their high efficiency, but rather to illustrate the progress of motor design between the years 1885 and 1888. Each machine is fairly representative of the year of its construction. The writer desires to draw particular attention to the gradual reduction of ohmic resistance, and the consequent decrease of current for maximum output.









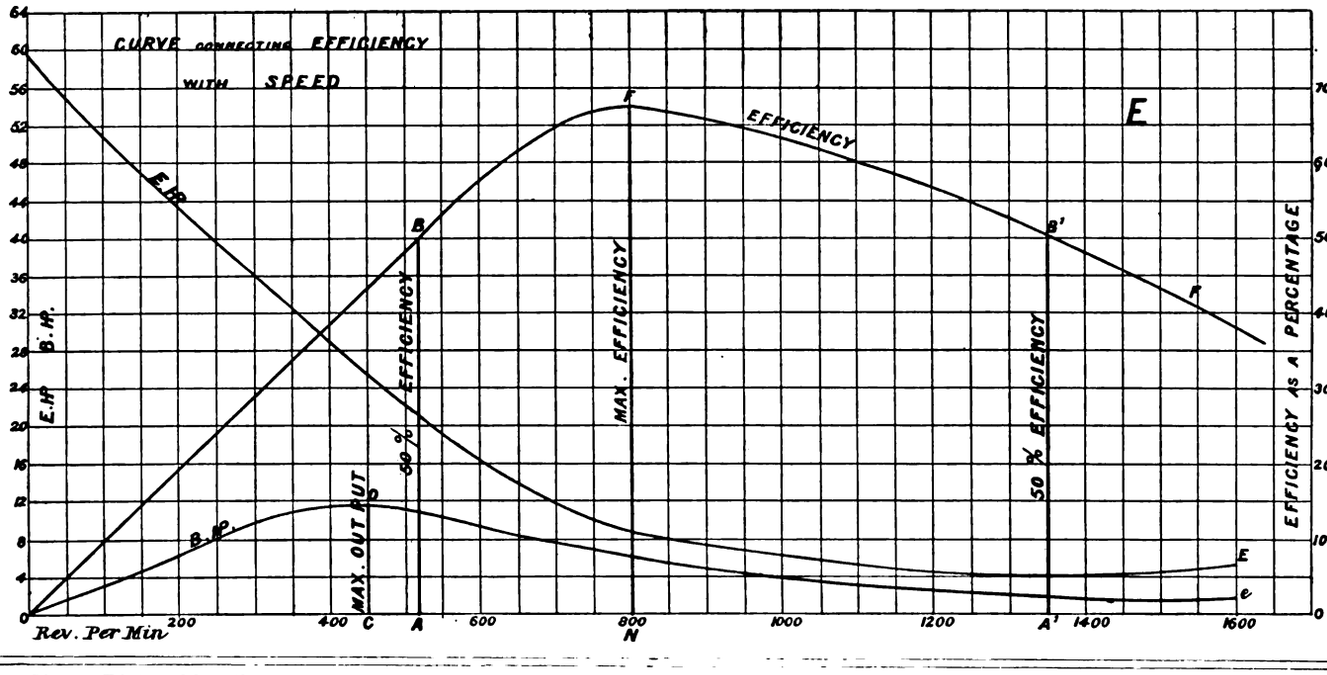


Diagram E is traced from the Sprague curves, with the B.H.-P. readings corrected as indicated by the writer. Curve E E is simply the values of the E.H.-P. for the different speeds. O e is an approximation to the corresponding B.H.-P, and O F F is the commercial efficiency. It will be noted that the efficiency increases at first with the speed, and, after attaining a maximum at 800 revolutions, slowly decreases, passing through two points of 50 per cent. efficiency. The first 50 per cent. is given at a speed of about 500 revolutions; the second at 1,350, approximately. Neither of these correspond with the maximum output, which is given at 450 revolutions. If the internal resistance were lower, the curve would reach its maximum more rapidly and approach the second 50 per cent. reading more slowly. That is, the distance between B and F would be less, and that between F and B' considerably increased. This would give a large range of work with a small variation of efficiency—one of the main considerations in motor design. On reference to the Sprague curves, it will be seen that the maximum output is assumed to be at 400 revolutions and 50 per cent. efficiency (the first one on Diagram E), and the efficiency to vary according to curve II.

-CURVES ILLUSTRATING ELECTRIC RAILWAY MOTOR CHARACTERISTICS.

The dotted curves 3, 4, and 5 are rough approximations to what would be obtained by brake tests. They severally refer to the Sprague curves III., IV., and V. Curve 6 is intended to show the order of the efficiency curve plotted as a function of the current.

expressed by the symbol C E. We know the current flowing for any load, but do not know the exact fraction of the applied E.M.F. usefully employed in external work. But if we divide the B H.P. expressed in watts by the known currents, the value of the unknown volts, e, is given. This quantity divided by n is plotted in the lowest curve. The efficiency is given by dividing the lowest ordinates by the value $\frac{E}{n}$ for the same currents.

The quantities are divided by n simply because it is practically difficult to make a test with constant values of n. Since n is nearly proportional to e, and is the same for the three ordinates corresponding to each value of c, no error of importance is introduced.

Indeed, very regular curves can be plotted from a series of tests giving large variations of n.

These curves show on inspection two things of great importance when considering the design of a motor. The height of

Digitized by Google

the ordinate between $\frac{E}{n}$ and $\frac{e}{n}$ shows the E.M.F. lost over the ohmic resistance of the machine; that between $\frac{e}{n}$ and the lowest curve shows the E.M.F. lost from all other causes, viz., material and magnetic friction, and by induction. These three curves give at a glance the value of the motor as a converter of energy, and they show not only where the losses occur, but they give the magnitudes.

Mr. Sprague has assumed that $\frac{e}{n} = \frac{\text{B.H.P. } 746}{n\,c}$ in his curves. In judging for himself of the value of such an assumption the reader is reminded that the difference in value between $\frac{e}{n}$ and $\frac{\text{B.H.P. } 746}{n\,c}$ will tend to increase largely as the current is raised (*see* diagrams A, B and D). This is due to the resulting intense magnetic field and the consequent errors from abnormal values of Foucault currents, hysteresis, induction, and variation of lead. The possible values of current in motors of English design are shown by the figures in the diagrams. The truth of these statements will be apparent to engineers accustomed to motor work.

It may be noted that in plotting these curves for shunt-wound motors it is necessary to run at a constant potential. This precaution is necessary since the field strength does not vary directly with that of the armature, but is simply proportional to the terminal E.M.F. A diagram, C, is given to show the order of these curves when plotted from a shunt-motor test. The large variation of efficiency for different loads and the point of maximum conversion are well marked.

Having thus given some general reasons for not accepting any but brake tests as criteria of the performance of an electric motor, it is proposed to examine some of the peculiarities of the Richmond type.

The writer first notes the high ohmic resistance. 3·65 ohms hot, for a series motor running with 400 volts and at speed varying between 400 and 1,400 revolutions per minute, is a very high resistance. English practice would reduce this to something like ·65 ohm. The gain would be obvious, the area enclosed between $\frac{e}{n}$ and $\frac{E}{n}$ would be reduced to about one-sixth; this means the heat-waste would be reduced by over 80 per cent. The self-induction of the armature would also probably be less. All of these mean a higher all round efficiency.

The evil effects of this high internal resistance are seen in the characteristic O A, which shows signs of drooping even with 25 amperes, or about one-half the current required to give the maximum work the motor is designed for. The writer believes that Mr. Sprague uses no external resistance for starting the motor. This may be the reason of the high ohmic value.

The English practice is to use a temporary resistance for starting and to run on a minimum motor resistance when under weigh. This economises power, for the loss is a maximum only when starting, and there is no continual heavy waste of power as must obtain with the Richmond motor if designed in this manner.

The writer is next astonished at finding the motor designed to give its greatest output at half the maximum current. One sees in all the text books the statement that a motor gives its maximum output with a value of $\frac{E}{2}$ for its back E.M.F. Now, as a mathematical illustration of an easy application of the calculus this is interesting; but even if it were true in practice the mere fact of the heat-waste being equal to the useful output should prevent one from designing a motor to work at this point. Take the Richmond motor, at half maximum current the speed is 400 revolutions, and the assumed effective horse-power is 14·65, and *the heat-waste is also 14·65 horse-power*. How long would the motor run with such a furnace at work inside it? And note the car speed for this current is about three miles per hour, and so this must occur frequently. Well, the writer cannot explain this, for the actual total losses would be far more, and the efficiency correspondingly less, if the value of $\frac{\text{B.H.P. } 746}{n\,c}$ were known.

In ordinary English practice a motor absorbing 50 amperes and say 100 volts, and running an eight-ton car at about three miles per hour, would have an internal resistance of some ·25 ohms. The waste heat would be some ·84 horse-power. The same motor would be designed to give a maximum output at about 200 volts and 100 amperes, the heat-waste then being approximately 3·35 horse-power, the speed about three miles per hour, and the efficiency some 60 per cent. But the makers would never think of running the motor at half the maximum current for the sake of getting maximum output. With this motor the $\frac{\text{max. C}}{2} = 400$ amperes. Indeed, the writer has made hundreds of brake tests of motors of all sizes between one-man power and 100 horse-power, but has never found it safe to push the load to this point. In fact, motors are so designed on this side of the Atlantic that at half the maximum current the safe working load would be far exceeded.

Exception must also be taken to the statement that "no matter how the field may be changed, the speed of the motor at 50 per cent. efficiency is a constant." This is true on the assumption that $\frac{e}{E}$ gives the efficiency; but a brake test would give very large variations of speed for a ratio of $\frac{\text{B.H.P.}}{\text{E.H.P.}} = ·5$ when the field windings are altered.

The writer is tempted to leave the simple question of motor design and consider the gearing of the Richmond cars. Here great ingenuity is displayed, and a sound mechanical method is employed which combines the advantages of a positive gear with the flexibility of a friction clutch or belt. In fact, the mechanical work seems to be better than the electrical.

If the Sprague motors, as exemplified by the Richmond curves, are fairly representative of the American machine, it would appear that the English electrical engineer has not much to fear in the matter of competition. The Richmond motor, indeed, seems to compare hardly favourably with the 1885 type of English manufacture, and it cannot be said to be on a level with the best home practice of the current year (judging from Mr. Sprague's Paper and curves). The writer, however, thinks that, in all probability, the success attained at Richmond is due to a better motor than the one selected for the curves.

However, be this as it may, it must be granted that commercially electrical engineering in America is far more advanced than in England. It will be profitable to ask why this is so, since in motor design we are apparently far ahead of the American engineer. The reasons are various, and not far to seek. England is an old-established country, with large vested interests, and necessarily a conservative spirit, not disposed to changes of any kind. Repressive legislation has also told its tale. Reckless speculation and often gross incompetency have further hindered the commercial progress of electricity. But practically great advances have been made in all departments. In America the case is very different. The general spirit is more liberal, and new things are readily tried, for novelty always tells. Moreover, success is judged on broad lines rather than details. There seems to be further a spirit of enterprise in America which is wanting in the old country. It is such a spirit that led to the Richmond tram line and gives America another *biggest thing*—this time in electric tramways.

CENTRAL INSTITUTE FOR TECHNICAL EDUCATION.—The Session of the Central Institution of the City and Guilds of London Institute will commence on October 2nd. The Clothworkers', Siemens', Mitchell, and Institutes' Scholarships will be competed for at an examination held on September 25th to 28th. We may remind our readers that the courses of instruction include lectures on Mathematics, Engineering, Chemistry, and Physics, and laboratory and workshop practice.

NOTICE OF REMOVAL.—Messrs. Thompson and Rew notify that on and after 1st Sept. their offices will be at 7, Westminster-chambers, Victoria-street, London, S.W.

ELECTRIC TRANSMISSION OF POWER FOR A WIRE-ROPE RAILWAY.

A correspondent of the *Daily News*, writing from Lucerne, gives an interesting account of a wire-rope railway or tramway line on the side of the Burgenstock, for which electric plant is employed to transmit energy from a waterfall three miles away to the hauling station at the upper end of the line. We have taken the liberty of slightly editing the technical details, but the article runs substantially as follows :—

"An electric mountain railway—the first of its kind—has recently been opened to the public at the Burgenstock, near Lucerne. The fact is interesting to tourists, because it opens up a charming mountain resort hitherto somewhat inconveniently approached, and it is important to electricians and engineers because of the novelty and skill which have entered into its accomplishment, and because of the extraordinary difficulties which have been surmounted. Hitherto it has been considered impossible to construct a funicular mountain railway with a curve, but the new line up the Burgenstock has achieved that feat under the superintendence of Mr. Abt, the Swiss electrical engineer. The rails, in fact, describe one grand curve formed upon an angle of 112 degrees, and, by an arrangement of wheels for the cars known as the 'System Abt' the journey is made as steadily and smoothly as upon any of the straight funiculars previously constructed. The Burgenstock being almost perpendicular, it would have been impossible to construct a railway upon the old plan. A bed has been cut for the most part out of the solid rock in the mountain side from the shore of the Lake of Lucerne to the height of the Burgenstock—1,330 feet above its level, and 2,860 feet above the level of the sea. The total length of the line is 938 metres, and it commences with a gradient of 32 per cent., which is increased to 58 per cent. after the first 400 metres, and this is maintained for the rest of the journey. A single pair of rails is used throughout, with the exception of a few yards at half distance to permit the two cars to pass. Through the opposition of the Swiss Government each car is at the present time only allowed to run the half-distance, and they insist upon the passengers changing, in order, as they say, to avoid collision or accident. I have made a number of journeys up and down the mountain in company with an engineer, and the experience is sufficient to prove that the prohibition is altogether unnecessary. A committee of Swiss, German, and French engineers have also examined the line, and state that each car could run the whole length without fear of accident. With the safeguards and precautions employed it appears to be well nigh impossible for the cars to meet at the passing point of the double rails.

"The current is generated by two dynamos, each of 25 horse-power, which are worked by a water-wheel of 125 horse-power, erected upon the River Aar at its mouth at Buochs, three miles away. The current is conducted by means of insulated copper wires to a pair of electric motors, of the same power, which are placed at the head of the railway. The loss of energy in transmission is estimated at 25 per cent. The motors are connected by leather belting with two large pulleys on a countershaft, which is connected with a set of movable conical cogs, from which the big wheel over which the wire-rope passes is driven. To give the rope adhesion it is wrapped under and over two smaller pulleys, and then for a second time over the larger wheel. The arrangements for applying the power are of the simplest character. Only one man is required to manage the train, and the movement of the cars is completely under his control. One dynamo is sufficient to perform the work of hauling up and letting down the cars containing fifty or sixty persons. With a switch the conductor regulates the amount of current according to his requirements. He communicates by electric signals with the man at the water-wheel when the cars are about to commence their journey, and the latter in turn regulates the water-power applied. A finger moving along a figured disc before him by means of a millimetre screw at the rate of a millimetre to every metre of the railway, enables him to see the exact position of the cars on the line at any given moment of the journey, and he can increase or slacken speed accordingly. In addition to this the cars themselves give him a signal at stated points. For instance, at a distance of one metre and fifteen metres respectively after the car leaves either the upper or the lower station, the flanges of the wheels pass over an electric plate, and a bell is rung in the machine room. The same signs are given when they arrive within fifteen metres and one metre of the half distance, so that the cars are themselves their own signalmen, and the driver knows exactly when to shut off power. At the end of the journey, completed in about fifteen minutes, at an ordinary walking speed, the car moves gently against a spring buffer, and is locked by a lever, without noise and without jolting the passengers.

"The precautions for safety are complete. In the first place it is well nigh a physical impossibility for the cars to collide at the passing point. In that part where the double line is laid for this purpose the two outside rails are direct, the inner rails 'broken' and guarded. The wheels on one side of each car have a double flange fitting the rail closely ; on the other side they are merely broad drums, which pass easily over the crossing ; and as there are no facing or other points, it is impossible for either car to move forward to the wrong set of rails. Then suppose the wire rope were to break, the car would simply stop dead. A double set of teeth are fixed in the middle of the track, and over them moves a cog-wheel running beneath the car. As soon as the tension of the rope ceases, a pair of steel bands fall upon the outer rim of the wheel, and hold it firmly there. The guard has a break lever, which he can instantly drop with similar effect. At the same time a steel 'anchor' moves forward underneath the two sets of teeth, and as the levers drop, the two 'arms' spring up and clench the car firmly to the rails from below. In such a contingency the passengers could easily step down and regain either the summit or the lower level by a flight of 3,000 steps built up the inner side of the track.

"This interesting undertaking has been carried out at a cost of £25,000. The water wheel is also employed to light the whole of the hotel buildings and its grounds by electricity, and when the railway is not working, another dynamo pumps up spring water a thousand feet for use in the establishment. To tourists the new railway will be the means of opening up the delightful views from the summit of the Burgenstock, which can be reached in half an hour's walk from its upper station."

From a rather obscure sentence which we have omitted above we gather that the motors derive their current from a set of accumulators at the station and not directly from the dynamos. This arrangement would probably be adopted not only for the sake of economy in the mains but also to avoid the possibility of accident arising from an interruption of the charging circuit.

TELEPHONE SYSTEMS OF LONDON, MANCHESTER AND GLASGOW.

The following article appeared in the *Financial News* of the 27th instant :—

"Agreeably to your request I have examined the various systems of telephonic communication in use in England and Scotland. I have treated the three great representative centres, viz., London, Manchester and district, and Glasgow and district, separately, and compared them with each other. I have looked at the subject from a technical point of view ; but, as far as possible, treated it in popular language, the intention being that your readers should be enabled to judge of the relative merits of the companies concerned, viz., the United, the Lancashire and Cheshire, and the National, and of their management.

"Beginning in the north, I examined first the National Company's system. This company has now in Glasgow 1,570 subscribers. The wires converge into six central exchanges, which are connected with each other by means of from eight to 25 junction wires. The wires are entirely silicium bronze of No. 18 gauge. This wire weighs only 35lb. to the mile against 220lb. per mile in the case of the old Post Office wires and the telephone wires commonly seen in London. The wire has the peculiar quality of returning to its normal position immediately after the snow or frost has melted off, and it contracts or expands but slightly through the action of cold or heat. Being very thin, it collects little snow, and owing to its lightness can, if broken, do little or no damage in falling. The wires are carried over the housetops by means of iron poles which rest in sockets on the roofs, and are supported by stays of twisted galvanised wire. On the principal routes five iron poles, with arms stretching across, after the pattern of a gridiron, are used. Thirty-two wires are fixed on each cross-bar, so that the five iron poles carry nearly 1,000 wires. As the distance from the exchange increases, and the number of wires becomes less, the poles are reduced to two, with 30 cross-arms carrying 10 wires each. Further on still, a single pole with 20 cross-arms carries upwards of 100 wires. The wires are attached to the arms by means of single porcelain insulators, and every joint is soldered. The use of these insulators and the soldering of the joints is of much value in producing good talking. In this connection it may be mentioned that every earth connection is also taken, regardless of distance, to the nearest water pipe and there soldered. The intercommunication, or 'switching,' is accomplished in the central offices by means of the so-called 'multiple' board system.

"Your readers are no doubt aware that a certain number of subscribers in every telephonic exchange is allocated to each of the operators in the central offices. The wires of these subscribers are all collected upon 'table,' by which means they are grouped under the control of this operator. The advantage of the 'multiple' board system is that while under the old plan great difficulty was found in practice in joining wires from table to table—that is to say, connecting with each other the groups worked by the various

Digitized by Google

operators—under the new plan each wire has a connecting wire to each other wire on each table. It is difficult to convey on paper a clear idea of how this is done. The plan, though effective, is very costly, a multiple board capable of carrying 2,000 subscribers' wires requiring 400,000ft. of these connecting wires. Great quickness in service results, however, as every operator has under direct control a branch wire to the wire of every other subscriber in the central exchange. All the ringing from the exchange is accomplished by means of magneto-electric generators worked by a small turbine, the power for which is got from the ordinary water mains. Each operator has a key or switch connected with this ringing apparatus, and can thus use the currents at will upon any line required. One operator is found to be able to attend in Glasgow to about 60 subscribers. As regards the subscribers' end of the wire, each subscriber is provided with a magneto ringing apparatus for the purpose of attracting the attention of the operator. The old and costly system of ringing by means of batteries has been entirely discarded.

"There is no special contrivance in Glasgow by which a subscriber can notify to the operator that his conversation is at an end. In Dundee the company has adopted a sytem which enables every subscriber to put himself at once—even, say, in the middle of a conversation with another subscriber—in communication with the central office. This system works well, and has been of great benefit in promoting quick service. The vexatious delays which occur when, as is too often the case, a conversation is interrupted by the central office under the impression that the interview is over, are impossible under this system. No telephonic system can be considered complete unless it embraces some contrivance for this purpose.

"Overhead cables are little used in Glasgow. In this respect Manchester, as will be seen later on, is ahead. The whole of the National Company's system, even down to the smallest exchange in a country town, is open all the year round, night and day. Glasgow is connected by means of trunk lines with all the neighbouring towns of any importance; indeed, all the principal towns in Scotland can either now or will be able very shortly to communicate by telephone with each other.

"The Manchester telephonic exchange system differs in many ways from that of Glasgow. There are 1,350 subscribers, and the whole of their wires have been concentrated in one central exchange. The wires, which are hard-drawn copper of No. 18 gauge, are carried over the housetops by means of wooden standards, with two poles and 10 cross-arms, each supporting 15 wires. On the routes requiring fewer wires single wooden poles, with 10 wooden arms carrying eight wires each, are used. Single and double shackles insulate the wires. Glover's anti-induction 20-wire cable plays an important part in the outside wiring, and is found to be very successful. Along one route there is one of these lead-covered 20-wire cables one mile in length, the induction on which is said to be imperceptible. Several hundred wires are carried in this manner in many directions from the central exchange. Your readers are no doubt aware that it is owing to 'induction' that one subscriber can overhear the conversations of another. Hence the importance of avoiding it in telephone work.

"The multiple board has been introduced in Manchester with good results. The ringing from the exchange is accomplished both by means of magneto-electric machines driven by water power and also by means of batteries. A most convenient test-board receives all the wires as they come in from the roof. It is arranged so that by inserting a small plug the wire is disconnected either on entering or leaving the test-board. By this means all the wires can be at once tested, and if not found to be in working order they can be repaired, it may be before the subscriber has discovered the fault. All the neighbouring towns of Lancashire and Cheshire are connected to Manchester by means of trunk lines. A special charge is made for each conversation on these trunk lines, and monthly accounts for these charges are rendered to each subscriber. In order to prevent disputes the particulars of these connections are written on a slip of paper, and this slip is placed in a small machine, which stamps on it the date and the time to a minute. Three operators attend to 200 subscribers.

"A special feature of the Cheshire Company's system is the use of what are called 'polarised indicators.' I can only hope to explain the effect of these to your readers, an idea of the mechanism not being easily conveyed. To attract the attention of the central office each subscriber has a battery of four cells, which is put in action by one of two push buttons—the one white and the other black. The white button sends a current which calls the attention of the operator in the usual way, thus notifying that the subscriber desires to be connected with some other subscriber. The operator having placed him in communication and his conversation being over, by means of the black button he is enabled to notify that the conversation is at an end, and in any case to make it clear in the central office that it is to them, if to anyone, he desires to speak. In other words, he has a similar advantage in this respect to the National Company's subscribers in Dundee. But this is gained at greater expense to the company, as the apparatus and accessories are costly and liable to get out of order.

"It now remains to consider the London system, where there are now upwards of 4,800 subscribers to the United Telephone Company's exchanges. The wires are concentrated into some 20 different centres, about half of which have between 100 to 600 subscribers each, the rest having a smaller number. The largest exchange is in Coleman-street, where there are about 500 wires. Hard-drawn copper wires are now being used on new work, but the bulk of the work has been done with steel wire of No. 8 gauge, and where the largest number of wires converge they are attached to massive angle-iron tower-shaped fixtures by means of single shackles. From each corner of these fixtures two sets of upwards of 50 wires each are led off in opposite directions. Thus each of these important fixtures is designed to carry only about 400 wires. The main routes are conducted over the housetops by means of single iron poles, each having twisted wire stays to support it. The wires are arranged in one row, say, of 20 to 30 wires, reaching in a line from top to bottom of the poles, and are attached by clips and double shackles. Overhead cables are very much used, upwards of 25 of these leading away from the central City exchange. In three or more of the principal centrals multiple boards have been introduced; but in all the rest the original single-wire system remains. This, of course, entails delay, and is the cause of many of the instances of bad service which occur. The exchanges have hitherto been closed at nights and on Sundays, and are now only open in part for a continuous service. The subscribers to the London system use the original form of electrical ringing apparatus, operated by a battery—there is no separate arrangement for ringing off or calling the central office, and, in fact, no improvement of any kind has been introduced in this connection since the beginning. There has hitherto been no system of public call offices, and, with the exception of Brighton and Tilbury, no towns are connected to London by telephone. The Tilbury wire is practically disused, and the Brighton wire has been so inefficient as to lead to no practical benefit. As regards trunk wires, in fact, London may be said to be quite isolated.

"Having thus described shortly the representative centres of British telephony, and stated the plain facts in each case, let me make a short comparison of the results obtained by the companies. The question first of all arises, is it wise to concentrate all your wires into one central, as in Mancheater, or to have many exchanges, as in Glasgow and London? Under existing circumstances, and unless some better system of interswitching between exchanges can be introduced, Manchester takes the lead. It must be admitted that the expense of concentrating is very great; but still, in telephony it is pre-eminently the case that the best service, although costly, is the one that will eventually pay the best. Then as to the wires; Glasgow and Manchester undoubtedly lead the way with silicium bronze and hard-drawn copper wires of a small gauge, which are better conductors, last longer, aed exert only one-sixth of the strain resulting from the old-fashioned steel or iron wires so much in use in London. The next point is the fixtures on which the wires are carried. London again is found behindhand, for while Glasgow and Manchester carry from 100 to 300 wires on each main route, London, *with practically, as regards way-leaves, the same outlay, carries only 20 to 30.* The large angle-iron central standards in London are undoubtedly substantial, and even artistic in design, but quite unsuited for the purpose, while the only parts of the structures themselves which could conveniently and economically be used for carrying wires, viz., the flat sides, are not made use of at all!

"In the manner of the attachment of the wires to the fixtures Glasgow stands first. Single insulators, as there invariably used, have eight times the insulation resistance of the double shackle of Manchester and London, and correspondingly good talking power. In cables Glasgow is left behind.

"Descending to the switching rooms, Glasgow and Manchester are on a level footing, whilst London is just awakening to the fact that improvements upon original types exist. Manchester and Glasgow have long had an all-night and Sunday service, while London has only just begun to follow them in this. With regard to the ringing-up systems with which subscribers are provided, undoubtedly the magneto system of Glasgow is the cheapest and most efficient. Still Manchester, with the white and black buttons, has a great advantage. The London electrical ringing system is at once the most expensive and the least efficient, and has not even the redeeming feature of a special ring-off system as in Manchester. In the matter of trunk lines, Glasgow and Manchester have been at work in earnest, while London has done in effect nothing.

"With regard to the practical working it may be stated generally that London is not to be compared with the others. The causes of the delays, the induction or leakage, and the continual disconnection during conversation, which render the telephone in London comparatively useless, are to be found in the defects of the system, which, as I have shown, is in every point inferior to that in other centres."

„ Aden, Borneo, Ceylon, China, India, Japan, Java, Labuan, Mozambique, New Caledonia, Persia, Philippine Islands, Siam, Transvaal, and Zanzibar	7 6	... 14 6	... 28 0
The rates for the United Kingdom remain as follows :—	5 0	... 10 0	... 19 6

TO ADVERTISERS.

"The Electrician" offers exceptional advantages to Advertisers. **It has the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application to this office.

Advertisements intended for the current issue must be handed in not later than 4 p.m. on Thursday.

TECHNICAL PRINTING.

"The Electrician" Printing and Publishing Company (Limited) *beg to inform Electricians and Electric Light Engineers that they make a specialty of Technical Printing, and have a Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electrical Catalogues and Electro-Technical Literature generally.*

The Electricians' Directory.

Royal 8vo. Cloth Boards, 3s. 6d. Boards, 3s.

At the end of December in each year is issued The Electricians' Directory and Handbook. *The Directory was established in 1888, and has now attained considerable proportions. Every care is taken to make the names and addresses of all persons engaged in the Electrical Industries absolutely accurate. Useful Tables and Electrical Formulæ are given, together with popularly-written Biographical Notices of the leading Electricians, accompanied in many cases by Portraits.*

THE DIRECTORY FOR 1889 IS IN PREPARATION.

THE BRITISH ASSOCIATION AT BATH: 1864 and 1888.

Although the British Association is now in its fifty-eighth year, only one of the annual gatherings has previously been held in the city which will give it a welcome reception next week. This circumstance is perhaps not surprising, for notwithstanding the claims which the ancient City of Bath may have on account of its antiquity, its historic interest, its famous though somewhat faded renown as a health resort, and its pretensions to the title of the English Florence, its attractions appeal to the fashionable rather than to the scientific world. Nevertheless, the forthcoming meeting promises to be one of some importance; and certainly there will be no shortcomings on the part of the local authorities and principal inhabitants to make it an interesting and enjoyable one; whilst the proximity of such places as Bristol, Cardiff, Chepstow, the Severn Tunnel, representing industry and mechanical enterprise; and of Tintern, Salisbury and Glastonbury, to say nothing of the Abbey Church at Bath itself, as examples of architectural splendour, will provide ample food for the miscellaneous excursionists.

We have already informed our readers as to the probable features of interest in the scientific Papers to be read at the meeting. But these Papers will derive some of their importance, over and above their intrinsic merits, from the evidence they will disclose of the progress which has been made in the

Digitized by Google

subjects of which they treat since the Association last visited Bath, twenty-four years ago. At the meeting of 1864, Sir CHARLES LYELL was the President, his address being appropriately occupied with the "Origin of Hot Springs and the Metamorphism of Sedimentary Rocks." But amongst the Papers in Section A we find several relating to matters of more immediate interest to our readers. Prof. FLEEMING JENKIN read a Paper "On the Retardation of Electrical Signals on Land Lines," a subject which was then little understood, and which has quite recently received much attention both from the theoretical and the practical sides. Submarine telegraphy being then in its infancy, several Papers were devoted directly or indirectly to that subject, amongst which we notice one by Captain SELWYN and another by WILLIAM FAIRBAIRN. Prof. JENKIN described an Electrical Resistance Balance of Prof. W. THOMSON, who a year later was knighted for his services in connection with the first wholly successful Atlantic cable. This is the instrument now well known under the name of the Thomson Bridge, and which is of such great value for the measurement of small resistances. Mr. J. B. THOMPSON submitted a contribution to the Mechanical Theory and Application of the Laws of Magnetic Induction and Electricity. A description of a Cheap Form of Automatic Regulator for the Electric Light was given by Mr. SAMUEL HIGHLEY; and Prof. W. B. ROGERS explained an invention by Mr. CORNELIUS, of Philadelphia, for Lighting Gas by Electricity.

Meagre as is the above list compared with what we are now accustomed to, some of the items are worth recalling even to-day. Mr. J. B. THOMPSON'S induction machine, which he exhibited at the meeting, was one of this kind. It was described briefly as follows:—"The chief points of novelty appear to be that it is self-acting; the current of voltaic electricity which produces the induced current also drives the machine; the machine can be so adjusted that the quantity and intensity of the induced current shall range from that of ten Daniell cells to that of 1,000, and this without employing more than three or four cells. . . . . In this machine it [the current] is apparently a continuous flow, and no spark will jump from one electrode to the other, unless first brought in contact, as in batteries. The construction of the machine is simple, and will not easily be worn out. When modified for electro-plating it is much more efficient than the ordinary battery; for although it deposits the metal more slowly on any one article, yet it deposits it much more firmly and with a better surface than the ordinary battery does, and it will deposit the same quantity on a thousand articles at once, which enables it to deposit ten times more metal in the same time than its own exciting battery would do."

It is perhaps a little doubtful whether the machine was ever actually employed for electro-deposition on so large a scale as is here indicated, or whether it would in that case have answered all the expectations of the inventor. The machine apparently belonged to the class now known as "motor-generators" or "dynamotors," and it would be very interesting to know the details of its construction and whether it is still in existence.

Prof. FLEEMING JENKIN'S Paper is also of great interest. He gives a curve showing the logarithmic growth of the current in a circuit; but he puts the equation to the curve in terms of the capacity of the circuit, whilst we should now use the inductance. Prof. JENKIN employs some experimental results of M. GUILLEMIN to determine the electro-static capacity per foot of the wire on which the experiments were made, and found it to be nearly three times greater than that indicated by theory, neglecting leakage and induction. He finally arrives at the conclusion that the speed of WHEATSTONE'S automatic transmitter will be limited to 120 words per minute at a distance of 530 miles; but that the limit may be extended by employing larger wires, fewer posts, and a better form of insulator. Everyone now knows that this speed has been greatly surpassed, not, however, by increasing the size of the wire nor even so much by improved insulation, but by the substitution of a non-magnetic metal for the iron wire which was at that time solely employed.

The only other feature at the Bath meeting in 1864 deserving mention here is a Report of the Committee on Standards of Electrical Resistance, confirming some of the conclusions submitted in their report of the previous year. The absolute electro-magnetic system of measurement had been adopted and expounded the year previous, and the committee were at this time engaged in settling the practical standards of measurement. But although the work was not yet complete, they had arrived at the conclusion that the principal standard of resistance should be made of platinum-silver alloy. The best metal for reproducing practical standards was still under discussion. Dr. MATTHIESSEN recommended lead as the most suitable material "when great care is used," but thought it should be checked by comparison with some other metal, preferably mercury. Dr. MATTHIESSEN'S preference for lead was apparently based upon the ease with which that metal can be obtained in the pure state. The value of the mercury unit was unsettled; the resistance of a column of mercury one metre in length and one square millimetre in section in B.A. units was thought to lie between 0·9564 (SIEMENS) and 0·9619 (MATTHIESSEN). Later observations have almost invariably yielded values somewhat lower than these. A determination which has just been made by Messrs. GLAZEBROOK and FITZPATRICK gives the value 0·95352.

Our space will not admit of more detailed account of the other electrical Papers to which we have adverted; but we have said enough to mark the vast difference which has arisen in the treatment of electrical science, and the attention it has commanded in the years intervening since the British Association last visited the City of Bath.

IMPROVEMENTS IN THE TELEPHONE SYSTEM OF GLASGOW AND THE WEST OF SCOTLAND.

By D. SINCLAIR, Engineer, National Telephone Company.

In the following Paper I propose to deal with some particular features of telephone engineering as practised by the National Telephone Company in the West of Scotland, with regard both to the different kinds of material employed and also to the system of our exchanges.

The telephone has brought with it many new things when compared with the older telegraph engineering, but in none has the change been greater or more radical than in the wire now used. Iron wire, which did service for so long, we have entirely given up, unless under special circumstances. For trunk lines, *i.e.*, lines connecting towns, we use hard-drawn copper. At first we tried No. 16 B.W.G. = ·065 inch, with a resistance of 13ω per mile and a breaking strain of 200lb., but we found it was not strong enough to stand the effects of the winter, and gave it up in favour of No. 14 B.W.G. = ·083 of an inch, weighing 110lb., and having a resistance of 8·25ω per mile and a breaking strain of about 350lb. This wire we find to be the best for long lines; its relatively low resistance, apart from the other considerations of capacity and self-induction, is of great value when dealing with such lines. Its lightness, as compared with iron wire, enables a better line to be

built where staying facilities for the poles are difficult to procure, and, of course, everything else being the same, the poles can carry a greater number of these than of iron wires. Fig. 1 is a sketch map, showing the towns in the West of Scotland joined up, and between any and all of which the telephone communication is a complete business success, working from week to week with pleasure and profit to all concerned.

These trunk lines are erected with the ordinary creosoted poles and best white Cordeaux insulators. On each line we have one single wire; the others are all twisted metallic loops. I may mention that we did not approve of the swan-necked insulators as used by the Post Office, preferring to use only the ordinary 24in. and 40in. arms and upright insulators. The other patterns are difficult to keep in their proper positions. Fig. 2 shows how we have done this work, and it will be seen that the long and short arm is used alternately on each pole, the twisted loop being formed by using the end of each arm on the same side of the pole. It is sometimes found necessary to put a greater number of wires on a line of poles than can be done on the above system, and our line between Glasgow and Paisley has been erected with four wires on each arm, which wires are four sides of twisted metallic loops, the second side of the loops being on the arm immediately below; thus two arms carry four loop circuits, as shown on Fig. 3. For clearness I have only shown two loops, the one plain and the other in dotted lines. These wires have been working for the last three years with the utmost satisfaction.

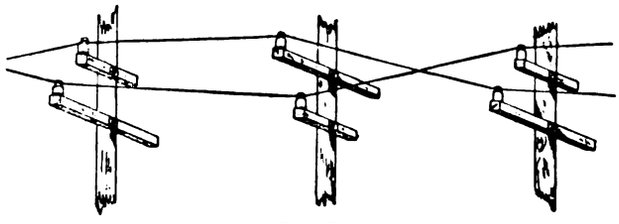

FIG. 2.

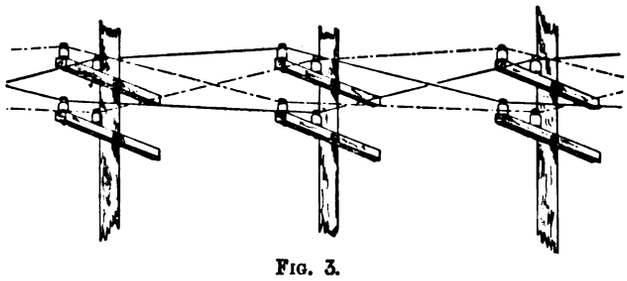

FIG. 3.

Method of Running Wires to Neutralise Induction.

Fig. 2 shows two loops on two arms (used on light lines). Fig. 3 shows four loops on two arms (used on heavy lines).

For our general exchange line purposes in towns and cities we use only silicium bronze wire, and leaving trunk lines for connecting towns out of consideration, silicium bronze wire has proved to be decidedly the best to use. We have adopted it of No. 18 B.W.G. = ·049 of an inch diameter, weighing about 39lb., and having a resistance of 75ω per mile and a breaking strain of about 200lb. The conductivity and breaking strain of this wire varies considerably, and as its breaking strain increases so does its resistance. The reasons for adopting this wire are:—

Firstly. Its great tensile strength when compared with other wires, a feature of vast importance in a city like Glasgow, where it is often imperatively necessary to have long spans of from 200 to 300 yards.

Secondly. The better appearance from the thinness of this wire causes it to be allowed by many proprietors who would certainly object to heavy iron wire.

Thirdly. The lightness of the wire permits with perfect safety the construction of standards on roofs on which can be put from 150 to 200 wires. On our ordinary single poles, as shown on Fig. 4, we consider that from 80 to 120 of these wires make a very safe and good line.

Fourthly. The most important consideration in using this silicium bronze wire is that it does not seem to deteriorate in any way. We have had it erected in Glasgow for four and a-half years. I examined samples of it lately and was not able to detect any rust or any difference in the size of the wire. This to me is very remarkable, and I wish much that the reason could be brought out. I can only say that the wire was coated with a mixture which, for want of a better name, I would call smoke and chemical impurities, which, however, are certainly successful in preventing oxidation. It may be that the compound of which the wire is made up is not affected by the Glasgow atmosphere, which has such a detrimental effect upon all kinds of iron material, and especially on iron wire.

The class of poles we use for carrying this bronze wire is shown on Fig. 4. They are made of the best rolled tube iron. The length in common use is 28ft., made up of two tubes, the lower half being 15ft. by 4in. by ¼ inch, and the upper half 15ft. by 3½in. by ¼ inch. They are jointed by the upper half being slipped into the lower two feet and secured with two strong bolts at right angles to each other, as shown on the figure. The pole is placed in a strong, cast-iron chair, made with a receptacle for it, and of such a shape as will fit the ridge of a house. When erected these poles are usually secured with eight stays, adding what more may be necessary for any special strain of wire. On these we fix channel iron arms, as shown at A on Fig. 4, using six-wire arms where pole space is of great value, and four-wire arms where there are not so many wires to be carried. This is the only class of poles we have used for the last five years for overhouse work, and we have about six hundred of them erected. They are easily converted into standards of any size required. We have some with ten-wire arms composed of two tubes in the form of the ordinary H-pole 40ft. high. These poles can be filled with arms and wires from top to bottom, and if well stayed are perfectly safe. In Glasgow they have stood the test of some very severe winters without one single mishap of any kind. Being easily erected and convenient they are doing the work required of them admirably. It is my decided and firm belief that if only these light poles and bronze wire had been universally adopted from the beginning, the principal cause for so many complaints against overhead wires would never have existed—viz., unsightliness.

LETTERS FOR LEARNERS AND UN-PROFESSIONAL READERS.

BY H. D. WILKINSON.

CHAPTER IX.—*Magnetic Fields.*

(Continued from page 508.)

126. *The Nature of Magnetism.*—At the point now arrived at, it may be of interest to discuss briefly what is the difference in the internal condition of a piece of iron or steel before and after magnetisation. In the first place, it has long been admitted that magnetism is *molecular* in its nature, which is evident from the fact that, however we subdivide a magnetised steel rod, we have in every portion so subdivided a perfect magnet, with two poles of opposite name; and this is true, however far we carry the subdivision. So that if we conceive the subdivision carried out until the molecule itself is reached, we should expect to find it a perfect magnet.

It is only by the generalisation of experimental researches, and in the endeavour to assign reasons for, and explanations of, the effects and phenomena we observe in Nature, that her laws are discovered and real progress made in any branch of science. A consistent and logical explanation of a set of observed effects is known as a "theory" of those effects. For a theory to be a true one it must explain *all* the observed effects and phenomena, and hence it sometimes happens that a new experiment or fact observed modifies or even upsets a previously accepted theory. But a theory, though imperfect, answering all the phenomena then known is decidedly better

Digitized by Google

than none at all, for some of our most reliable and adaptable theories at the present time have been the outcome of a long process of evolution from previously held theories.

In magnetism the observed effects to be explained might be summed up in the following questions :—

1. What is the condition of the molecules in a mass of iron or steel before the mass is magnetised ?
2. What is their condition after the mass is magnetised ?
3. On ceasing the process of magnetisation of the mass why is the polarity retained when the mass is of steel, and almost completely lost when it is of soft annealed iron ?
4. Why do blows from a hammer and mechanical strain or stress assist the process of magnetisation when the mass is in the presence of an inducing cause, and facilitate the disappearance of magnetisation when the inducing cause is removed ?
5. Why does heat produce the same effect ?
6. What is the cause of the elongation of iron when magnetised ?
7. What is the reason for the audible sounds emitted by iron during its magnetisation ?
8. If we take a magnet and de-magnetise it until there is no evident magnetism left in it, is the condition of the molecules the same as that previous to magnetisation ?

Those who were present at the Society of Telegraph-Engineers and Electricians on the 24th May, 1883, when Prof. D. E. Hughes, F.R.S., read a Paper on "The Cause of Evident Magnetism in Iron, Steel, and other Magnetic Metals," will not easily forget the enthusiasm with which the author's new theory of magnetism therein contained was received. Perhaps the greatest claim to general acceptance, and certainly the charm most attractive to his hearers, lay in the fact that Prof. Hughes completely demonstrated his theory experimentally. This, in itself, was a refreshing contrast to the necessity for imagination required in grasping the previous theories of Coulomb, Poisson, and Ampère ; the two former of whom supposed the molecule to be spherical, containing two opposite magnetic fluids, which were separated when magnetised, and mixed when demagnetised or neutral, and that a peculiar force, called coercive force, present in molecules of steel, retained the evident magnetism by preventing the involuntary mixing of the two fluids. Of this there was no experimental demonstration. Ampère supposed each molecule to be an electro-magnet; that is, an electric current was supposed to be constantly flowing round it, and that under magnetisation the molecules were symmetrically arranged, while in a neutral state they were arranged in haphazard directions. Besides other objections to this theory we have the anomaly of assuming a coercive force in soft iron to cause the rotation of at least half the molecules in order to bring about neutrality. De la Rive, Weber, and Maxwell made a step in advance by propounding the *inherent polarity or magnetism af the molecule*—that is, magnetism or polarity is a property with which the molecule is *originally endowed*, and that magnetisation of a mass of iron consists in arranging the molecules all in one direction, not developing magnetism in them. This theory also assumed that neutrality was brought about by a haphazard arrangement of the molecules.

Prof. Hughes' experiments confirm the theory of the inherent polarity of the molecule, and prove that in neutrality the arrangement of the magnetised molecules is not haphazard, but perfectly symmetrical. He also proves that simple molecular rigidity explains all the effects of the retention of magnetism previously assigned to the mystical coercive force, and sums up his theory in these remarkable words :—

"From numerous researches I have gradually formed a theory of magnetism entirely based on experimental results, and these have led me to the following conclusions :—

"1. That each molecule of a piece of iron, steel, or other magnetic metal is a separate and independent magnet, having its two poles and distribution of magnetic polarity exactly the same as its total evident magnetism when noticed upon a steel bar-magnet.

"2. That each molecule, or its polarity, can be rotated in either direction upon its axis by torsion, stress, or by physical forces such as magnetism and electricity.

"3. That the inherent polarity or magnetism of each molecule is a constant quantity like gravity ; that it can neither be augmented nor destroyed.

"4. That when we have external neutrality or no apparent magnetism the molecules or their polarities arrange themselves so as to satisfy their mutual attraction by the shortest path, and thus form a complete closed circuit of attraction.

"5. That when magnetism becomes evident, the molecules or their polarities have all rotated symmetrically in a given direction, producing a north pole if rotated in that direction as regards the piece of steel, or a south pole if rotated in the opposite direction. Also, that in evident magnetism, we have still a symmetrical arrangement, but one whose circles of attraction are not completed except through an external armature joining both poles.

"6. That we have permanent magnetism when the molecular rigidity, as in tempered steel, retains them in a given direction, and transient magnetism whenever the molecules rotate in comparative freedom, as in soft iron."

While referring the reader to the original Paper we may mention therefrom a few prominent points and experiments.

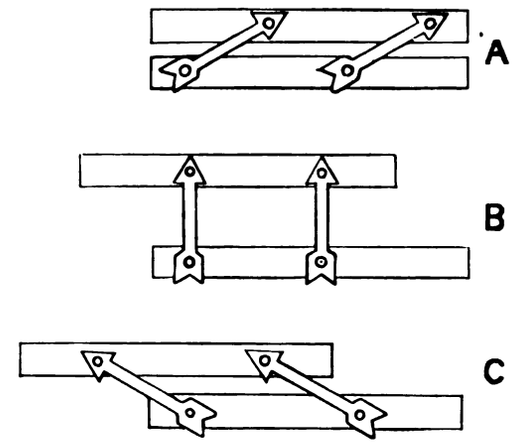

Fig. 98.

The rotation of the molecules under the action of an inducing field is rendered evident by taking a rod of soft iron and bending up the ends, by which a twist can be imparted to the rod while held vertically. The moment this is done the

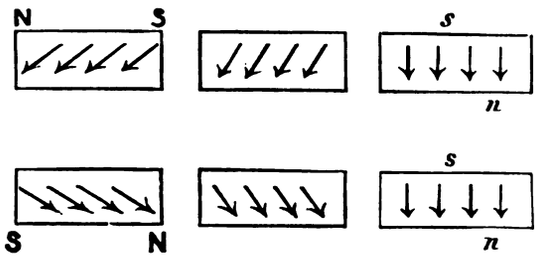

Fig. 99.

rod becomes magnetic, the field of the earth (assisted by the molecular freedom imparted by twisting) causing all the molecules to be attracted and rotated in one direction. The lower end of the rod will be found to be north. On reversing the rod and applying a twist the molecules will rotate right round, and the external polarity will be reversed, the north pole being at the end which is now the lower. With a strip of soft Swedish iron, 1ft. long by 4½ centimetres wide and ½ millimetre thick, the writer obtained by twisting while held vertically a strength of pole equal to 7·3 C.-G.-S. units, as measured on the magnetometer. A mechanical model exhibited by Prof. Hughes to illustrate the rotation of molecules is shown in Fig. 98. It is on the principle of the parallel ruler, and is shown in the three positions in which A represents the direction of the molecules when a mass of iron is magnetised one way, C their direction when the polarity is reversed, and B the immediate stage of transversal polarity. In Fig. 99, the

Digitized by Google

molecules are shown as they exist in polarised iron or steel. The transversal polarity shown at *n s* has the external appearance of neutrality as far as the ends of the bar are concerned, but while there are external poles at all, although at the side, there is no neutrality. We have only perfect neutrality when all the mutual attractions of the molecules are satisfied *amongst each other* in the interior of the mass, and no external polarity is evident.

The inherent polarity of the molecules may be observed by drawing a rod of soft iron over the pole of a permanent magnet. This powerfully magnetises the rod and it retains sufficient magnetism when withdrawn to strongly deflect a directing needle. A few twists of the rod then completely discharges its magnetism. If the operation of magnetising,

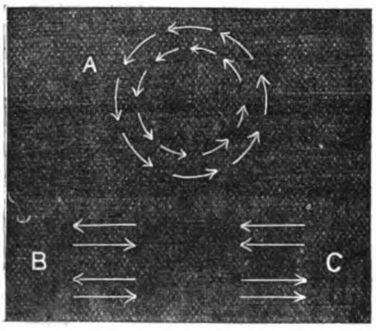

FIG. 100.

withdrawing and discharging were kept on we should expect to weaken the strength of the permanent magnet, and eventually draw all the magnetism out of it. But we do no such thing. The molecules are simply rotated each time, and the mechanical energy spent by the experimenter is proportional to the molecular rigidity of the metal.

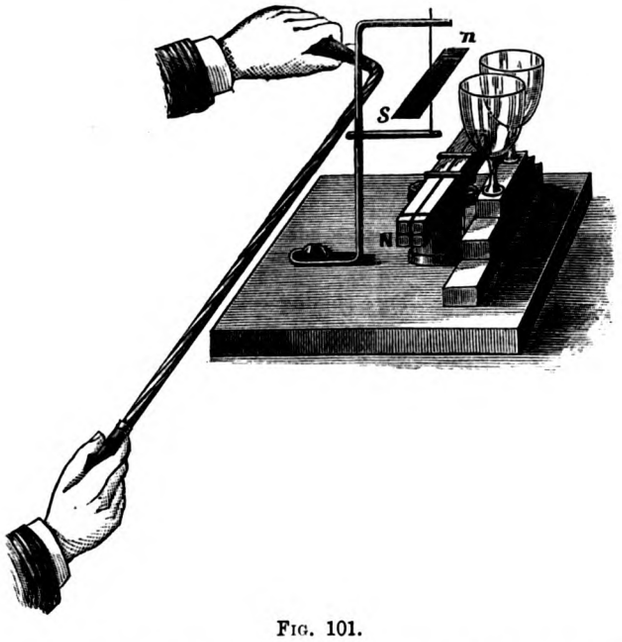

FIG. 101.

Prof. Hughes has shown that by magnetising a rod in a given direction, and then slowly demagnetising it, and again magnetising it in the opposite direction, that there is no haphazard arrangement ; every change takes place with perfect regularity and symmetry. In Fig. 100, at B and C is shown the neutral arrangement of the molecules, and at A a circular neutral arrangement effected by passing a current of electricity longitudinally through the rod.

To show the effect of torsion on the rotation of molecules, Prof. Hughes took a strand composed of about ten untempered cast-steel drill wires, each 1 millimetre in diameter, and about 1 foot long, of the kind in use by watchmakers, and fastened handles at the ends of the strand, as shown (Fig. 101). Holding one handle fast, he imparted two entire right-handed twists to the strand with the other, and strongly magnetised it on the north pole of a magnet while under this torsion. He then released the two right-handed twists, and gave it two entire twists to the left, and oppositely magnetised it on the south pole while under the torsion. On releasing the torsion the strand possessed the remarkable property of a double polarity—that is, either end could be made north at pleasure by simply twisting it one way or the other. In the figure is shown the simple bell apparatus constructed by Prof. Hughes to demonstrate the marvellous transformation of one kind of mechanical movement to another through the medium of molecular motion. The magnetic armature *n s* is held in its position by the directive force of the magnet beneath it, and when the doubly-polarised strand is held near to the armature and twisted consecutively in alternate directions, the pole of the strand near to the armature changes in name for every alternate twist and produces attraction and repulsion of the armature, which can be made to strike against the rims of the two small wine glasses some six times per second.

(To be continued.)

THE TAINTER-BELL GRAPHOPHONE.

In the account of Edison's new phonograph in a recent issue we reserved our remarks on the graphophone until we should have had the opportunity of examining and testing the instruments then on their way to England. This we have now been able to do, the machines being on view at Messrs. Glover and Co.'s office, 10, Hatton-garden, Mr. H. Edmunds, a member of that firm, having been appointed as English agent for the Volta-Graphophone Company, of Washington, U.S.A. On the day of our visit a phonogram had just been received from Mr. Chichester A. Bell, one of the patentees of the instrument, who is now in America. His voice is well known to us, and was instantly recognised as soon as the instrument was set in motion. Owing to rough treatment in the post the cylinder had been quite bent out of shape, and we were agreeably surprised to find that in spite of this only one or two words out of a long letter were slightly indistinct.

The writer has had many opportunities during the last eighteen months of experimenting with a graphophone of an earlier pattern, and though it articulated exceedingly well, the present instrument is a very great advance upon it, the improvements consisting chiefly in simplification of details of the mechanical construction, and representing the results of Mr. Tainter's ingenuity and perseverance during the last two years. The machine is driven by a treadle which runs very lightly, and it is only necessary to maintain a speed above a certain minimum, as a simple but very ingenious governor devised by Mr. Tainter causes the cylinder to rotate at the same definite speed independently of that at which the treadle is worked. The work required to drive it is much less than for a sewing machine, and a small electro-motor may of course be used if desired. The inventors, however, are of opinion that it is better dispensed with, so long as primary batteries have to be used as the source of energy, and we have no doubt that such of our readers as have used primary batteries to drive electro-motors will agree with us.

If, while dictating to the machine, the speaker wishes to pause for a moment, or if it is desired to reproduce the record sentence by sentence, for the purpose of writing it down from the dictation of the instrument, the rotation of the cylinder and the simultaneous advance of the recording or reproducing style respectively can be checked, and started again instantaneously by a slight pressure of the finger on the button of a small lever. The arrangement adopted is very much simpler than the one used for the same purpose in Edison's new phonograph.

Another great advantage of the graphophone is that when once properly adjusted by the makers no further adiustment has to be made by the user, while Edison's phonograph has to be adjusted every time a cylinder is put on, and can therefore only give satisfactory results in the hands of an expert. In Edison's instrument the wax of the cylinders is of considerable thickness, which allows each cylinder to be shaved to a perfectly cylindrical form as the record is being imprinted upon it. This has the advantage of obviating the possibility of bubbles in the surface occasionally interfering with the uniformity of the record ; but except for exhibition purposes, and possibly for the reproduction of music, the advantage is not an important one, and is more than counterbalanced by the largely increased cost of the cylinders.

It should be borne in mind that while Mr. Edison in one of his phonograph patent specifications had stated that cylinders of paper

Digitized by Google

covered with wax, paraffin, or some such material might be used with advantage, he accompanied the statement by the explanation that the wax was only to serve as a base for a sheet of foil, of tin or other metal, on which the record, consisting of a series of indentations, was to be impressed.

The credit of replacing the imperfect indentation record by a record consisting of a continuous curve, actually representing the sound-waves, is therefore entirely due to Mr. Chichester A. Bell, who accomplished the purpose by making the record upon the surface of the wax directly. This improvement, simple though it may seem when once the idea has occurred to the inventor, was only accomplished practically by a series of careful and laborious experiments, as the heavier styles suitable for the tinfoil record were quite unsuited for use with the wax surface, and numerous difficulties had to be overcome before the present delicate and beautiful diaphragms and styles, used respectively for recording and reproducing, were perfected.

EXPERIMENTS ON CARBON AT HIGH TEMPERATURES AND UNDER GREAT PRESSURES, AND IN CONTACT WITH OTHER SUBSTANCES.*

BY THE HON. CHARLES A. PARSONS.

The primary object of these experiments was to obtain a dense form of carbon which should be more durable than the ordinary carbon when used in arc lamps, and at the same time to obtain a material better suited for the formation of the burners of incandescent lamps.

There were a considerable number of experiments made in which the conditions were somewhat alike, and many were almost repetitions with slightly varying pressures and temperatures. They may, however, be divided into two distinct classes: the first in which a carbon rod surrounded by a fluid under great pressure is electrically heated by passing a large current through it, the second in which the liquid is replaced by various substances such as alumina, silica, lime, &c.

The arrangement of the experiment was as follows:—A massive cylindrical steel mould of about 3in. internal diameter and 6in. high was placed under a hydraulic press; the bottom of the mould was closed by a spigot and asbestos-rubber packing—similar to the gas check in guns; the top was closed by a plunger similarly packed; this packing was perfectly tight at all pressures. In the spigot was a centrally bored hole into which the bottom end of the carbon rod to be treated fitted, the top end of the carbon rod was connected electrically to the mould by a copper cap which also helped to support the carbon rod in a central position. The bottom block and spigot were insulated electrically from the mould by asbestos, and the leading wires from the dynamo being connected to the block and mould respectively, the current passed along the carbon rod in the interior of the mould.

The fluid was run in so as to cover the rod completely. The plunger was then free to exert its pressure on the liquid without injuring the carbon. The pressure in the mould was indicated by the gauge on the press.

Experiments.—Class I.

Among the liquids tested were benzene, paraffin, treacle, chloride and bisulphide of carbon.

The pressures in the mould during the several experiments were maintained at from 5 to 15 tons per square inch; the initial size of the rod was in all cases ¼in., and the current from 100 to 300 amperes.

Results.—In some of these experiments a considerable quantity of gas was generated, and the press had to be slightly slacked back during the experiment to accommodate it and maintain the pressure constant.

In all cases there was a soft friable black deposit of considerable thickness on the carbon.

In no case was the specific gravity of the carbon rod increased by this process. There was no change in appearance of the fracture, excepting when chloride of carbon had been the fluid; it was greyer in this case.

The rate of burning of samples placed in arc lamps was not diminished by the process. Various rates of deposition were tried, but with the same result, and the conclusion seems to be that under very high pressures, such as from 5 to 15 tons per square inch, the deposit of carbon by heat from hydrocarbons, chloride of carbon, bisulphide of carbon, treacle, &c., is of a sooty nature, and unlike the hard steel-grey deposit from the same liquids or their vapours at atmospheric or lower pressures.

Experiments.—Class II.

In these experiments the asbestos-rubber packing was omitted, the plunger and spigot being an easy fit in the mould. A layer of coke powder under the plunger formed the top electrical connection with the rod.

No. 1. Silver sand or silica was run around the carbon rod, and pressures of from 5 to 30 tons per square inch applied; the rod was usually about ¼in. diameter, and currents up to 300 amperes passed.

Results.—The silica was melted to the form of a small hen's egg around the rod. When the current was increased to about 250 amperes the rod became altered to graphite; the greater the heat apparently the softer the graphite. There was no action between the silica and the carbon, the surface of the carbon remained black, and there were no hard particles in or on the carbon rod.

Other substances, such as a hydrated alumina and mixtures of alumina and silica, gave the same results.

The density of the carbon was considerably increased, in some cases from normal at 1·6 to 2·2 and 2·4; in these cases the carbon appeared very dense, much harder than the original carbon, and about as hard as the densest gas-retort carbon. No crystalline structure was visible.

The specimens were treated with solvents, and there appeared no indication of the surrounding substance having penetrated the rod; the carbon was undoubtedly consolidated by 30 per cent.

In some cases, when the material surrounding the rod was alumina saturated with oil, soft crystals of graphite exuded from specimens that had been kept for some weeks.

No. 2. Pure hydrated alumina, carbonate and oxide of magnesia and lime all rapidly destroyed the carbon rod, by combining with it, the hydrated alumina forming large volumes of gas, of which it appeared to be a constituent. On account of the great diminution of bulk no analysis was made; the gas issued from the mould explosively at from 10 to 12 tons per square inch. The alumina was found in a crystalline crust, like sugar, around where the rod had been. Hardness that of corundum, almost translucent.

No. 3. The following is the most interesting experiment of the series:—

On the bottom of the mould was a layer of slaked lime about ¼in. thick, over this silver sand 2in., then another layer of lime of the same thickness as the former, finally a layer of coke dust, and then the plunger. With a pressure of from 5 to 30 tons per square inch in the mould, and the carbon of from ¼in. to $\frac{5}{16}$in. diameter, currents from 200 to 300 amperes were passed.

In from 10 to 30 minutes the current was generally interrupted by the breaking or fusing of the rod, or by the action of the lime in dissolving it at the top or bottom. On opening the mould when it had cooled a little, the silica usually appeared to have melted to an egg-shaped mass, and mixed somewhat at the ends with the lime; the surface of the carbon appeared acted on, and sometimes pitted and crystalline in places; silica adhered to the surface, and beneath, when viewed under the microscope, appeared a globular cauliflower-like formation of a yellowish colour, resembling some specimens of "bort."*

After several days' immersion in concentrated hydrofluoric acid, this formation remained partly adherent to the carbon; on the surface of the carbon was a layer or skin about $\frac{1}{64}$th of an inch thick of great hardness, on the outside grey, the fracture greyer than the carbon, but having a shining coke-like appearance under the microscope.

What part the lime and silica play, whether the former only supplies moisture and oxygen which combine with the carbon, or whether the presence of lime is necessary to the action, is not clear.

We may, however, observe that so far it seems as if the lime and moisture combining with the carbon form a gas or liquid at great pressure, which, combining with the silica, forms some compound of lime, silica, and carbon, or perhaps pure carbon only, of great hardness.

* *Proc.* Roy. Soc., Vol. XLIV., No. 270.

* The bort-like powder is not acted on by hydrofluoric and nitric acids mixed.

ON AN EXPLANATION OF THE ACTION OF A MAGNET ON CHEMICAL ACTION.†

BY PROFS. HENRY A. ROWLAND AND LOUIS BELL.

In the year 1881 Prof. Remsen discovered that magnetism had a very remarkable action on the deposition of copper from one of its solutions on an iron plate, and he published an account in the *American Chemical Journal* for the year 1881. There were two distinct phenomena then described—the deposit of the copper in lines approximating to the equipotential lines of the magnet, and the protection of the iron from chemical action in lines around the edge of the poles. It seemed probable that the first effect was due to currents in the liquid produced by the action of the magnet on the electric currents set

† Paper read at the Manchester Meeting of the British Association, Sept., 1887. (Now first published in the *Phil. Mag.* for August.)

Digitized by Google

up in the liquid by the deposited copper in contact with the iron plate. The theory of the second kind of action was given by one of us, the action being ascribed to the actual attraction of the magnet for the iron, and not to the magnetic state of the latter. It is well known since the time of Faraday that a particle of magnetic material in a magnetic field tends to pass from the weaker to the stronger portions of the field; and this is expressed mathematically by stating that the force acting on the particle in any direction is proportional to the rate of variation of the square of the magnetic force in that direction. This rate of variation is greatest near the edges and points of a magnetic pole, and more work will be required to tear away a particle of iron or steel from such an edge or point than from a hollow. This follows whether the tearing away is done mechanically or chemically. Hence the points and edges of a magnetic pole, either of a permanent or induced magnet, are protected from chemical action.

One of Prof. Remsen's experiments illustrates this most beautifully. He places pieces of iron wire in a strong magnetic field, with their axes along the lines of force. On attacking them with dilute nitric acid they are eaten away until they assume an hour-glass form, and are furthermore pitted on the ends in a most remarkable manner. On Professor Remsen's signifying that he had abandoned the field for the present, we set to work to illustrate the matter in another manner, by means of the electric currents produced from the change in the electro-chemical nature of the points and hollows of the iron.

The first experiments were conducted as follows:—Two bits of iron or steel wire, about 1 millim. in diameter and 10 millim. long, were embedded side by side in insulating material, and each was attached to an insulated wire. One of them was filed to a sharp point, which was exposed by cutting away a little of the insulation, while the other was laid bare on a portion of the side. The connecting wires were laid to a reflecting-galvanometer, and the whole arrangement was placed in a small beaker, held closely between the poles of a large electro-magnet, the iron wires being in the direction of the lines of force. When there was acid or any other substance acting upon iron in the beaker, there was always a deflection of the galvanometer due to the slightly different action on the two poles. When the magnet was excited the phenomena were various. When dilute nitric acid was placed in the beaker and the magnet excited, there was always a strong throw of the needle at the moment of making circuit, in the same direction as if the sharp-pointed pole had been replaced by copper and the other by zinc. This throw did not usually result in a permanent deflection, but the needle slowly returned towards its starting point, and nearly always passed it and produced a reversed deflection. This latter effect was disregarded for the time being, and attention was directed to the laws that governed the apparent "protective throw," since the reversal was so long delayed as to be quite evidently due to after effects and not to the immediate action of the magnet.

With nitric acid this throw was always present in greater or less degree, and sometimes remained for some minutes as a temporary deflection, the time varying from this down to a few seconds. The throw was independent of direction of current through the magnet, and apparently varied in amount with the strength of acid and with the amount of deflection due to the original difference between the poles. This latter fact simply means that the effect produced by the magnet is more noticeable as the action on the iron becomes freer.

When a pair of little plates exposed in the middle were substituted for the wires, or when the exposed point of the latter was filed to a flat surface, the protective throw disappeared, though it is to be noted that the deflection often gradually reversed in direction when the current was sent through the magnet—*i.e.*, only the latter part of the previous phenomenon appeared under these circumstances.

When the poles, instead of being placed in the field along the lines of force, were held firmly perpendicular to them, the protective throw disappeared completely, though as before there was a slight reverse after-effect.

Some of Prof. Remsen's experiments on the corrosion of a wire in strong nitric acid were repeated with the same results as he obtained, viz., the wire was eaten away to the general dumbbell form, though the protected ends instead of being club-shaped had the ends perceptibly hollowed. When the wire thus exposed was filed to a sharp point the extreme point was very perfectly protected, while there was a slight tendency to hollow the sides of the cone, and the remainder of the wire was as in the previous experiments. In both cases the bars were steel, and showed near the ends curious corrugations, the metal being left here and there in sharp ridges and points. In one case the cylinder was eaten away on sides and ends, so that a ridge of almost knife-like sharpness was left projecting from the periphery of the ends.

These were the principal phenomena observed with nitric acid. Since this acid is the only one which attacks iron freely in the cold, in Prof. Remsen's investigations this was the one to which experiments were in the main confined. With the present method, however, it was possible to trace the effect of the magnet whenever there was the slightest action on the iron, and consequently a large number of substances, some of which hardly produced any action, could be used with not a little facility.

In thus extending the experiments some difficulties had to be encountered. In many cases the action on the iron was so irregular that it was only after numerous experiments under widely-varying conditions that the effect of the magnet could be definitely determined. Frequently the direction of the original action would be reversed in the course of a series of experiments without any apparent cause, but in such case the direction of the effect due to the magnet always remained unchanged, uniformly showing protection of the point so long as the wires remained parallel to the lines of force. When, however, the original action and the magnetic effect coincided in direction, the repetition of the latter showed a decided tendency to increase the former.

When using solutions of various salts more or less freely precipitated by the iron, it frequently happened that the normal protective throw was nearly or quite absent, but showed itself when the magnetic circuit was broken as a violent throw in the reverse direction, showing that the combination had been acting like a miniature storage battery which promptly discharged itself when the charging was discontinued by breaking the current through the magnet. The gradual reversal of the current some little time after exciting the magnet was noted frequently in these cases, as before. Owing to this peculiarity and their generally very irregular action, the various salts were disagreeable substances to experiment with, though as a rule they gave positive results.

Unless the poles were kept clean experimenting became difficult from the accumulation of decomposition products about them and oxidation of their surfaces. A few experiments showed how easily the original deflection could be modified, nearly annulled, or even reversed in direction by slight differences in the condition of the poles. These difficulties of the method are, however, more than counterbalanced by its rapidity and delicacy when proper precautions are taken.

Nearly thirty substances were tested in the manner previously described, but comparatively few of them gave very decided effects with the magnet, though, as later experiments have shown, the protective action is a general one. The substances first tried were as follows. The table shows the various acids and salts tried, and their effects as shown by the original apparatus.

Several things are worthy of note in this list. In the first place, those solutions of metallic salts which are precipitated by iron all show distinct signs of protective action when the current is passed through the magnet. Of the various acids this is not generally true, only those showing the magnetic effect which act on iron without the evolution of hydrogen, and are powerful oxidising agents. In general substances which acted without the evolution of hydrogen gave an effect with the magnet.

Substances.	Effect due to magnet.	Notes.
Nitric acid	Strong	Always powerful protective throw.
Sulphuric acid	Little or none	Does not act very readily on the iron.
Hydrochloric acid	,, ,,	
Acetic ,, ...	None	
Formic ,, ...	,,	
Oxalic ,, ...	,,

From these experiments it was quite evident that the protective action, whatever its cause, was more general than at first appeared, and steps were next taken to extend it to the other magnetic metals. Small bars were made of nickel and cobalt, and tried in the same manner as before. These metals are acted on but very slightly by most acids, and the range of substances which could be used was therefore very small, but all the substances which gave the magnetic effect with iron poles gave a precisely similar, though much smaller effect, whenever they were capable of acting at all on the nickel and cobalt. This was notably the case with nitric acid, bromine water, chlorine water and platinum tetrachloride, which were the substances acting most readily on the metals in question. Even with these powerful agents, however, the magnetic action was very much less than with iron, and experimentation on metals even more weakly magnetic was evidently hopeless.

As a preliminary step towards ascertaining the cause of the magnetic action, and its non-appearance where the active substance evolved hydrogen, it now became necessary to discover, and if possible eliminate, the cause of the reversal of the current which regularly followed the protective throw. Experiments soon showed that it could not be ascribed to accumulation of decomposition products around the electrodes, and polarisation, while it could readily neutralise the original deflection, could not reverse its direction. Whatever the cause, it was one which did not act with any great regularity, and it was soon found that stirring the liquid while the magnet was on uniformly produced the effect observed. Since one pole was simply exposed over a small portion of its side while the other had a sharp projecting point, it was the latter which was most freely attacked when there were currents in the liquid, whether these were stirred up artificially, or were produced by the change in galvanic action due to the presence of the magnet. When the poles were placed in fine sand, saturated with acid, this reversing action was much diminished, and, in fact, anything which tended to hinder free circulation of the liquid produced the same effect. Several materials were tried, and of these the most successful was an acidulated gelatine, which was allowed to harden around the poles. In this case the protective throw was not nearly as large as in the free acid, since the electrodes tended to become polarised while the gelatine was hardening, and only weakly acid gelatine would harden at all; but the reversing action completely disappeared, so that when the magnet was put on a permanent deflection was produced instead of a transitory throw.

This point being cleared up, attention was next turned to the negative results obtained with acids which attack iron with evolution of hydrogen. The galvanometer was made much more sensitive and removed from any possible disturbing action due to the magnet, and with these precautions the original experiments were repeated, it seeming probable that even if the magnetic effect were virtually annulled by the hydrogen evolved, some residual effect might be observed.

This residual effect was soon detected, first with hydrobromic acid, and then with hydrochloric, hydriodic, sulphuric, and others. The strongest observed effect was with hydriodic acid; but as this may possibly have contained traces of free iodine, it may be regarded as somewhat doubtful. The effect in all these cases was very small, and though now and then suspected in the previous work, could not have been definitely determined, much less measured.

Some rough measurements were made on the electromotive forces involved in this class of phenomena by getting the throw of the galvanometer for various small known values of the E.M.F. The values found varied greatly, ranging from less than 0·0001 volt in case of the acids evolving hydrogen, up to 0·02 or 0·03 volt with nitric acid and certain salts. These were the changes produced by the magnet, while the initial electromotive forces normally existing between the poles would be, roughly speaking, from 0·001 to nearly 0·005 volt, never disappearing and rarely reaching the latter figure.

From these experiments it therefore appears that the protective action of the magnetic field is general, extending to all substances which act chemically on the magnetic metals. While this is so, the strongest effect is obtained with those substances which act without the evolution of hydrogen. But the series is really quite continuous, perchloric acid, for instance, producing but little more effect than hydrobromic, while this in turn differs less from perchloric than from an acid like acetic. It seems probable that the action of the hydrogen evolved is partially to shield the pole at which it is evolved, and lessen the difference between the poles produced by the magnet. It probably acts merely mechanically, for it is to be noted that those acids which evolve a gas other than hydrogen (perchloric acid, for instance), which is not absorbed by the water, tend to produce little magnetic effect compared with those which act without the evolution of any gas.

As to the actual cause of the protective action exercised by the magnetic field, all these experiments go to show that it is quite independent of the substance acting, with the exception above noted, and is probably due to the attractive action of the magnet on the magnetic metals forming the poles subjected to chemical action, as we have before explained.

In the first place, whenever iron is acted upon chemically in a magnetic field, those portions of it about which the magnetic force varies most rapidly are very noticeably protected, and this protection, as nearly as can be judged, varies very nearly with the above quantity. Wherever there is a point there is almost complete protection, and wherever there is a flat surface, no matter in how strong a field, it is attacked freely. Whenever in the course of the action there is a point formed, the above condition is satisfied and protection at once appears. Thus, in the steel bars experimented on, whenever the acid reached a spot slightly harder than the surrounding portions, it produced a little elevation from which the lines of force diverged, and still further shielding it produced a ridge or point, sharp as if cut with a minute chisel. Nickel and cobalt tend to act like iron, though they are attacked with such difficulty that the phenomena are much less strongly marked. With the non-magnetic metals they are completely absent. Now, turning to the experiments with the wires connected with a galvanometer, the same facts appear in a slightly different form.

When the poles were placed perpendicular to the lines of force instead of parallel to them, the magnet produced no effect whatever: showing, firstly, that the effect previously observed depended not merely on the existence of magnetic force, but on its relation to the poles, and, secondly, that when the poles were so placed as to produce little deflection of the lines of force, the protective effect disappeared.

When the pointed pole was blunted the effect practically disappeared, the poles remaining parallel to the lines of force, and when plates were substituted for the wires no effect was produced in any position, showing that the phenomena were not due to the directions of magnetisation, but to the nature of the field at the exposed points. In short, whatever the shape or arrangement of the exposed surfaces, if at any point or points the rate of variation of the square of the magnetic force is greater than elsewhere, such points will be protected, while if the force is sensibly constant over the surfaces exposed, there will be no protection at any point. With all the forms of experimentation tried this law held without exception. It therefore appears that the particles of magnetic material on which the chemical action could take place are governed by the general law of magnetic attraction, and are held in place against chemical energy precisely as they would be held against purely mechanical force. To sum up:—

When the magnetic metals are exposed to chemical action in a magnetic field, such action is decreased or arrested at any points where the rate of variation of the square of the magnetic force tends towards a maximum.

It is quite clear that the above law expresses the facts thus far obtained, and while in any given case the action of the magnet is often complicated by subsidiary effects due to currents or bye-products, the mechanical laws of motion of particles in a magnetic field hold here as elsewhere, and cause the chemical action to be confined to those points where the magnetic force is comparatively uniform.

The effect of currents set up in the liquid during the action of the magnet cannot be disregarded, especially in such experiments as those of Nichols (*American Journal of Science*, Vol. III., pp. 131, 272), where the material acted on was powdered iron and the disturbances produced by the magnet would be particularly potent. The recent experiment of Colardeau (*Journal de Physique*, March, 1887), while perhaps neglecting the question of direct protection of the poles, have furnished additional proof of the purely mechanical action of the magnet by reproducing some of the characteristic phenomena where chemical action was eliminated, and the only forces acting were the ordinary magnetic attractions.

An attempt was made to reverse the magnetic action, *i.e.*, to deposit iron in a magnetic field, and increase its deposition where there was a sharp pole immediately behind the plate on which the iron was being deposited. This attempt failed. The action was very irregular and the results not decisive. The question of stirring-effect was also examined. Usually stirring the liquid about one pole increased the action on that pole, but sometimes produced little effect, or even decreased it. This, however, is in entire agreement with the irregular action sometimes observed in the case of the after-effect in the original experiments.

An excellent method of experiment is to imbed an iron point in wax, leaving the minute point exposed: imbed a flat plate also in wax and expose a point in its centre. Place the point opposite to the plate, but not too near, and place in the liquid between the poles of a magnet and attach to the galvanometer as before.

There is a wide field for experiment in the direction indicated above, for it is certainly very curious that the effect varies so much. If hydrogen were as magnetic as iron, of course acids which liberated it would have no action. But it is useless to theorise blindly without further experiment, and we are drawn off by other fields of research.

In the *American Journal of Science* for 1886, p. 372, Professor

Digitized by Google

E. L. Nichols has investigated the action of acids on iron in a magnetic field. He remarks that the solution of iron in a magnetic field is the same as removing it to an infinite distance, and hence the amount of heat generated by the reaction should differ when this takes place within or without the magnetic field. Had he calculated this amount of heat due to the work of withdrawing it from the field, he would probably have found his method of experiment entirely too rough to show the difference, for it must be very small. He has not given the data, however, for us to make the calculation. The results of the experiments were very inconclusive as to whether there was greater or less heat generated in the field than without.

In the same journal for December, 1887, he describes experiments on the action of the magnet on the passive state of iron in the magnetic field. In a note to this Paper, and in another Paper in the *American Journal of Science* for April, 1888, he describes an experiment similar to the one in this Paper, but without our theory with regard to the action of points. Indeed, he states that the ends of his bars acted like zinc, while the middle was like platinum, *a conclusion directly the opposite of ours*. The reason of this difference has been shown in this Paper to be probably due to the currents set up in the liquid by the reaction of the magnet and the electric currents in the liquid.

In conclusion, we may remark that our results differ from those of Professor Nichols in this: firstly, we have given the exact mathematical theory of the action, and have confirmed it by our experiments, having studied and avoided many sources of error, while Professor Nichols gives no theory, and does not notice the action of points; secondly, our experiments give a protective action to the points and ends of bars, while Professor Nichols thinks the reverse holds, and that these are more easily dissolved than unmagnetised iron.

ON THE ELECTRICAL CONDUCTIVITY OF SUPER-SATURATED SALINE SOLUTIONS.*

BY C. HEIM.

The author points out that the only previous experiments of the same kind are those of Von Beetz† with zinc sulphate, and F. Kohlrausch‡ with ammonic-chloride and sodic-sulphate. Kohlrausch obtained continuous curves of conductivity right up to the point when crystallisation began, and according to Von Beetz the curves showed no sudden change, even when the solution became solid throughout.

The method employed was F. Kohlrausch's§ Wheatstone bridge method with alternating currents, but using a telephone in place of an electro-dynamometer. The solutions were contained in a V-tube (Fig. 1) furnished with platinum electrodes, which were re-

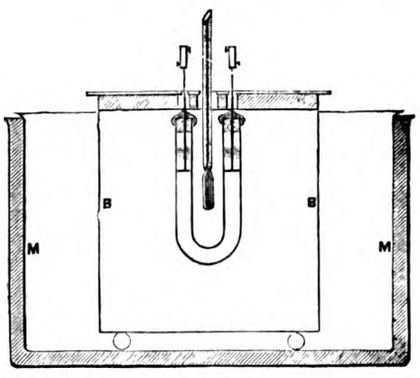

FIG. 1.

platinised before each experiment, and thick platinum conducting wires passing through corks sealed with shellac. The V-tube was fixed within a glass vessel, B, which was itself placed within a larger iron vessel, M. B was filled with a solution of salt, and had a felt cover, and M was filled with water, and connected with supply and waste pipes, by means of which a current of cold water, regulated at will by the experimenter, could be made to flow through it, and its sides and bottom were cased in felt. Both vessels were provided with apparatus for keeping the liquids in them in continuous circulation during the whole time of an experiment. To get rid of polarisation it was found necessary to have a very rapid make and break arrangement in the primary circuit, and a tuning-fork making 256 vibrations a second was used, which completely answered the purpose.

In making an experiment the whole apparatus was warmed up to a temperature some 10° higher than that at which it was desired to take the first readings, and very gradually cooled, the lower temperatures being attained by the use of ice, and finally of a freezing mixture of snow and salt in the outer vessel. In the first experiments the cooling was continued uniformly, and a great degree of uniformity could be attained after a little practice, at the rate of about 1° C. in four minutes; but the plan finally adopted was to regulate the rate of cooling so that it should be extremely slow in the neighbourhood of the readings, which were taken at every 5° and more rapid, in the intervals. The salts used were the sulphates of zinc sodium and magnesia, chloride of calcium, and carbonate of sodium. Fig. 2 shows the curves obtained from the means of a large number of very concordant experiments, and they exhibit the relation between the temperature and the observed resistance in Siemens mercury units. The figures attached to the symbols of the salts give the proportion of the salt to 100 parts of water, and the vertical dotted lines show the temperatures of saturation. It is evident from the figure that there are no sudden jumps in the curves at the points of saturation, but that they remain continuous as they pass through it. The author finds that

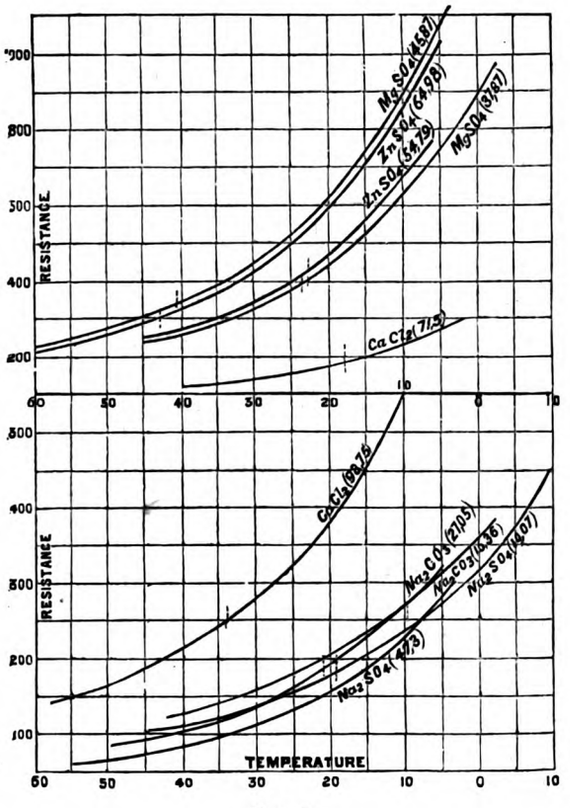

FIG. 2.

the relation between the conductivity k_t at temperature $t°$ and the conductivity k_0 at O° is given to a very close approximation by Kohlrausch's formula

$$k_t = k_0(1 + a\,t + b\,t^2)$$

where a and b are constants.

Owing to the small quantity of solution used, and its small amount of exposed surface, no difficulty was found in carrying the cooling far below the temperature of saturation without solidification taking place. When this happened a sudden increase in the resistance was observed in every case, the resistance in some cases becoming trebled within the space of half a minute, a result which does not agree with that obtained by Von Beetz in the case of sulphate of zinc.

The author's curve for this salt agrees well down to 1° with that obtained by Von Beetz, who cooled his solution down to O°, and the author conjectures that the solidification may have taken place immediately after his last reading, though, as he points out on the other hand, W. Kohlrausch* found no sudden increase in the resistance of fused iodide of silver when it became solid.

F. Kohlrausch also found in the case of chloride of ammonium and acetate of sodium that the curves were continuous up to the

point of crystallisation, and his not having observed the sudden increase in the resistance at this point was probably due to the relatively small super-saturation attained in his experiments; for crystallisation always begins at some one point, and spreads thence throughout the solution, and therefore the increase in the resistance cannot be of the nature of an absolutely sudden jump, but it will be greatest when the solution is so highly super-saturated that the whole crystallisation takes place so rapidly that the temperature does not perceptibly fall during the process, but may even rise slightly in spite of the extreme cooling.

ON THE SPECIFIC RESISTANCE OF MERCURY.*

BY R. T. GLAZEBROOK, M.A., F.R.S., AND T. C. FITZPATRICK, B.A.

The Paper contains an account of experiments made to determine the value of the resistance of a column of mercury, 1 metre long and 1 sq. mm, in cross section, in terms of the B.A. unit. The method employed differed very slightly from that of Lord Rayleigh and Mrs. Sidgwick (*Phil. Trans.*, 1883). Tubes of about 1, 2, and 3 sq. mm. in cross section were calibrated and filled with mercury; they were then immersed in melting ice, and their resistance compared with that of the B.A. standards, using Carey Foster's method and the B.A. bridge. The length of the mercury column, occupying nearly the whole of the tube, was measured, and the mass of the same determined. From this the average cross section is obtained, and hence the value of r, the resistance of a column 1 metre long, 1 sq. mm. in cross section. The mercury used to find the cross section was with few exceptions that which had been employed in finding the resistance. The results of the measurements are given in Table I.

	2.	,,	,,	0·329867	0·95357	

In the table, Column 1 gives the number of the tube, Column 2 the number of the observation. L is the length of the tube, and a the mean radius of the cross section, R the observed resistance in B.A. units. The mean value of r found from the three 1 mm. tubes is 0·95354 B.A. unit. The other four tubes of one-half and one-third unit respectively lead to the value $r = 0·95344$ B.A. unit. The difference between the two is considerable, and reasons are given for assigning more weight to the first value.

For an account of the experiments and of the small precautions necessary to secure accuracy, reference must be made to the Paper.

Table II. gives a list of the various values which have been found for r, with the lengths of the column of mercury which, according to the different observers, has a resistance of 1 ohm (10^9 C.-G.-S. units of resistance). In combining our own observations we have assigned weights to the various tubes inversely proportional to their diameters, and we find as our final value

$$r = 0·95352.$$

* Abstract from the *Proc.* Roy. Soc., Vol. XLIV., No. 270.

TABLE II.

Observer.	Date.	Value for r in B.A. units.	Value of ohm in centimetres of mercury at 0°.
Lord Rayleigh and Mrs. Sidgwick...	1883	0·95412	106·23
Mascart, Nerville, and Benoit	1884	0 95374	106·33
Strecker.....	1885	0·95334	...
L. Lorentz.....	1886	0·95388	105·93
Rowland	1887	0·95349	106·32
Kohlrausch	1888	0·95331	106·32
Glazebrook and Fitzpatrick	1888	0·95352	106·29

The Paper contains a discussion of the above results. It is shown that probably Lord Rayleigh's value of r may be too high by as much as 0·0002, in consequence of the fact that the mercury in his terminal cups was 5° or 6° C., but no complete explanation of the differences between his result and those of Rowland, Kohlrausch, and ourselves has been found. The difficulty of working with tubes such as those used by the Lorentz, 1—2 metres in length, and 1, 2, and 3 cm. in diameter, may perhaps account for his value for the ohm, viz., 105·93.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *August 18th*, 1888.

England having given us so many surprises lately in the way of decisions in electric lighting suits, turn about is fair play, and we can now contribute our share from this side. As some of your readers are perhaps, aware, an infringement suit has been pending in Boston by the Westinghouse Electric Company against the Sun Electric Company, seeking an injunction to prevent the latter company from operating its alternating system as devised by Mr. M. M. M. Slattery. A decision has now been rendered by Judge Colt, in the United States Circuit Court, dismissing the Bill. The main question considered was as to the scope of the patent, in view of a disclaimer which had been made by the plaintiffs. The Goulard-Gibbs patent, as originally drawn, was intended to cover all forms of converters for alternating-current service. The Patent Office, however, required the applicants to make their case conform to the arrangement of converters on the series system, as shown in an article in *Engineering* of March 2nd, 1883, which, it was said, contained a description of the invention. The plaintiffs having made this disclaimer, the Court holds that it is now too late for them to say that it means nothing; on the contrary, it limits the scope of the patent to the series system, and therefore the defendants who were using their converters in multiple arc did not infringe. It will be seen that this is a highly important decision, though it will, in all probability, be appealed. As far as the Sun Company is concerned, it might not mean much, that company being practically out of the business; but it happens that the Fort Wayne Jenney Company had taken up the work where the Sun Company had left off, and with the assistance of Mr. Slattery has lately been engaged putting its own converter system on the market with great activity, the converters being run in multiple arc. The decision is also regarded with pleasure by other concerns, such as the United States Company, who have lately entered the alternating field. Another decision of some importance has been rendered in the electric lighting business; it comes from the same judge, who, having in the first case upset a patent, proceeds in the next to support one. The suit was brought by the Thomson-Houston Company against the Citizens' Electric Light Company, using the American or Fuller-Wood system, for an infringement of one of the patents granted to Profs. Thomson and Houston in 1881, for improvements in current regulators for dynamos. Those familiar with the Thomson-Houston machine will remember that in it regulation is effected by a shifting of the brushes. In the American machine the same result is attained by analogous devices, and the Court now holds that there has been an infringement. This may prove a hard blow to the

Digitized by Google

American Company, which had lately been struggling bravely through its financial difficulties.

It will probably surprise many of your readers to learn that we have more than one telegraph company in this country. The Postmaster-General has just issued his annual circular prescribing the rates to be paid by the Government for its telegraphing during the current year. In this circular he gives a list of no fewer than ninety-one telegraph companies which have accepted the conditions according to law, and are subject to the provisions of the order. Of course it goes without saying that most of these lines, though they may still keep up a separate organisation, are in alliance with, or owe allegiance to, the Western Union Company. Many of them, too, are railroad lines; but still the fact remains that even to-day, after all the consolidation and combination that has gone on, there are just upon one hundred telegraph corporations in the country. As regards the Western Union Company, it may be mentioned that its finances appear to be in better shape than ever. At the present time its business is averaging about £15,000 a week better than it was last year, and this handsome increase will undoubtedly enable it to pay a higher rate of dividend. The reports that have been current as to the proposed change in ownership or management have died away, but their renewal may be looked for at any minute. Graphic reports come from Saratoga to some of the papers with regard to the state of Mr. Gould's health, which, it will be remembered, is none too good, though decidedly on the mend. Quite a sensational story, by the way, got afloat last week with regard to Mr. Robert Garrett, who has been very ill. It was stated that the acquisition by Mr. Gould of the Baltimore and Ohio telegraph system had so preyed on Mr. Garrett's mind that at last it had given way under the strain, and he had practically become a monomaniac on the subject, believing that everybody whom he met had been in conspiracy to deprive him of that old family property. If one were to believe all that finds its way into print about these two magnates, they are as sick and wretched men as can be found all the conntry through, but then newspapers occasionally print something besides news.

Now that the phonograph and graphophone are before the public, attention is once more drawn to the problem of obtaining a record of telephonic conversation. Various efforts have been made in this line, none of which appear to have been at all successful, however ingenious. A new method is now announced to have been hit upon by a Mr. Paramore, of Philadelphia, in conjunction with Mr. Bonta, whose telephone was lately before the public as circumventing the Bell patent. Very few details about the new apparatus have been gained, but it is stated that while the receiver is in use any communication coming to it is committed to wax paper. This serves as a record, and also answers the purpose of registering the communications which may be sent in while the person whom it is desired to call up happens to be away from his office. On his return this person observes indications of the use of the instrument, and by passing the wax paper through the instrument, he can, it is said, hear the communication just as it was originally sent. The record sheets are said to be 8in. by 11in. They can at any time be replaced in the machine, and the record be heard, all of which is very interesting, if true. The man who brings out a good telephonic record system ought certainly to make money in America, if nowhere else.

The proceedings of the Board of Electrical Control continue to occupy public attention in various ways. The Board has now written to the Commissioner of Public Works, and to the aldermen of the city, describing its efforts in getting wires under ground, and inviting assistance and co-operation. It points to the fact that though 122 complaints have been made to the Department of Public Works as to wires and poles that should be removed, up to date nothing has been done to remove the obstructions. It also states that the United States Company, its pet offender, has never been duly authorised to stretch wires overhead, and that the extraordinary number of no fewer than 528 violations of the law and the rules have been reported against this flagrant sinner, upon whom, by the way, summons and complaint in the city suit, asking for $5,000 damages, have just been served by the Corporation council. As regards the alternating-current controversy, I hear that the Board has placed all the documents relating thereto in the hands of Dr. Wheeler, its electrical expert, requesting him to draw up such regulations as, in his opinion, will ensure public safety with the use of the alternating current.

I think I wrote you the other day to the effect that Mr. D. H. Craig, one of the pioneers of the Associated Press, had obtained permission to exhibit his machine telegraph system in the Senate wing of the Capitol at Washington. It is not every inventor that enjoys such an opportunity, and it is said that Mr. Craig has some hopes of inducing Congress to buy him out, and adopt his system as the basis of a Government telegraph service. Mr. Craig claims to be able to telegraph 2,000 words per minute from one end of his wire, and in order to get this amount of matter over the wire, he prepares his copy after the usual manner of perforation, with the addition that the machine which is perforating also prints in plain Roman letters a copy of the message which is sent. It is stated that the perforator experts prepare 50 words per minute in good shape, or 3,000 words per hour. Mr. Craig claims that the actual cost of transmitting 1,000 words 1,000 miles is not over 2 cents. The cost of paper to perforate 1,000 words is 1 cent, and for recording paper 2 cents. The perforating is done at the rate of 10 cents for 1,000 words, and the same for copying on the typewriter, making a total of 25 cents for completing 1,000 words. On this basis it would cost for labour and for paper less than £6 to telegraph and complete 48 columns of an ordinary newspaper from New York to Chicago. Some of these figures seem rather finely drawn. Ten cents per thousand words for perforation strikes one as rather a low rate of pay, and as for the typewriting, the average standard price at the present time is not 10 cents per thousand, but 5 cents per hundred. Mr. Craig, in addition to having a complete transmitting system, has also invented, it is said, a new silicon bronze wire, especially light, strong and conductive.

The newspapers print some queer stories occasionally as to the effects of electric currents on persons who happen to get an accidental shock. One of the funniest that has fallen under my observation is that with regard to an *employé* of the Electric Light Company at Hartford, Ct. This man appears to have been re-carboning some arc lamps, and while doing so to have placed himself in a live circuit. He got a pretty bad shock—so bad, indeed, that as the story reads it killed him. He fell, but in his downward course he struck against another wire, and the back of his neck touched it. When he reached the ground several people went to his assistance and carried him off. Since that time he has recovered, and the doctor in attendance, in commenting on this remarkable case, says "he was undoubtedly dead when he fell from his perilous position, but the lower wire touching his neck while falling restored him to life." It is to be hoped that the experts who have been experimenting on dogs at Columbia College will take note of this extraordinary episode. It might be suggested to them as a new experiment, that after killing the dog with one wire they should drop him on to another, bringing him to life again, and hence meeting some of the objections made by the Society for the Prevention of Cruelty to Animals. One obvious suggestion arising out of this is, that if a man were very ill, and on the point of death, it might be well to kill him with one wire and to bring him to life again with another, thus euchreing Nature; and if this were done once there is no reason why it should not be repeated indefinitely.

Considering the awe with which the Clark standard cell has been regarded up to the present, and the restrictions with which it seems to have been hedged about for practical work, your readers will undoubtedly be surprised to learn that a portable voltmeter has been brought out in this country in which the Clark cell is employed as the standard of reference. As is well known, the Clark cell, as heretofore employed, though admirable in all qualities relating to constancy, has been somewhat difficult to prepare, and, unfortunately, it has been constructed in such a form that it required great care in handling when moved from place to place. Hence its application in a portable instrument has been simply out of the

Digitized by Google

question. Mr. John W. Howell, whose indicating instruments are well known, has heretofore employed as a standard of reference in his instrument a portable form of the Daniell cell, which, though it answered the purpose very well, still had some disadvantages in requiring the renewal of the cell at more or less frequent intervals. Recognising the value of the Clark cell, however, Mr. Howell has devised a portable form which he now embodies in his voltmeters, and which, after extended use, proves satisfactory in every way. In order to test the portability of the cell, Mr. Howell carried one around with him loosely in his pocket for several months, and frequent tests showed that it remained absolutely constant during all that time. In order to show, also, how long one of these cells would last when giving current, an engine room indicator was made in which this cell was employed. It has been in circuit eleven hours a day for ten weeks, the battery giving or receiving current under every variation of pressure on the line. During this time the indicator has always indicated correctly well within the limits of practical work, and, according to Mr. Howell, the cell is apparently as good in all respects as it was when first set up. In the voltmeter there are two cells. Each of these may be used independently as a check upon each other, or they may be both combined so as to increase the limits within which each indicator can be used, the scale readings then being multiplied by two. In order to take account of the temperature, Mr. Howell has added a thermometer to the instruments, which is not graduated in degrees, but is so arranged that the mercury points directly to the number of volts or fraction of a volt which has to be added or subtracted in order to make the reading correct. This instrument is evidently a great advance on the instruments previously in use for this purpose.

You will probably still bear vividly in mind the coulombmeter brought out last year by Prof. Forbes, and which commanded great attention on account of the ingenuity of the apparatus and the utilisation of the principle involved. Reasoning probably from the same premises as before, Prof. Forbes has just secured a patent in this country for a meter in which the principle of the heat generated by current is again utilised as a means of indication. In this instrument, however, instead of heat creating a motion which is registered, Prof. Forbes employs it to evaporate a liquid, such as alcohol, which is condensed, and thus affords a measure of the work done by the current. The apparatus consists of an inverted U tube. One of the legs of the tube is open, and is fixed in the stopper of a vessel containing the volatile liquid. From this open end there hangs an absorbent material, such as cotton, which sucks up the liquid for a short distance into the tube and around that portion of the leg which contains the cotton there is wound a few turns of wire placed in the circuit. The heating of this wire evaporates the liquid, which passes from it into the other leg, and is there condensed, falling to the bottom. Thus the scale attached to the closed leg measures the height of the condensed liquid, and affords a direct indication of the amount of electrical energy passed through the circuit.

NOTES FROM PARIS.

(FROM OUR OWN CORRESPONDENT.)

August 28th, 1888.

The Paris Municipal Council is not favourable to electric traction, and the plan proposed by M. Lartigne for a single-rail electric railway has been rejected, as well as the tubular one of M. Berlier. However, Messrs. Philippart Brothers say they are about to get permission for an experimental electric tramcar of their own invention. This car will run between the Arc de Triomphe and the Porte Maillott. It will have nearly the same external appearance as the large horse trams belonging to the Cie. des Omnibus. The total weight will be 9,440 kilos, or about 10 tons, viz. :—50 passengers, 3,400 kilos ; car, 3,500 ; accumulators, 1,800 ; electric motor, 350 ; sundries, 390. The battery will consist of 144 cells of the Faure-Sellon-Volckmar type, with a nominal output of 7 horse-power, and able to develop 20 horse-power on occasion. I hope that these experiments, which are of particular interest to the Parisian population, will soon begin, and if so I will send further details.

Electric lighting remains in the same dull state, and nothing new will come out before the beginning of October, when the Municipal Council will meet for its autumn session. The demands for concessions made by the Rothschild Company and the Edison Company will then be examined, but as it is said that their contents do not agree with the terms of the Cahier des Charges, they will certainly be rejected by the Council. Some other demands by the Compagnie d'Eclairage Electrique, M. Sencier, and others, are spoken of, but I doubt whether their proposals are likely to meet the views of the authorities. As has already been announced in your columns, the French patents of the Cruto lamps have been purchased by Messrs Rothschild on behalf of the "Société pour le Travail Électrique des Métaux." The factory is situated in the Rue Didot, and is well provided to meet all possible demands. Another lamp is, therefore, added to the many already in the market. The last arrival presents no remarkable features which should cause it to be preferred to any of its competitors. The makers guarantee a life of 1,000 hours and an efficiency of 3·5 watts per candle-power, in which there is nothing unusual. The lamps, however, are cheap, the price varying from 4fr. 50s. to 3fr. 75c., according to the number ordered. The Benardos process is apparently not very paying, since the company formed to work it has betaken itself to such a very different field. It may be interesting to some of your readers to hear that both M. Popp's private house and his station for compressing air, which are opposite one another in the Rue St. Fargeau, are lit by electricity. The plant comprises a 16-unit Gramme machine, driven by a 25 horse-power engine, and a 16-unit Thury compound dynamo, driven by a 40 horse-power engine. There are in all 400 incandescent lamps and 25 Mornat arc lamps, M. Popp's house being lit by 100 incandescents and 25 arcs. Attached to the station there is an electrical laboratory and lamp-testing room.

In my correspondence of the 10th July, I mentioned some experiments upon a new military microphone. I have since made the acquaintance of the inventor, who is at present at the Camp de Châlons, where he is engaged in some interesting experiments about which I hope soon to send you an account, and to give you the description of the microphone, which is an entirely new development.

As you probably know, the Prix Volta of 50,000fr. has been awarded by the Technical Commission to M. Z. Gramme, for his improvements in dynamo design. This decision, which has to be confirmed by a vote of the Chamber at its next meeting in October, has been cordially accepted by all the French electricians, who appreciate the qualities of this indefatigable worker.

I cannot conclude this letter without speaking of a new application of electrolysis, which, if introduced into general use, would open a rather large field to electricians in the undertaker line of business. A chemist of Brest, M. Kergovatz, seems to be the first who has pointed out the advantages we can get from electro-plating in lieu of the old fashions of embalming, burning, &c. The body, having been rendered a good conductor by a coating of plumbago or by immersion in a bath of nitrate of silver, is then placed in a galvanic bath, where it is coated with copper, brass, silver, or even with gold, according to taste and means. When so prepared, the body is entirely preserved from atmospheric action, and can be kept in this state probably for hundreds of years, if not for thousands. Although this application of electrolysis may not be very attractive, I thought it worth mentioning, as it is the first advance upon the Egyptian way of preserving the human body from decomposition.

NOTES FROM VIENNA.

(FROM OUR CORRESPONDENT.)

VIENNA, *Aug. 27th*, 1888.

Messrs. Siemens and Halske are inviting residents in the inner district of Vienna to apply to them to have their houses lit up by electric light, as they have completed, or are rather just completing, their large central station. They hope to be able to supply the light to any applicants before Christmas.

Considerable doubts, however, are expressed by those who have had experience in these matters in Austria of their ability to fulfil their promises, as municipal objections generally manage to postpone if not stop such enterprises.

If there is a firm that can succeed it is Messrs. Siemens and Halske, and the development of their new enterprise will be watched with much interest.

The same firm have also been negotiating the lighting of the small town of Purkersdorf, a favourite summer resort of the Viennese. The matter seems so far settled that the town may be lit up next spring with the electric light. An electric railway connecting Purkersdorf with Gabletz is also proposed. When all is completed the whole is to be handed to the Town Council (who buy it from Messrs. Siemens), who will carry it on on their own account.

Digitized by Google

The Imperial Continental Gas Association have succeeded in lighting the Opera for nearly a year now without a hitch, and to the entire satisfaction of the Opera authorities. They have spared no trouble or expense to make their central station a model one, and have certainly succeeded so far, although they are continually carrying out improvements in detail.

CORRESPONDENCE.

MR. MOSELEY'S TELEPHONE SYSTEM.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The reply of Mr. W. Moseley to a letter of mine on the above subject leaves me still, I regret to say, somewhat sceptical as to the merits of several points in his article on "A Proposed Telephone System," and I should again like to draw attention to the subject.

Mr. Moseley refers us for information on this subject to a most valuable and interesting portion of your paper, viz., the "American Notes." I find those from which he quotes are in your issue of 13th January, 1888. and, having carefully read the paragraph in question, I would ask Mr. Moseley to do the same, as he appears to have somewhat misunderstood it. I should like to quote it in full, but as any of your readers who are interested in the subject can refer to it, it will be sufficient for me to say that the subject of the paragraph is the construction of the one large Telephone Exchange in New York—which is to take the place of several comparatively small existing ones—and the placing under ground of all the lines which rendered it necessary that they should be made complete metallic circuits. "This," the paragraph goes on to say, "involved many changes and much new work, and a total expense to date of £60,000." Thus, £60,000 covers a great deal more than the cost of an unfinished switch-board for 6,000 lines, as Mr. Moseley suggests—in fact, the cost of the switch-board was but a fraction of this amount; in addition to which, I may add, it is not merely a switch-board for 6,000 lines, but so constructed as to be capable of being extended to over 10,000. I would not deny for one moment that a switch-board after Mr. Moseley's design for 6,000 subscribers could not be made at a less cost than £60,000, but it would have to cost *very* much less than this if it is not to be expensive, and I am still of opinion that Mr. Moseley's switch-board would be a very costly apparatus both to erect and maintain as compared with the present form of multiple switch-board.

As regards the chains which he uses in his switch-board, I regret that I could only assume in my last letter that the description and drawings he himself gave of the board were correct. It now appears that this is not the case, for in Fig 8 of his drawings there is something so well representing the joints of pieces of wire to the last links of the chains that I have not yet found anybody with sufficient mechanical knowledge to say that it represents continuous chain as Mr. Moseley now tells us they represent. Steel chains would no doubt be less liable to break and stretch than a composite length of chain and wire, but they are objectionable on the score of extra expense, and on account of the chances of the chain twisting and becoming thereby shortened being increased—a probable event which I pointed out in my previous letter. Mr. Moseley tells us that the difficulty of repairing these chains is less than that of repairing overhead wires when broken down by a snow-storm. I am glad to hear it; but, although the latter is a known quantity of considerable dimensions, the comparison, I regret, does not give much information as to the method by which a chain may be repaired or replaced.

The fact that the contact between X and Z (Fig. 12 of his drawings) is not broken until the plug W is withdrawn for more than one-half of an inch, which Mr. Moseley now tells us is the case, only increases the chances of the faults which I pointed out, occurring in this part of the apparatus. The wire—I may here mention that again in this drawing a wire and not a chain is shown—has now only to stretch one inch in its whole length and the contact will not be broken by the placing of a plug in the plug hole, and similarly the chain will only have to get twisted sufficiently to shorten the whole length by one-half inch and the contact will not make. As Mr. Moseley compares this piece of his apparatus to the steering gear of a ship and a chronometer, perhaps there are some further intricacies which are also not "obviously shown." He considers that no difficulty exists in leading the wires for the electrical connections to the plug holes, except in my imagination. I must own that, until I had practical experience in the designing and erection of multiple switch-boards, I scarcely thought that this detail would present any trouble; but the difficulty has formidably presented itself not only to me but to all who have had similar experience. If Mr. Moseley has a method successfully overcoming this "self-inflicted" (?) difficulty, I feel sure that he will benefit not only very many telephone experts, but probably himself in addition by telling us how we are to rid ourselves of our self-imposed burden.

Next, as regards the dimensions of the switch-boards, we shall find that here again Mr. Moseley has gone wrong in his quotation from the "American Notes." It is a switch-board for 10,000 lines that is to occupy 300ft. in length, not one for 6,000, as he would have us believe. The New York switch-board is being constructed to operate 6,000 lines, and is divided into sections. Some of the sections will be arranged to attend to trunks only, the others to 200 subscribers each. The dimensions of these latter sections will be 6ft. in length, and the height from the top row of "spring jacks" to the floor will be between 4ft. 6in. and 5ft. We will now see how this compares with the dimensions that Mr. Moseley gives us of his board. First, as to the number of sections. On this point Mr. Moseley's statements are somewhat contradictory. He first tells us that he accepts my figure, viz., that 200 subscribers is the right number to be attended to on each section, and then he says that 26 sections will attend to 5,500 lines. If he intends to operate 200 lines on each section he will require 27½ sections occupying in length 137ft. 6in., instead of 130ft. for 26 sections. Now 27½ sections of the New York multiple board will occupy 165ft., and thus Mr. Moseley's board will take 27ft. 6in. less than this board, provided he can get it into the length he says he can. I am certain, however, that he cannot get a workable board for 5,500 lines on his principle into that length. This brings me to a second point of comparison, viz., the sizes of the sections in the two forms of multiple boards. We have seen that the space occupied by each section of the New York board was 6ft. in length by between 4ft. 6in., and 5ft. in height, which includes space for running gear for plugs and cords and keys, &c., for working the plugs, and also about 6in. between the adjacent "spring jacks" of each of the sections, which space is necessary for the leading of the electrical connection wires to and from the different sections. Now, as each plug hole of Mr. Moseley's board is ¾in. square, 5,500 of these will fill a space 4ft. 8½in. square—Mr. Moseley says 5ft. square; this allows room for a frame 1⅞in. all round the plug holes. He will find that it is not practicable to place the lowest row of plug holes lower than 2ft. 6in. above the floor, above which the upper plug holes will then be 7ft. 6in., rendering the placing of a plug in these holes, although a gymnastic performance, certainly not an easy or a rapid one. To reduce this height it will be necessary to increase the length of each section, and if the height is reduced to the same as the New York boards, the length will have to be exactly doubled; and his switch-board for 5,500 lines will occupy a space of 275ft. in length, whereas the New York board for 6,000 will only be 180ft. long.

I now come to the portion of the paragraph in the "American Notes" on which Mr. Moseley has pinned his faith. It states, at a second conference of telephone experts connected with the American Bell Telephone Company, "one result arrived at, *it is said*, is the decision that . . . it is desirable in large cities to combine all the wires and connections as much as possible under one roof up to the number of at least 5,000 subscribers. Beyond that point the conclusion *seems to be* it is better for the present to relieve the central office by a system of minor exchanges." The fact that your correspondent has expressed himself in this somewhat cautious manner with reference to the opinions of the experts on this

Digitized by Google

point, would rather lead one to believe that they were by no means agreed on the subject, which I have heard is the case. However, there are but few towns in the world in which one exchange with a capacity of 5,000 would not be sufficient to meet all demands for some time to come, and as there is at present, as far as I know, no exchange working with as many as 3,000 lines but little is at present known as to how a very large centre would work. In New York, at all events, the experts appear to be of the opinion that an exchange for 6,000 lines will succeed.

In conclusion, I may add for Mr. Moseley's information that though the heading to his letter has an imposing appearance, it unfortunately is not correct. I am unable to say whether the opinion of the United Telephone Company as regards *the new* public telephone system agrees with mine owing to the fact that I left that company's service some time prior to the date when I wrote my former letter. While mentioning this company, I would like to draw attention to another slight inaccuracy of Mr. Moseley's when, in the first of his articles, he states that the telephone master patents expire in three years from the date he wrote. One master patent, no doubt, does expire about that time, but the most important one does not run out until some three years after that.—Yours, &c.,

F. B. O. HAWES.

UNIPOLAR INDUCTION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I think I have shown that the evidence upon which Mr. Tunzelmann based the theory put forward in his articles on this subject is quite incompatible with Faraday's theory, or even with that stated in the concluding paragraph of my last letter.

I have also shown that the results of Exner and Czermak's experiments, upon which most reliance has been placed, were not deserving of credit, and therefore not evidence at all. So we are left no nearer a solution of the fundamental problem attacked.

The "incontestable fact," which Mr. Tunzelmann characterises as my "bare assertion," that the number of lines within the circuit in any case of strictly unipolar induction does not vary, was accompanied by a demonstration, and I fail to see anything in it inconformable with the views of Faraday; but at the same time, the accepted *statement* of Faraday's law of electro-magnetic induction does not fit the case of unipolar induction with sliding contacts. This, however, is a mere matter of language.—Yours, &c.,

R. SNOWDON.

Thirlmere Aqueduct, Staveley, Chesterfield,

FLASHED FILAMENTS AND LAMP VOLTAGE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Referring to the leader in your issue of July 27th, one or two points appear to require comment, as they seem likely to be misunderstood. You seem to point out that the process of flashing is principally of importance for "making lamps all alike as regards resistance," and therefore that the difficulty of making unflashed lamps arises out of the variation of resistance in such lamps.

Now, a recent publication of experiments with flashed lamps shows that equality of resistance will not necessarily produce lamps of equal E.M.F. This was shown to be due to variations in the method of flashing, coupled with the inevitable variation of dimensions caused by the process itself. A contractor of experience, who tests a few sample lamps before he settles upon using a certain class of lamp, ought to prefer to use unflashed lamps, for the carbons must be really good if free from spots, &c., as only a first-rate unflashed carbon will be free from obvious defects, such as spots or bright points, whereas a really poor carbon may be made to appear pretty even as regards brilliancy by its "veneer" of flashed carbon, which cannot stand for long the strain to which it is put, but is torn off, and the lamp then rapidly becomes worthless. The reason for which small makers have failed with unflashed lamps is simply because they have always attempted to work with worthless carbons. If cheap lamps would be the result of competition by such makers, I do not consider that electric lighting would gain much by having such competition. You state that the Brush Company and Messrs. Woodhouse and Rawson may be able to overcome the difficulty of making, say, 1,000 lamps all alike as regards resistance. Since the Cheesborough patent was upheld Messrs. Woodhouse and Rawson have stated that for the last year or two they have made nothing but unflashed filaments. Perhaps this has been possible owing to the excellence of their carbon, and it shows that if one can only get a high enough quality of carbon one can do without the Cheesborough process. It is of course possible that Messrs. Woodhouse and Rawson have perfected some other method of reducing their lamps to a common resistance. It is well known, however, that they endeavour to get buyers of lamps to order a few volts on one side or the other of the standard E.M.F.'s, and this looks as though they had a certain number of lamps that did not come out exactly to a given E.M.F.

The transformer system will doubtless give a considerable impetus to the manufacture of the lower E.M.F. lamps, which have fallen out of use to some extent, and if some of the transformer makers were to wind their transformers to give slightly different E.M.F.'s from the normal 100 volts now generally adopted they would find that they got on an average better lamps. If this were done there is little doubt that the price of lamps might be reduced; but whether the millenium of good lamps at 1s. 6d. each is likely shortly to be reached depends partly upon the adoption of some method such as the above for immediately utilising *all lamps* made. Contractors would also gain by not having to wait so long for lamps, the delay generally arising from the fact that there is such a demand for lamps of one or two E.M.F.'s.—Yours, &c.,

EXPERIENTIA.

REPORT OF MR. GISBERT KAPP ON THE LINEFF SYSTEM OF ELECTRIC TRACTION.

A copy of the following report came into our hands several months ago, but at Mr. Lineff's request we have withheld its publication until now. The report is as follows:—

To the Chairman of the West Metropolitan Tramway Company.

Dear Sir: I have examined and tested the electric tramway line on the Lineff system, which has been laid down for experimental purposes at the Chiswick depot of your company. The car is a small open car, fitted with a 4 horse-power (nominal) Immisch motor. The transmission of power from the motor to the car wheels is by means of a countershaft and two Renold's chains, and, in this respect, does not differ from that used on other electric cars. There are, however, two special appliances peculiar to the Lineff car. The one is a movable dash-board at each end of the car, which upon striking an obstacle automatically reverses the direction of rotation of the motor, and causes the car to run back; and the other is a magnetic brake.

The object of the dash-board and automatic reversing gear is to more quickly stop the car, if through the negligence of the driver it should run into an obstacle. In this case the dash-board causes the brake to go on, and the motor to be reversed. The putting on of the brake is a good feature, but I do not consider the advantages of automatically reversing the motor sufficiently great to compensate for the complication which the arrangement entails.

The magnetic brake can also be put on by hand, being actuated by the same switch lever by which the driver controls the speed of the car. I consider this brake an extremely valuable feature of the Lineff car. When the car was fully loaded and running at full speed, the distance traversed after cutting off the current and putting on the brake was only 9ft. It is needless to say that no hand-brake could effect a stop in so short a distance. As it is, however, not always necessary to stop so quickly, the switch controlling the brake-magnet should be provided with intermediate contacts and resistance coils, to enable the driver to stop more slowly if desired.

Digitized by Google

The experimental line is about one-tenth of a mile in length, and is provided at one end with a crossing point, having the usual automatic switches, so that the car runs out on one side and home on the other side. The curves are very sharp—one having only 21ft. 6in. radius—and the line is rather in a bad condition throughout, being built mostly with old and discarded rails, so that the power required to propel the car is much greater than would be the case on a good line. Although a car of that size would usually be drawn by one horse, on the experimental line one horse is hardly enough to move the car on the sharpest curve, where the pull as measured by a dynamometer reached 380lb. This is the reason why the power required to work the car as given in the appendix is rather greater than would generally have to be provided for a car of that size. I have nevertheless based my estimate for the plant required for the Kew Bridge-Hammersmith line upon the data obtained in my tests with the small car, in order to have ample margin of power. This estimate is given in the appendix.

The Lineff tramway system belongs to that class where the current is supplied to the car by means of a conductor placed under ground, but whereas in other systems the metallic surface of the conductor is exposed along its whole length, and a contact brush or slider rubs along it to take the current off, in the Lineff system nearly the whole length of the conductor is insulated, and the current is taken off at certain points, abouth three feet apart. At these points are fixed small saddle-shaped contact pieces, over which trails the bight of a metallic rope, suspended from shoes which pass through the slot of a channel, and are attached to a flexible beam under the car. The rope consists of a stranded wire cable protected with gunmetal ferrules, which can be easily renewed when worn. It is insulated from the shoes which pass through the slot, and the connection between it and the main controlling switches is also insulated. The rope in passing over the contacts collects the current, which is thus led to one of the main controlling switches, and from there to the motor, returning through the framework and wheels of the car to the rails. The great difficulty with all underground conductors for tramways is their insulation. A cable protected by insulation over its whole surface may be buried in the ground, and no escape of electricity can take place. If, however, the insulation is removed at certain points along the cable, so as to expose at intervals the metallic surface, electricity can escape at those points, and it is evident that the escape will be the greater the more the conductor is bared. A conductor only partially insulated cannot be simply buried in the ground, but must be supported on insulated brackets clear of the surrounding ground or masonry. Even if so supported, a certain amount of electricity is lost by leakage, and, generally speaking, the loss will be in proportion to the metallic surface exposed. Now, in other systems of underground conductors, the metallic surface is exposed from one end of the line to the other, and the leakage resulting therefrom must obviously be very much greater than with Mr. Lineff's arrangement, where nearly the whole of the conductors may be covered by insulation, and only a few inches of metallic surface are exposed at intervals. It is doubtless due to this arrangement that the insulation resistance, even after the very severe test described in the appendix, was yet found to be as high as 10,000 ohms, being at the rate of 1,000 ohms per mile. With this insulation resistance, the loss of current over a double line between Kew Bridge and Hammersmith would not reach two amperes, and the power wasted would amount to about three-quarters of a horse-power, or about 1 per cent. of the power required to work an eight minutes' traffic over this line. I know of no other underground system which comes anywhere near this in perfection of insulation.

Another advantage of the Lineff conductor is the facility with which crossings can be arranged. The conductor consists of iron piping, with a copper conductor inserted. The saddle-shaped contacts are screwed into the pipe, which is sub-divided into sections, each sufficiently short as not to be influenced by changes of temperature. Connection between adjacent sections is made by short pieces of insulated cable, and it is thus an easy matter to arrange for two conductors to cross each other without interference. Such crossings have been fitted at one end of the experimental line, as already stated; and I have found the car and its collectors to take these crossings easily, the working being facilitated by the ingenious manner in which the shoe beam is attached to the under side of the car.

The direction of motion is controlled by a reversing lever, and the speed by a switch lever. Ordinarily, during the journey, the driver has therefore to attend to one handle only, by which he controls the speed and puts on the brake.

Having carefully examined and tested the Lineff system, I have come to the conclusion that it is superior to other systems employing an underground conductor, and that it will be found suitable for suburban lines having a heavy traffic.

The results of my experiments and estimates of the Kew Bridge-Hammersmith lines are given in the appendix.

Appendix to Report on the Lineff Tramway.

Object of Experiments.—The object of my examination and experiments was, in the first place, to ascertain the electrical condition of the experimental line laid down on the Lineff system at the depot of the West Metropolitan Tramway Company; and, in the second place, to estimate what amount of steam and electrical plant would be required to work on the same system a given line adapted for a definite traffic.

Instruments Used.—All resistances were taken by a Wheatstone's bridge and mirror galvanometer, whilst current and pressure were measured by Miller's patent ampere and volt meters, newly calibrated.

Insulation Test.—This was made by measuring the resistance between the rails, which carry the return current, and the central conductor, which carries the outgoing current. During these tests the car was placed in the shed, and that portion of the conductor which is within the shed was disconnected, so that leakage by current through the switches and various connections in the car should not interfere with the test. The insulation resistance of the whole conductor was found 25,400 ohms. As this insulation resistance necessarily depends to a certain extent upon the state of the atmosphere, and must be lower in wet weather, I determined to test it under the most unfavourable conditions possible; and for this purpose I ordered an attendant to play into the central channel from a water hose, and another attendant to throw buckets of water over the slot all along the line. Under this treatment, which was intended to imitate a heavy shower, the insulation and resistance gradually diminished until it reached 10,000 ohms, after which point there was no further reduction.

Resistance of Conductor.—The resistance of 174 yards of conductor was found to be ·170 ohm. The calculated resistance of copper wire within the pipe is ·240 ohm, so that the resistance of the iron pipe must be about ·580 ohm.

Resistance of Earth Return.—The resistance of 174 yards of earth return circuit formed by the tram rails, the girders of central channel, and the earth, was found to be ·145 ohm. This, at the rate of 1·47 ohm per mile, was very much higher than I expected to find. The probable reason for this high resistance is that the material of the rails and girders has not been specially selected with regard to its electrical properties. The rails utilised in the experimental line were worn-out and discarded rails of various patterns. According to the chemical composition of steel, its resistance may vary from six times to about forty times that of copper, and it is quite possible that the high resistance of the return circuit is entirely due to the particular quality of which these old rails consist. Rails can now be obtained of steel having about seven and a-half times the resistance of copper, and if this steel be used the resistance to the return circuit need not exceed ·25 ohm per mile.

Power Test.—The car employed was an open summer car, carrying 20 passengers, besides driver and conductor. I estimate the weight of car, as fitted with a 4 horse-power Immisch motor and chain gear, magnetic brake, and other accessories, at 35cwt., without passengers. The line consists of a straight portion, a curve of fairly large radius, and a crossing point, over which occur very sharp curves, one of only 21ft. 6in. radius. Owing to the rails being worn, and originally of different patterns, the wheels ran at times on their flanges, which causes a greater resistance to the motion than would be the case on a properly-built line. To find the electrical energy required to propel the car, I observed the pressure and current whilst the car was travelling up and down the line, over the straight portion and the curve, but not over the crossing points, because when passing these the current underwent such rapid variation that it was impossible to obtain correct readings. In all there were made ten runs, with the car containing only three persons, and the average current for the straight and curved part of the line, and for the slight rise at either end, was 11 amperes, at a pressure of 231 volts on the motor terminals, when the car was travelling at full speed, or about seven miles per hour. The energy supplied to the car when running light was therefore 3·4 E.H.P. The car was then loaded with 40 cast-iron rail chairs, weighing 86lb. each, and in addition carrying two persons, the total load being 3½cwt., and ten runs were made. The average current required was now for full speed thirteen amperes, at a pressure of 230 volts on the motor terminals, corresponding to an electrical energy of 4 horse-power, for a total rolling load of 3·4 tons.

Power Required to Work a Full-Sized Car.—The average electrical energy which will have to be supplied to each of a number of cars running simultaneously can be compiled on the basis of these experiments. I make no allowance for the following considerations, viz.:—1. The tractive force per ton of rolling load will be less on a properly-constructed line, with rails in good condition. 2. The efficiency of the motor and gear in a large car must be greater than in a small one; and 3. The car does not always carry its full complement of passengers. All these points tend to reduce the power required, but I leave them out of consideration in order to have an ample margin of power. A full-sized car capable of

Digitized by Google

accommodating 46 passengers, and fitted with electric gear, will weigh about three tons, and the passengers, with the driver and conductor, represent an additional 3·4 tons, so that the total rolling weight will amount to 6·4 tons. The electrical energy which has to be supplied to propel this car at a speed of seven miles per hour is, therefore, $4\frac{6\cdot4}{3\cdot4}=7\frac{1}{2}$ horse-power. This is represented by a current of 20 amperes and a pressure of 230 volts.

Plant required for working a double line between Kew Bridge and Hammersmith, with an eight minutes' service, six or seven cars being simultaneously in motion. The gradients are only trifling, and need not be taken into account where the current is divided between several cars. The maximum current required for seven cars will be 140 amperes, and the pressure 300 volts, allowing 20 volts loss along the line. The conductor will consist of a ¾in. gas tube, with a central No. O B.W.G. copper wire or bare cable of equivalent area. The resistance of the conductor and earth return formed by the rails and channel girders will be ·75 ohm per mile. At the depot there will be three dynamos, each having an output of 30 horse-power (electrical), and three steam engines, each of 45 horse-power. Two sets to work the traffic, and the third in reserve.

With a Four Minutes' Service, fourteen cars will be simultaneously in motion. The conductor will consist of 1in. gas pipe, with a 19 strand No. 11 bare copper cable. At the depot there will be three dynamos, each having an output of 60 horse-power (electrical), and three steam engines, each of 80 horse-power, two to work the traffic, the third being in reserve.

Capital Outlay.

In estimating the cost of plant required to operate this line, I leave out of account the cost of buildings and permanent way, as both items are approximately the same as for horse traction. The building for the machinery will be less costly than the equivalent stabling; but, on the other hand, the permanent way will be slightly more expensive for electrical traction on account of the greater care which will be required in making good electrical connection between adjacent rails and the side rails, and the central channel girders.

Thus, we may take it that the total expense will remain about the same. As regards the cost of the central channel, I take this to be £2,000 per mile, which I understood is the figure arrived at by Mr. Lineff, from his actual expenditure incurred on account of the central channel on experimental line.

Cost of plant and reserve gear, including foundations and labour for a service of

	8 min.	4 min.
Central channel	£12,000	£12,000
Conductor	2,280	3,060
Boilers, engines, belt, feed-heaters, &c.	2,200	3,500
Dynamos, switch-blocks, instruments, &c.	1,000	1,500
Cars fitted with motors and gear (£350 each)	2,450	4,900
Contingencies	1,070	1,540
	£21,000	£26,500

Annual Working Expenses.

Coal, water, oil, &c.	£660	£1,100
Wages, including drivers	1,200	2,000
Maintenance channel and conductor, 5 per cent.	715	755
Maintenance cars (£70 each)	490	980
Maintenance steam plant, 7½ per cent.	165	265
Maintenance electric plant, 10 per cent.	100	150
Stores	200	300
Supervision and general expenses	470	650
	£4,000	£6,200

LEGAL INTELLIGENCE.

Fyfe v. Gwynne.

In the Court of Chancery, on Friday last, a motion came before Mr. Justice Denman, in which the plaintiff, suing on behalf of himself and all other shareholders of the Pilsen-Joel Electric Light Company (Limited), asked that an alleged agreement for the sale of the undertaking of the company to the defendant Gwynne, stated to have been adopted at a meeting of the shareholders of the company held on August 16, 1888, might be declared fraudulent and *ultra vires*, and not binding upon the company, and for an injunction to restrain three of the directors of the company, Mr. Horace William Scriven, Mr. Wheatley, and Mr. Rawson, from carrying out or proceeding with the alleged agreement, and to restrain the defendant, Mr. James Eglington Gwynne, from entering into possession, dealing with, or disposing of the property of the company, and for the appointment of a receiver. The Pilsen-Joel Electric Light Company (Limited) was formed in 1882 for the purpose of working a number of patents connected with electric lighting, and there were 430 shareholders, holding 22,000 shares, and 12s. per share remained uncalled. The plaintiff was the holder of 665 shares in the company. The company held thirteen patents for electric lighting, and had three stations for installation—one at Holborn, one in Stanhope-street, and one at Bethnal Green Museum, and at each station the company had considerable engineering plant. Amongst other contracts the company had one for lighting the Bethnal-green Museum, for which they were paid £1,200 a year by the Government, and altogether the income of the company was not less than £5,000 a year. The plaintiff stated in his affidavit that no less than £87,000 had been placed in the hands of the directors, in addition to the income which they had received. Prior to June of the present year great dissatisfaction had been felt by the shareholders with regard to the management of the company, and on June 27 a committee, consisting of four shareholders—the plaintiff, Mr. Parish, Mr. Phillips, and the defendant Gwynne—and the directors, was appointed to see whether a sale of the undertaking of the company could not be effected. The committee advertised for tenders, and the only offer received was from Mr. Gwynne, to take over the assets and liabilities of the company for the price of £4,500. The plaintiff strongly objected to that offer being accepted, on the ground that it was an inadequate price; but the committee resolved to accept it, and called a meeting of shareholders for Aug. 16, at which the offer was accepted. The plaintiff alleged that the meeting was not a valid one, there being only 27 shareholders out of 430 present at the meeting, and of those 13 only voted in favour of the resolution and 12 against, two not voting. On behalf of the defendants it was alleged that Mr. Gwynne's offer was the only one received, and that it was a fair and reasonable one. It was admitted that the income of the company from its contracts was £5,400 per annum, but it was alleged that the expenses of carrying on the company came to more than that amount, and that a loss resulted.

Mr. Kennedy, Q.C., and Mr. Pochin appeared in support of the motion; Mr. Marten, Q.C., and Mr. M'Laren for Mr. Gwynne; and Mr. Millar Q.C., and Mr. Rawson for the directors and for the company.

His lordship granted the injunction in the terms asked.

PATENT RECORD.

RECENT APPLICATIONS FOR PATENTS.

Note.—*The undermentioned applications are not open to public inspection until after the acceptance of the complete specification. The names within parentheses are those of communicators of inventions.*

11,766. F. James. London. An improved electro-ozone producing apparatus. August 15, 1888.

11,779. E. E. de Facien. London. Improvements in galvanometers. August 15, 1888.

11,782. E. Correns. London. Means for disengaging the regulating mechanism of electric arc lamps and clockworks which disengage by electricity. August 15, 1888.

11,793. W. Woodall (trading as J. Macintyre and Co.). London. Improvements in fittings for electric bells. August 16, 1888.

11,809. A. H. Maurice, L. Carr and D. Owen. Cardiff. Improvements in electromotors and apparatus for measuring the electric potential of the earth and of its atmosphere, and of any other body or gas. August 16, 1888.

11,817. J. C. Hobbs. United States. Improvements in electric furnaces. August 16, 1888.

11,858. O. C. D. Ross. London. Improvements in electric batteries. August 16, 1888.

11,897. O. B. Schallenberger (United States) or W. P. Thompson, as a communication from G. Westinghouse. Electrical indicators. (Date applied for under Section 103 of the Patents, &c., Act, 1883, January 21, 1888.) August 17, 1888.

11,898. O. B. Schallenberger (United States) or W. P. Thompson, as a communication from G. Westinghouse. Electrical indicators. (Date applied for under Section 103 of the Patents, &c., Act., 1883, January 21, 1888.) August 17, 1888.

11,917. J. G. Lorrain. London. Improvements in or connected with the transmission of electric energy. August 17, 1888.

11,925. H. W. Edlin. London. Improvements in electrical switches. August 17, 1888.

11,929. G. Binswanger. London. Improvements in electrical indicators. August 18, 1888.

11,937. F. C. Lynde. Manchester. Improvements in apparatus for driving dynamos and similar machines for electrical purposes. August 18, 1888.

11,963. M. H. Smith. London. Improvements in or connected with electric rail or tramway systems. August 18, 1888.

12,010. C. F. E. Berg. Berlin, Germany. Electric signal lantern (the firm of Keiser and Schmidt, Berlin). August 20, 1888.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended August 24th, 1888, amounted to £5,229.

LANCASHIRE AND CHESHIRE TELEPHONIC EXCHANGE COMPANY.—The report of this company states that on the past year's working the profit is £32,466, which, with a credit balance of £1,497 remaining from previous account, makes a total fund of £33,963. After deducting from this sum bank interest, interest on reserve fund, and the interim dividend declared in February last, there remains a balance of £19,421. The directors now recommend a further dividend at the same rate as in February, making a complete dividend of 7 per cent. for the year ended June 30th, which will absorb £14,000, and leave a balance of £5,421. The directors propose that £3,000 of this shall be placed to the reserve fund (making a total reserve, including interest of £8,650), and that the remaining £2,421 be carried forward.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended August 24th, 1888, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company, were £4,367.

NOTICE OF REMOVAL.—We are informed that Mr. Alexander Bernstein, late of Commercial-road, Pimlico, has removed his works to Hamburg. His address in future will be—Electrische Fabrik, Mühlenkamp, Hamburg.

Offices—WINCHESTER HOUSE, OLD BROAD STREET, LONDON, E.C.

The principal objects of the Corporation are:—

1. Performing the duties of Trustee, Executor and Administrator.
2. The Insurance of Bonds, Shares and all other Securities lodged with the Corporation against risks of all kinds.
3. The Issue of Warrants and Certificates against Securities deposited, and making and procuring advances on such Warrants.

The Office of Trustee or Executor is to private persons usually a thankless post, involving much anxiety, time and money, and frequently leads to serious actual loss; whilst death, illness and change of residence necessitate frequent fresh appointments, and consequent expense to the parties interested. The Corporation undertakes all the duties of Executor, Trustee or Administrator for reasonable remuneration proportioned to the work and responsibility in each case.

The Corporation insures existing Trustees and Executors against all risks attending those positions, where the business is conducted by the Solicitors to their Trusts under the supervision of the Corporation, it not being the desire of the Corporation to interfere in any way with the duties of the family solicitor.

The Corporation acts as Trustees for the Debenture Holders in Public Companies.

For terms, &c., application should be made to the General Manager at the Company's Office.

GEORGE PEARSON, *General Manager and Secretary.*

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL SCIENCE, INDUSTRY AND ENGINEERING.

No. 538.—Vol. XXI. FRIDAY, SEPTEMBER 7, 1888. Price 4d.

NOTES.

From the opening sentences in his very admirable Presidential address in "Section G" we gather that Mr. Preece is not fully prepared to endorse the views of Dr. Oliver Lodge on lightning-flash phenomena. The nature and extent of his antagonism will doubtless be more fully disclosed in the discussion on the whole question which is about to take place. Mr. S. A. Varley also, who is writing an entertaining though somewhat *omnium gatherum* and decidedly dogmatic series of articles in a contemporary journal, finds much to dissent from in Modern Views of Electricity as expounded by Dr. Lodge. Without proposing to take upon ourselves the task of buttressing the theories of Dr. Lodge or Mr. Heaviside, we should like to offer a few remarks upon the present stage of the controversy. Mr. Varley goes so far as to avow his belief that "the surging of currents through lightning conductors, to which Prof. Lodge gives so much prominence, is more imaginary than real." Now, we take it that the discovery of the (sometimes) oscillatory character of the lightning flash is, *if true*, one of the most beautiful, and will prove to be one of the most pregnant, scientific discoveries of recent date. There is, therefore, all the more reason that it should sustain the closest scrutiny before it is allowed to take the place of an established canon of electrical science. At the present moment the history of the subject may be briefly summarised thus:—In 1847 Helmholtz (*Die Erhaltung der Kraft*) proved that, under certain conditions, a condenser discharge would assume an oscillatory character, and the theorem was extended by Sir William Thomson in 1855. In his Dr. Mann lectures before the Society of Arts early in the present year, Dr. Lodge showed some novel experimental results dependent upon this fact; and, moreover, he proved that some of the recorded phenomena of lightning—notably "side-flash" from earthed conductors—were of the same general character (see *Electrician*, June 22nd, 29th and July 6th, 1888). In August last Dr. Lodge showed further, in the *Phil. Mag.* (see also *Electrician*, August 10th), that under certain not unreasonable assumptions, the conditions of a discharge from a thundercloud would lie within the limits which determine the existence of oscillations. This is, in brief, the basis of the deduction which Mr. Varley has characterised as more imaginary than real, and which Mr. Preece scarcely thinks to be logically sound.

It should, however, be noted that the argument does not by any means rest wholly upon the mathematical treatment of quantities whose values are only assumed as reasonably probable—though the support which is furnished by such calculations is undeniably valid so far as it goes. On the contrary, we have striking experimental verification in the shape of the artificial reproduction of known and hitherto unaccountable phenomena which are sometimes attendant on the lightning flash. The exact nature and degree of the analogy between observation and experiment affords, of course, a legitimate ground for criticism; and we think it will be admitted that in a case like this, where the natural phenomenon necessarily takes place upon a scale of incomparable grandeur compared with the laboratory experiment, that the highest value attaches to the results of direct or indirect observation. It seems worth while, therefore, to draw attention to the fact that, other things being equal, an oscillatory discharge must have a greater total duration than a direct or continuous discharge. It is true that the numerous experiments carried out by Arago, and by others after him, have led to the conclusion that the duration of a lightning flash is not greater than one-thousandth of a of a second; but, on the other hand, Dr. Lodge finds that the period of oscillation in a special case which he investigated would have been of the order of one-millionth of a second; so that, although the theory does not by any means say that all flashes are oscillatory, yet some of those observed by Arago might still have consisted of many hundreds of such oscillations. Perhaps Dr. Lodge or Mr. Heaviside will be able to calculate the probable total duration of a visible oscillatory discharge under given conditions. The importance of the point is enhanced by the circumstance (which we recorded in our issue of the 17th ult., p. 458) that an observation recently made in France by M. Trouvelot furnishes ground for believing that a single flash on one occasion had a total duration of no less than three seconds at the least. We are glad to learn that M. Trouvelot intends to follow up the question of duration by aid of the camera, and it would seem certain that such observations would throw much additional light upon the whole question.

We are a little surprised to learn from Mr. Preece that "the engineer and the physicist are completely at variance" on the question of "What is Electricity?" If this be so we take it that the disagreement can only be on a point of nomenclature. Electricity to the physicist is a term which, when standing alone, refers to that entity which we measure quantitatively in coulombs or dynamically in amperes. (We must, respectfully but firmly, decline to adopt Mr. Preece's new-coined term "coulombism," which is indeed, to our ears, what Walt Whit-

Digitized by Google

man calls a "barbaric yawp.") But Mr. PREECE says that "the engineer regards electricity, like heat, light and sound, as a definite form of energy." It would follow immediately that if electricity give rise (say in an incandescent lamp) to a definite amount of energy in another form, as heat or light, a definite amount of electricity must itself disappear in the process—for of course the conservation of energy is not called in question. But in reality no electricity disappears on passing through an incandescent lamp. The current on each side of the lamp is of identically the same value; *ergo*, electricity is not a form of energy. But Mr. PREECE is necessarily familiar with this reasoning, and we gather that he chooses to reserve the term electricity for the product "C E"—which we should call "electric energy." When, however, we remember that engineers are already perfectly familiar with "energy" as consisting of two factors, a "quantity" and a "pressure," it has always seemed to us an advantage rather than otherwise that electric energy should be capable of the same form of expression as that derived from air, or water, or steam. If, however, an engineer wants a working definition of electricity (in the more usual sense of the term) he may be well content to say that electricity is "a vehicle of energy." This is indisputably true, and does not commit one to any assertion as to the identity of electricity either with luminiferous ether or with any other form of matter. It even leaves the door open for the assumption that electricity is simply *sui generis*, although capable of interacting both with ether and with matter.

IN connection with this question, which, like all ultimate problems, is apt to become more and more unintelligible the more closely it is examined, it is worth while to recall a suggestion of Prof. CLIFFORD'S, made many years ago (we believe it will be found in the *Camb. Phil. Trans.* for 1870 or 1871). CLIFFORD suggested that if we assumed space to be of four dimensions, then it might be imagined that a flow of electricity involved or was determined by a local bending of our ordinary space of three dimensions. The equations which arise from such a proposition are, he tells us, precisely similar to those of electro-magnetic induction and its propagation. We commend this idea to the mathematicians to whom we are already so vastly indebted for the proof that in space of four dimensions a straight line is not necessarily the shortest distance between two points, that (as Prof. NEWCOME showed) a solid ball may be turned inside out without stretching or tearing, that no knot (as KLEIN showed) can there be tied in any string, but (as Prof. S. P. THOMPSON recently informed us) any amount of knots can be tied in a line of force.

PROFESSOR FITZGERALD, in Section A, presented a most valuable and profoundly interesting exposition of the recent work of HERTZ, who has detected the phenomena of interference in electro-magnetic waves. This is an *experimentum crucis* which is sufficient single-handed to overthrow for ever the advocates of the "action-at-a-distance" theory, if any such remain. Prof. FITZGERALD characteristically omits any reference to his own earlier work in this direction, but at the Southport meeting of the British Association in 1883 he read a Paper "On a Method of Producing Electro-Magnetic Disturbances of Comparatively Short Wave Lengths," wherein he showed how extremely small wave lengths might be obtained by the discharge of a condenser through a circuit possessing a suitable time-constant. He also pointed out that by this means we might fill up the whole existing gap between the rates of vibration of sound and light. It is upon this basis that HERTZ has been able to achieve his remarkable success.

PROFESSOR AYRTON'S lecture on the Transmission of Power at Bath this (Friday) evening will afford one of the most, if not the most, complete exemplifications of the conversion and transmission of power by electricity which has ever been given. Very elaborate preparations have been made for the running both of motors, alternators, transformers, motor-generators, and continuous-current dynamos on the platform of the hall. Amongst the types of apparatus to be exhibited may be mentioned the Thomson-Houston, Brush, Immisch, Paris and Scott, and others. If the good ship "Britannic" arrives in time we *may* see a Tesla motor. Power is supplied by a Thomson-Houston 18-lighter, driven by a portable engine in a temporary shed outside. From a technical point of view, the most interesting experiment that will be shown is the running of two Immisch constant-current motors on a Thomson-Houston circuit. These two motors are self-governed, and the loads can be independently varied without affecting the speed.

THE reduced tariff for inland telegrams having been in operation during two complete years, the POSTMASTER-GENERAL, in his Annual Report for the year ended 31st March, 1888, is able to make a comparison showing the progress of telegraph business with popular prices. During 1887-8 the number of messages affected by the new tariff—that is to say, inland messages exclusive of press messages—increased by 7·45 per cent. over the previous year's total, while the receipts increased by 6 per cent. The annual deficit, which last year was larger, we believe, than it had ever been has this year fallen considerably, being rather lower than it was five years ago, before preparations were made for introducing sixpenny telegrams. This year's deficit is, in fact, a little less than the annual interest on the original purchase money; in other words, were it not for the interest still charged to it the telegraph service would now show a balance on the right side.

IT has often been suggested that this charge for interest ought to be discontinued, and we certainly cannot see the good of debiting the Postal Telegraph Department with it year after year. Should business go on improving at the present rate for another four or five years, the net receipts will about cover the interest on capital, but not the arrears, which now amount to such a very large sum that not even the Treasury can ever hope to get it paid back again out of profits on telegraph business.

IN this issue we bring to a conclusion the very interesting Paper by Mr. SIDNEY EVERSHED on "Electric Traction on the Inner Circle." Putting aside the question of accumulators,

Digitized by Google

which (with one singular and to us unaccountable exception) no competent electrical engineer has seriously contemplated, two conclusions at least have, we think, been made perfectly clear. First, that electric traction is a practical and an economic possibility on the metropolitan railways. Secondly, that it will demand the fullest consideration on the part of the most able and best-informed engineers before such a project can be carried to a successful issue. As in so many other engineering problems, we have to face the difficulty of adapting new proposals to existing conditions; but that this difficulty can be successfully grappled with we make no doubt whatever. And provided a well-considered scheme be adopted, we are equally confident that the financial results will be such as to fully justify the necessary addition to the capital account of the railway companies. It is most unfortunate that the Circle line should belong to two separate companies, whose mutual hostility is apparently irreconcileable. We fear that in reality nothing whatever will be done (at least, on the main line) until either the concerns are amalgamated or their long-standing feud has been extinguished. The Metropolitan Company possesses an unchallenged right to run its trains over the District line by means of any motive power whatever; but of course it has no power to interfere with the permanent structure of that portion of the line. This fact no doubt accounts for the circumstance of Sir EDWARD WATKIN being bitten by the accumulator idea, but it does not account for a responsible firm of electrical engineers being found to back him up. Meanwhile we learn that the District Company is thinking of trying a conductor system on the branch line from Earl's Court to Putney Bridge. There are some heavy gradients on this line, but there is no reason why electric traction should not be completely successful.

IF Mr. WILLIAM WEBSTER's present anticipation that over a million gallons of sewage can be dealt with in twenty-four hours by an expenditure of 25 horse-power and one grain of iron per gallon (say six or eight shillings' worth of iron per million gallons) be capable of actual realisation, then we think that the electrolytic treatment of sewage will very soon become an important branch of electro-technics. Mr. WEBSTER has such faith in the efficacy and economy of his process that not only is he erecting works at Crossness, at his own expense, to deal with one million gallons per diem, but he has also publicly expressed his willingness to make experiment with the effluent fluid in his own proper person (*experimenta in corpore vili*) as a table water. For our own part, without undue scepticism, we shall prefer to base our judgment upon the results of six months at Crossness.

Turin.—The Turin authorities have just issued an order directing that no theatre is to be allowed to remain open after the 1st November unless lit by electricity.

The Acme Electric Works.—The Acme Electric Works, of Finsbury, have been so successful that they have been compelled to remove to more commodious premises at Ferdinand-street, Chalk Farm-road.

Personal.—Mr. James Swinburne has severed his connection with the firm of Crompton and Co. (owing to the expiration of agreement). Mr. Swinburne, whose address will still be at Chelmsford, intends to practise as a consulting electrical engineer.

City Office Lighting.—We hear that Messrs. Drake and Gorham have recently been entrusted with the lighting of Messrs. Johnson, Budd and Johnson's new city offices. The plant will consist of a set of Drake and Gorham accumulators, together with an Elwell-Parker dynamo and Otto gas engine.

The London Electric Supply Corporation.—This corporation is about to remove to 3, Adelphi-terrace, Strand. The new central generating station of the corporation at Deptford is rapidly approaching completion.

Theatre Lighting.—The proprietors of the Zarzuela Theatre, Madrid, have contracted with the firm of Bloss for the lighting of that building with the electric light. The installation is to cost $24,000 (£4,800), and the machinery will include two engines of 150 to 200 horse-power. The installation is to be complete early in October, and to begin working by the 15th of that month.

New South American Telephone Company.—A "Telephone Construction Company" has been formed in the United States, the object of which is stated to be the establishment of telegraphic and telephonic communication between the town of Valdivia, in Chili, at one extremity, and New York at the other, the line running through Bolivia, Ecuador, and Columbia.

The C. and C. Electric Motor.—The *Electrical World* gives a list of users who have adopted this motor in New York, where over 300 have been installed on the Edison, Brush and other circuits. The motors are used for driving sewing machines, boot and knife-cleaning machinery, small coffee mills, ventilating fans and other small electric-power purposes. Messrs. Shippey Bros. (Limited) are the agents for the system in this country.

Barnet.—The street lighting installation at Barnet, put in by Messrs. F. Joel and Co., commenced operations on Saturday last. There are at present 71 lamps of 32 candle-power. The wires are partly overhead and partly under ground. It is intended to provide for a private-house supply on a large scale on a separate system of mains. We understand that a considerable number of applications have already been received.

Mr. Blakesley's "Wandering Spark" Experiment.—A reference to this remarkable experiment occurred in our recent review of M. Planté's work on "Atmospheric Electricity." Mr. Blakesley now writes to correct an error in detail as follows:—"On looking at the Aug. 3rd *Electrician* I see you mention my experiment with the wandering spark as having been made on a photographic plate *after development*. For after read *before*."

Chinese Telegraph Convention.—Advices from China announce the signature of the Telegraph Convention between the Chinese Government and the two companies having cables to China. The text of the convention is the same as that which appeared recently in *The Times*. The only change is said to be that the Chinese may withdraw from the arrangement at any time in case they find it injuriously affects their own telegraph system.

Telephones for the King and Queen of Portugal.—We have recently had an opportunity of inspecting a special pair of telephones made by the Consolidated Telephone Construction and Maintenance Company for the King and Queen of Portugal. They are of the Gower-Bell pattern, into which several

Digitized by Google

important improvements have been introduced. The instruments are mounted on very handsome West India rosewood panels, and are altogether a very creditable piece of work.

Sewage Purification by Electricity.—Mr. Webster, whose system of sewage treatment by electricity has been already referred to in this paper, has found, since filing the specification of his patent, that the employment of positive electrodes of any other material than iron is of little or no practical value in treating sewage and similar impure liquids. He has therefore filed an amendment limiting the patent to the use of positive electrodes of iron, except in the case of the filtering process.

The Thomson-Houston Litigation.—It will be remembered that last week our New York correspondent informed us that the Thomson-Houston Company had been successful in establishing an action for infringement against the Citizen's Electric Light Company, using the American system, in regard to their use of the Thomson-Houston method of current regulation. We now learn by cablegram that the judge has granted an order restricting the American company from selling or shipping goods infringing this patent.

The Telegraph Manufacturing Company.—The Telegraph Manufacturing Company of Helsby have just completed another large addition to their already extensive factory. This is for the special work attached to vulcanised electric light leads, which the company can now supply to any possible specification. Extra lighting plant has also been added, making an installation of over 500 incandescent lamps for the lighting of the shops alone. The company are full up with orders, and in one department are running night and day.

Woodhouse and Rawson's Catalogue.—We have received from the Woodhouse and Rawson Electric Supply Company a copy of a new edition of their catalogue and price list of switches and cut-outs. The articles made by this company are doubtless already familiar to the majority of our readers. The new catalogue, however, still shows signs of the care and attention which is being devoted to the perfection of minor details. The various switch-boards which are described and illustrated for installations of various types and sizes will be found of special interest.

Otley Local Board.—At the ordinary meeting of the Otley Local Board, held on Monday night, Mr. Johnston suggested that the water of the Ellar Gill would be ample to supply power for the generation of electric light for the whole of Otley.—The chairman said he was perfectly willing for the Board's property to be put to any useful purpose, and he had no objection to inquiring into the practicability of the proposal. After further discussion a sub-committee was appointed to obtain information on the subject, and to report to the Board at its next meeting.

Electric Lighting at North Shields.—At a quarterly meeting of the Tynemouth Town Council, held in the Town Hall, North Shields, last Friday, Ald. Joseph Green moved that the Council make application for a provisional order for lighting the public buildings and streets of the borough with the electric light. Councillor A. N. Dodds moved as an amendment that the question be referred back to the committee for further consideration. After a lengthy discussion, voting on the subject resulted in five votes for the amendment and ten for the resolution, which was declared carried.

Copper.—Messrs. Merton and Co.'s copper statistics for August put the deliveries in France and England during the month at only 3,270 tons, being the lowest for at least three years past. They, moreover, remark that 3,875 tons were taken as delivered in July, whereas this quantity was merely transferred to Continental stock, and the net deliveries in July were only 5,891 tons. This explains the continued increase of visible supplies. In England, France, and afloat the stock is now altogether 86,701 tons, being probably the highest on record, and more than half as much again as the average stocks last year.

The Rouen-Havre Telephone Line.—The telephone service between Rouen and Havre has not hitherto proved a financial success. It was carried out by the Government at the solicitation of the Chambers of Commerce in those towns, who guaranteed a minimum revenue of 6,000fr. That sum has never yet been earned, and the Chambers of Commerce have always had to make up the deficit. They now wish to terminate the arrangement, and refuse to pay the loss in 1887, on the ground that the service does not give satisfaction. The Government has commenced proceedings to compel them to carry out their engagement.

Brussels.—During a violent storm on the 25th July last a fire broke out at the Hôtel de Ville. A strict investigation as to its origin was made by Professor Courtois, and it was discovered that the fire arose from the sparking which took place between a lightning rod and a piece of iron underneath the roof. This sparking set light to some woodwork and caused the fire. Professor Courtois does not attribute this occurrence to any defect in the Melsens conductor, but simply to the fact that M. Melsens' instructions were not carried out in their entirety, a few of the iron supports of the roof being left unconnected to the lightning conductor.

Electric Light for Railway Signalling.—According to the *Railway World*, electric lamps are now used in place of oil lamps in the railway yard at Oakland, Cal., with every appearance of economy and improved service. Sixteen candle-power lamps, run at only 12 candle-power, are employed, the reduced candle-power insuring a long life for the lamp. These lamps, without any difficulty or attention other than occasionally cleaning the glass lens on the outside of the lantern, have been burning over 2,600 hours up to date; and, according to Mr. Slater, they are probably good for another year. The current is furnished from arc machines, and the lamps placed in multiple series.

The Manchester Multiple Switchboard.—After the annual meeting of the Lancashire and Cheshire Telephonic Exchange Company at Manchester, on Tuesday last, a number of gentlemen accepted the invitation of the directors to inspect the new switch room arrangements. All the wires are now brought to the one central office at the Royal Exchange, where a fine multiple switch-board, capable of accomodating, if necessary, 4,200 subscribers, has been erected. Upwards of 100 miles of wire is used in joining up the various sections, and some 65,000 soldered connections have been made. The switch room is 120ft. long by 24ft. wide, and is thoroughly well ventilated, warmed, and lighted.

Vienna.—The electric lighting of the Court Theatre at Vienna has now been completed. All parts of the building—stage, auditorium, and corridors—is brilliantly illuminated. Every precaution has been taken against accident, and arrangements of the most elaborate character are provided for switching the light on and off in particular parts of the building. The total display includes over 5,000 lamps of from 10 to 40 candle-power each. Arrangements are also made for tinted lamps, by means of which coloured effects will be produced, instead of by the old clumsy use of chemical compositions. This splendid building has now cost about £2,400,000, and it is one of the finest theatres in the world.

Digitized by Google

The Postmaster-General's Report.—According to the recently published report of the Postmaster-General, the total number of telegrams forwarded during the year ended 31st March last was 53,403,425, being an increase of 3,159,786 over the year 1886-87. The total for 1870 was 9,850,000. The London local messages show an increase of 13·8 per cent., the total number being 4,337,907. The total number of telegraph offices in the United Kingdom is now 6,810, 257 new ones having been opened during the year at post offices and 39 at railway stations. Of the 1,745 lines of wire entering the General Post Office not one is overhead. The use of copper wire has been prevented for the present by the abnormal rise in the price of copper.

Dublin.—Last week Major Marindin, C.E., C.M.G., attended at the City Hall, Dublin, on the part of the Board of Trade, with reference to the local inquiry which had been sought for by the Alliance Gas Company, regarding an application made by the Corporation for powers to light the streets with electricity, utilising for the purpose the water power, the property of the Corporation, at Island Bridge Mills. The inquiry became purely formal, as the gas company had decided not to persevere in its opposition to the scheme, and the tramway company, which had also raised objections to the granting of the license, finally determined not to proceed any further in the matter. The inquiry was therefore limited to a clause sought for by the Port and Docks Board for the protection of bridges and other works under its care. It is anticipated that the license will be issued without further delay.

Dumfries.—Last Friday afternoon the introduction of the telephone into Dumfries was formally inaugurated. A luncheon took place in the ball room of the King's Arms Hotel, to which a number of gentlemen, including subscribers and the leading tradesmen and merchants of the town, were invited by the manager of the National Telephone Company. Mr. Bennett, general manager for Scotland, made a very telling speech, and the proceedings were brought to a close by a practical demonstration of the powers of the telephone. A violinist at Maxwelltown was asked to play a selection of Scotch airs, and the music could be distinctly heard in the ball room by means of the receivers. All the subscribers, numbering some 34, are now in connection with each other, and the exchange has already been frequently in use. Dumfries is not at present in connection with any other town, but it is intended before long to connect it southward to Carlisle and northward to Ayr and Glasgow.

A New Soft Solder.—According to an American paper, a soft alloy which adheres so firmly to metallic, glass and porcelain surfaces that it can be used as a solder, and which is invaluable when the articles to be soldered are of such a nature that they cannot bear a high degree of temperature, consists of finely pulverised copper dust, which is obtained by shaking a solution of sulphate of copper with granulated zinc. The temperature of the solution rises considerably, and the metallic copper is precipitated in the form of a brownish powder; 20, 30, or 36 parts of this copper dust, according to the hardness desired, are placed in a cast-iron or porcelain-lined mortar and well mixed with some sulphuric acid having a specific gravity of 1·85. To the paste thus formed are added 70 parts (by weight) of mercury, constantly stirring. When thoroughly mixed, the amalgam must be carefully rinsed in warm water to remove the acid and then set aside to cool. In ten or twelve hours it will be hard enough to scratch tin. When it is to be used, it should be heated to a temperature of 700° F., when it becomes as soft as wax by kneading it in an iron mortar. In this ductile state it can be spread upon any surface, to which, as it cools and hardens, it adheres very tenaciously.

The Lighting of Eastbourne.—At the recent Lighting and General Purposes Committee meeting of the Eastbourne Town Council, the following letter was read from Mr. Henry Towner, secretary of the Eastbourne Electric Light Company (Limited): —"Aug. 20.—My directors have to-day considered your letter of the 14th August, and have come to the conclusion that they cannot supply the Parade arc lamps at less than £35 (thirty-five pounds) per lamp per annum. My directors desire me to add they are fully sensible of the support the company has always received from the Corporation, but they feel the Council would not wish them to enter into a contract which would be a source of loss to the company. The price of £35 per lamp gives but a narrow margin of profit. The directors are quite prepared to prove the accuracy of the figures they have quoted as to the cost of production of the light to each lamp, and when I point out to you that the works are open and the machinery running up to one o'clock each night, it will at once be seen that the difference of half an hour proposed by you is of very little practical account to the company.—Yours faithfully, Hy. Towner, Sec." It was resolved "That this committee cannot see their way to recommend the Council to renew the contract for lighting the Parades by the electric light at the rate of £35 per lamp per annum, at the expiration of the present contract, the Electric Light Company having definitively refused the compromise proposed by the Council."

Norwich.—At the last meeting of the Norwich Town Council Mr. Squirrell moved "That a committee be formed, to be called the Lighting Committee, and that it should forthwith inquire into the cost and method of electric lighting in Brighton, Taunton, Eastbourne, Poole, Bradford, and any other towns in which electric lighting is in use, and report to the Council at its next meeting." His object in bringing this question before the Council was that they might be posted up with the fullest information as to the improvements and progress of electric lighting. Since they tried the experiment of the electric light in Norwich he believed great improvements had been made in the methods of lighting, and the Council ought to have ample information on this subject. In twenty towns in England electric lighting had been established. He moved that the committee should consist of the Mayor, Sir Harry Bullard—who had recently had some experience of the electric light—Mr. Hackblock, Mr. Saul, Mr. Cunnell, Mr. Holmes, and himself.—Sir H. Bullard, in seconding, said this committee would be very useful, and he thoroughly agreed with the resolution. Material improvements in electric lighting had been made since the experiment was tried in Norwich; and the failure of that experiment was due to the fact that it was only directed to public lighting. The point to be aimed at was to have the light so that it could be supplied to shops.—Mr. Hackblock said at present the Corporation had no powers, for their provisional order had expired; but Sir H. Bullard thought the Corporation could apply for such powers under Mr. Chamberlain's Bill.—After a few remarks from Mr. Watson the motion was adopted.

Collisions at Sea.—Mr. J. H. A. Macdonald, of North Berwick, writes to *The Times* of September 5th as follows: —In thinking the matter over I fell upon an idea which, as it has received four awards in electrical and life-saving exhibitions, and was the means of obtaining for me the membership of the Society of Telegraph-Engineers, may be thought worthy of publication in the present correspondence. An

Digitized by Google

electric light with holophote reflector, similar to what are known as search lights, is placed on the bridge, under the control of the officer in command. The handle by which this light can be moved is regulated absolutely by the position of the helm. If the helm is amidships it is held firmly in its place and cannot be moved. If the helm is put to port, the detent which locks the handle on the starboard side is removed, and the light can be swept over the water from amidships to starboard, the pencil of light and its reflection on the water giving the same signal to the other vessel as the driver of one vehicle meeting another can do with his hand. When the light has completed its sweep to starboard it is automatically shut out, and is not again exposed till the handle is brought amidships, when it can again be swept to starboard, and this can be repeated as long as the helm is to port. *Vice versâ*, if the helm is put to starboard, the light can be swept from amidships to port. The light thus sweeps the water over which the vessel will go in paying off. It is thus obvious that the pencil of light distinctly informs the other vessel of the direction in which the coming ship is heading at the moment, and of the fact that she is paying off either to port or starboard.

Cheltenham.—At a meeting of the Cheltenham Town Council, held on Monday last, the Electric Lighting Committee reported that they had held two meetings. At the first, which took place on the 13th ult., it was resolved "That it is desirable that the lighting of the streets by electricity be carried out by the Corporation rather than by contract with a company or private individuals, if this course can be adopted at no large increase of cost, it being the opinion of the committee that the creation of another private monopoly to be hereafter purchased by the town should, if possible, be avoided, and that the retention of the supply under the control of the town will secure greater efficiency; that the Town Clerk be requested to report on the legal position of the Town Council in the matter, and as to what powers it will be necessary to obtain to enable the Corporation to lay down the proposed service and supply private individuals with the light, and what steps it will be necessary to take to obtain such powers; and that he be asked to make inquiries with the view of obtaining the professional services of a competent expert to advise the committee as to the installation; that the Borough Surveyor be requested to report what sites now belonging to the Corporation are available for generating stations."—Meeting again on August 31st, the committee received a report from the Town Clerk, prepared in accordance with the terms of their instruction. The Borough Surveyor also reported, suggesting sites that might be utilised for the erection of the necessary buildings and apparatus for the proposed installation. The Town Clerk laid before the committee the draft of a letter to the gas company, which was approved and ordered to be sent to the clerk of the company; and the further consideration of the matter was then adjourned. Mr. G. Norman proposed the adoption of the proceedings of the committee, and Alderman Simms Bull seconded. Alderman Parsonage thought that the Council and ratepayers were entitled to know what expense the scheme would involve, and after a lengthy discussion an amendment of Alderman Parsonage's was embodied in the resolution. As finally drafted, Alderman Parsonage's addendum was as follows: "That, except for the purposes of inquiry, the Electric Lighting Committee do, before any further step is taken, bring up an approximate estimate of the cost of their proposal." With this addition the minutes were unanimously agreed to.

Whitworth Scholarships for 1888.—The engineering scholarships founded twenty-one years ago by Sir Joseph Whitworth have undoubtedly been of the utmost value to this country in enabling young men of more than average ability to complete a course of practical and theoretical engineering which would else have been beyond their means. Sir Joseph Whitworth's munificent endowment permits an outlay of no less than £3,000 a-year for this purpose. From 1869, when the first competition was held, until 1879, the Whitworth scholarships were of the value of £100 a year, and tenable for three years. At first ten were awarded annually, but in 1873, in order to show the devotion of the scholars to the studies and practice necessary for mechanical engineering, the number of scholarships was reduced to six, and a system of extra payments was instituted on the results of examinations held during the tenure of the scholarships, so that the best scholar of the year's batch could obtain as much as £800 in all, and the others in proportion. From 1880 to 1887 the scholarships were awarded for one year only, and without bonus, there being usually one of £200, eight of £150, and sixteen of £100. The experience of past competitions led the Science and Art Department last year to again revise the rules for the administration of the Whitworth endowment. As before, candidates must be under twenty-six years of age, and have been engaged at handicraft for at least three years in the workshop of a mechanical engineer; but henceforth some of the awards are to be known as exhibitions tenable for one year, and others as scholarships tenable for three years. Both exhibitioners and scholars require to follow out a course of work or study satisfactory to the department. While doing so exhibitioners are permitted to hold posts of profit or emolument as well as the Royal exhibitions and national scholarships of the Science and Art Department, but scholars will be required to devote their time *entirely* to the prosecution of their education as mechanical engineers, and cannot hold Royal exhibitions or national scholarships. Exhibitioners and holders of one year scholarships are eligible for the three-year scholarships. An immediate effect of these changes has been to render the competition for Whitworth scholarships this year excessively keen. The awards have just been issued, and include four scholarships of £125 a year for three years, twenty exhibitions of £100, and ten of £50 for one year. We are glad to see that the Glasgow and West of Scotland Technical College, which, in racing phraseology, holds the record for Whitworth scolarships, has once again distinguished itself by carrying off no less than nine out of the 30 events. This year's successes comprise two scholarships of £125 a-year each for three years—the 2nd and 4th; six exhibitions of £100—the 3rd, 4th, 10th, 12th, 17th, and 20th; and one exhibition of £50—the seventh; total value £1,400. The 8th £100 exhibitioner was for several sessions a student here, so that the college deserves some credit for his success also. As showing the severity of the competition this year, we note that the first and third men were first in the Whitworth lists for 1887 and 1886 respectively, and the fourth man second in 1887; the second man does not appear to have been present at any previous competition. This makes the 32nd Whitworth gained by the students of this college at the last *five* competitions, making a total value of £4,250. For 1889 four scholarships of £125 a year, ten £100 exhibitions, and twenty £50 exhibitions will be open for competition in the following subjects:—Practical geometry, machine drawing or building construction or naval architecture, mathematics, theoretical and applied mechanics; sound, light, and heat; magnetism and electricity, inorganic chemistry, metallurgy, steam, and free-hand. Of these, practical geometry, mathematics, and theoretical mechanics are compulsory subjects, in which a certain pass must be obtained.

ELECTRIC TRACTION ON THE INNER CIRCLE.

BY S. EVERSHED.

(Concluded from page 501.)

The large difference between the maximum and average power required by each train, and the still larger variation in the current taken by the motors, is perhaps the most serious difficulty in applying electric traction on a large scale, and will therefore be dealt with first.

The necessity for this great variation in power is due simply to the fact that the motors have been assumed to work under the same conditions as are imposed on the present locomotives; indeed, had a different cycle of operations been proposed the variation in power or in current might not have been apparent, and no pains were therefore taken to conceal the difficulty by assuming the motors to work either at constant power or with constant current. The power used by a train is given by the equation

$$p = \mathrm{M}v\frac{dv}{dt} + kv,$$

in which k is the total tractive force necessary, and if the power is constant this equation integrated gives the relation between velocity and time thus :—

$$t = \frac{\mathrm{M}}{k}\left\{\frac{p}{k} - v - \frac{p}{k}\log_e\left(\frac{p}{k} - v\right)\right\}.$$

If this expression is expanded, we have

$$t = \frac{\mathrm{M}v^2}{2p}\left(1 + \frac{2}{3}\frac{k}{p}v + \frac{2}{4}\frac{k^2}{p^2}v^2 + \ldots\right),$$

from which it is clear that the curve between v and t is parabolic in form, becoming, of course, a true parabola when the friction is nothing. It need not be pointed out that no locomotive is worked under such conditions. On the other hand, if constant current is made a condition, the power is proportional to the speed, and the integral of the above equation becomes simply

$$v = \frac{h - k}{\mathrm{M}}t,$$

where h is the ratio of power to speed. This relation nearly represents the way in which a locomotive starts a train, but would only be true with electric motors for a few seconds after starting, as it would then be more economical to increase the power at a much greater rate until maximum speed was reached.

The times allowed for starting, running and stopping, have been obtained from observations on the present underground trains, and are only true for the lighter ones among them. In particular, it should be noted that the time allowed for stopping (10 seconds) is shorter than the average obtained from the writer's observations. Most of the engines are, however, able to reach full speed in 20 seconds. It is at least doubful whether motors will ever be made capable of working under these conditions, and it may be better to increase the time allowed for reaching full speed, and consequently diminish the power during the interval; this necessitates an increase in the maximum velocity, and since the time interval between stations is constant the total work done is increased, as also is the work done in stopping the train. For example, if we increase the time of acceleration from 20sec. to 40sec. while still maintaining the same average velocity, the maximum speed must be increased from 23 to 25·4ft. per second, or 17¼ miles per hour, and the time allowed for stopping must be increased, in proportion with the increase in v^2, to 12sec. It will be found on working out that the power required during acceleration is now only 146 W.H.P., as against 200 W.H.P. in the estimate made in the last article; but the power required during the remainder of the run from station to station is increased from 56·5 to 67·2, and the average power from 80 to 108 W.H.P., an increase of 35 per cent., necessitating a corresponding increase in the fixed plant; the difference would be even greater than this since the friction would be somewhat increased at the higher speed. It would evidently be more economical to increase the size of the motors, even at some sacrifice of average efficiency, in order to secure the great advantage of a rapid start and low speed, for it should be clearly understood that when a train of given weight has to be moved from one station to another in a given time the least total work is done when the train acquires its full speed in the shortest time, the variation in power being, however, a minimum when the total work done is a maximum, and it will certainly be easier to overcome a few difficulties with the starting mains and the motors than to obtain capital for additional fixed plant.

When one looks at descriptions of early railway sand locomotives one is amazed to find what clumsy expedients were sometimes employed for want of a really ingenious idea. Look at Stephenson's original reversing gear, for instance—what a terribly unmechanical affair it was, yet it served its purpose until someone thought of link motion. Or the old spring buffers, three or four feet long, to avoid shocks in starting and stopping, yet when Booth brought out his screw-coupling with right and left-handed threads everyone said, "Oh! of course." Again, what a nightmare of bellows and fans the old engineers suffered to get a draught until they turned the exhaust into the chimney! The present want of a mechanical variable gearing has only to become acute as electric traction develops, and the right thing will, no doubt, be forthcoming as perfect in its way as link motion, as simple as Booth's coupling, and as obvious, after it has been done, as the steam blast.

The different forms of gearing at present known, including Mr. Beaumont's exceedingly ingenious idea, are either too crude or too complex for everyday work; they correspond with the early locomotives, which pushed themselves along with legs, or laid down a short railway and then ran over it, or painfully hauled their clumsiness over the rough road by means of a rack and cog-wheels. Such ideas are generally laughed at; but, in reality, they are extremely useful, indeed invaluable, as the right way of doing anything is not often discovered until ten wrong ways have been investigated. On the whole, we may look forward confidently to a happy solution of this problem rendering a near approach to the theoretically best method of running trains with frequent stoppages not only possible but economical both in first cost and working expenses.

Since the total amount of plant required varies directly with the weight of the trains, it will be well to reduce the dead load as much as possible. In the case of the present locomotives, there is not the same inducement to reduce the train weight, as the engines themselves form a very large proportion of the total load. The weight of the carriages or cars might be very considerably reduced if the companies concerned only realised that their lines are more akin to tramways than railways. There seems no good reason for adhering to three classes on the Inner Circle at all events; it is very difficult to understand why a system of caste which has disappeared from the streets should still linger in what is, after all, only an underground street. The abolition of first-class coaches would alone effect a large reduction in dead weight, for taking the weight of the lightest rolling stock of which the writer has any knowledge, namely, that used on the South London lines of the Brighton Railway Company, we find third-class coaches weigh ·135 ton per passenger, second – ·151, and first – ·247. Now, if the Circle trains are made up to carry 300 second and third class passengers, with a dead weight of ·143 ton per passenger, the total dead weight is only 43 tons, plus, let us say, 8 tons for motors and 18 tons for passengers, we have a total load of only 69 tons, thus saving over 20 per cent. in the weight of the trains, and therefore in the first cost of the fixed plant, besides effecting a considerable reduction in working expenses and maintenance of permanent way; the rails, having no longer to bear the pounding of a 40-ton locomotive every two or three minutes, may weigh less than 90lbs. per yard; half that weight would be sufficient, one would think.

No sooner are the trains satisfactorily started than they have to be stopped. There is not much difficulty in doing this by friction brakes, as at present, the only change being in working them by air pressure maintained by a pump worked from one of the axles in place of the steam pump or ejector. But, of course, a train driven by electricity ought to have

Digitized by Google

electric brakes, or even stop itself by converting the motors into dynamos and restoring some of the energy of the train to the mains. That is in everyone's mind who has ever given a moment's thought to electrical railways, but when we have devoted two moments to the question, the answer seems less obvious. How much power can be saved by a dynamical brake, and how much is wasted in working a friction brake? We will endeavour to find answers to these questions. Still keeping to the arbitrary units of 90 tons for the weight of a train, and 15·6 miles per hour as its maximum velocity, the work the train is able to perform in stopping is 1,650,000 foot-pounds; as 10 seconds are allowed for this, the distance run before coming to rest will be 115ft., assuming, as before, that the average speed at this time is equal to half the maximum. Taking 15lb. per ton as the retarding force due to train friction, 155,250 foot-pounds will be spent in overcoming it, leaving nearly 1,495,000 foot-pounds available for reconversion. Now, if the gearing efficiency is ·85 and that of the motors working as dynamos under unfavourable conditions as to speed, load, &c., is ·6, the whole efficiency is only 51 per cent., so that about 760,000 foot-pounds for each stop made is all the return to the mains which can be reasonably expected. Even if the stop is made more slowly—in 20 seconds, for instance—the motors will have to work as dynamos under a heavy strain, and, considering that the distance run would increase nearly in proportion to the time, the energy available would be still less were it not for the fact that the maximum speed must be increased in these circumstances, the net result being that possibly 900,000 foot-pounds might be coaxed back into the mains during a stop. Now, the total energy supplied to the mains by the power stations to carry a train from one station to the next is over 9,000,000 foot-pounds, so that the electro-dynamical method of braking will only enable an economy of about 10 per cent. in power to be effected, under present conditions with known appliances be it observed, for, of course, the gearing which has been prophesied would put the matter on a different footing. Further, when we consider that a dynamical brake does not and never can fulfil all the requirements of railway working, a statical (friction) brake being absolutely necessary to keep a train standing on an incline, it really seems as though the play would never be worth the candle.

The energy wasted by a mechanical friction brake, though, of course, considerable, is not of much importance. The writer has roughly calculated the work to be done by a pump driven from an axle, in compressing air sufficient for one application of a continuous brake on a 90-ton train, and allowing ample margin for leakage, waste of power in friction, &c., not more than 50,000 foot-pounds will be necessary. But it may be said, and indeed Mr. F. Sprague, in his Paper on the Richmond tram line, has said it, we must use the surplus power in running down gradients to help trains up. This may be possible on a tram line with 5 per cent. gradients; but on the Inner Circle, where the ruling gradients are not more than one-tenth of this amount, and the maximum gradient only 1·43 per cent., there will be very few places where trains can become sources of power, since a gradient of ·5 per cent. is only equivalent to a tractive force of 11·2lb. per ton.

Although it would perhaps be unwise to abandon friction brakes, there is no reason why they should not be worked electrically. Considering the immense advantages any electric brake must possess over even a high-pressure air brake, it is not a little surprising that so little has yet been done in this direction. So far as the writer is aware, the Achard electric brake is the only one ever put to the test of experience on a practical scale. The simplest frictional brake would consist of an electro-magnet, with jointed pole-pieces embracing an iron drum on the axle, and serving as brake blocks. The magnet might be made to act directly on the wheel tyres, but this would require additional power to be spent in excitation to obtain sufficient induction through the wheels. An electric brake has one superlative advantage in that its action is absolutely simultaneous throughout the longest train, thus obviating all the shocks and strains on drawbars, and other serious evils attending the use of most air and vacuum brakes. An electric brake would not be quite instantaneous in its action, as anyone knows who has watched the slow increase of the current through the coils of a massive electro-magnet after closing the circuit.

It is perhaps premature to enter into the *pros* and *cons* of automatic blocking, but it should be noticed that no visual signals will be wanted in any case. Accidents from drivers misinterpreting or not seeing signals will become things of the past, for the most reckless driver will be unable to move his train over a blocked section where the power is cut off and the conductors short-circuited. There is a refinement of block-working for a line where trains are run at regular intervals, which, though impracticable under present conditions, is quite feasible with electric traction by conductors. The writer has only sufficient space at his disposal to briefly indicate the nature of it. To preserve the proper interval between the trains, it might be arranged that each train should vary, instead of cutting off, the power from the following train whenever it approaches within the prescribed distance; the following train would thus have its speed diminished until it equalled that of the train in front. Now, provided this can be done without wasting power in resistance, it is obvious that the slowest train on the line would find the conductors at the highest potential difference, and consequently its speed would be increased until it ran at the average rate. This system would obviate the present absurdity of trains starting and having, perhaps, just reached full speed, they are stopped either at an advanced starting signal or an intermediate block cabin, resulting in considerable waste of time and power. It would not necessarily interfere with the method described for preventing more than a certain number of trains from starting at the same time, nor would it prevent the adoption of a dead section behind each train as an additional security against accident.

In conclusion, whatever may be the precise details of the scheme eventually adopted, electrical traction must sooner or later displace steam on the Underground Railway, and the writer trusts he has succeeded in giving readers of *The Electrician* some idea of the magnitude of the undertaking.

REPLY TO PROF. ARMSTRONG'S CRITICISMS REGARDING THE DISSOCIATION THEORY OF ELECTROLYSIS.

BY SVANTE ARRHENIUS.

In his communication to the Electrolysis Committee of the British Association (printed in *The Electrician* for August 26th, 1887), Prof. Armstrong has honoured my views on electrolysis with a critical analysis from a chemist's point of view. In the following lines I will attempt to show how the chief objections that he has made can be removed, and also that his views present difficulties which greatly militate against their acceptance.

1 and 2.* Prof. Armstrong finds it difficult to explain why some single bodies, *e.g.*, silver iodide, conduct electrolytically, whereas other pure bodies, *e.g.*, water or hydrogen chloride, are non-conductors. We certainly are bound to assume that fused silver iodide is to a sensible degree dissociated into its ions, and that the dissociated parts of the non-conductor escape our observation. But it may be remarked that no exact comparison can be made between the two cases, silver iodide being examined at temperatures above 530° (the melting point of AgI), H_2O and HCl at ordinary temperatures, it being very probable that dissociation increases rapidly with the temperature. Also too much stress must not be laid on the behaviour of pure bodies or of concentrated solutions, as experience shows that dilute solutions are characterised by very remarkable regularities, analogous to those which obtain in the case of gases, and that these regularities vanish as the solutions attain a greater degree of concentration; indeed, there seems to be no connection between the facility with which compounds are electrolytically dissociated in dilute solutions, and the stability of

* The numbers correspond with same numbers in Prof. Armstrong's Paper above referred to, "Comparison Between the Views of Dr. Arrhenius and Prof. Armstrong on Electrolysis."

Digitized by Google

the same compounds in the pure state, as Faraday has already remarked. Because of the regularities which characterise dilute solutions, the dissociation hypothesis has reference almost exclusively to matter in this state, and has, in my opinion, very successfully explained a great many of its properties.

3. Prof. Armstrong asserts that solutions in absolute alcohol oppose a practically infinite resistance. This view is not supported by the recent investigations of Fitzpatrick and Hartwig, from which it seems to follow that "any neutral solvent renders electrolysis possible," in accordance with the demands of the dissociation electrolytic hypothesis.

4. According to Prof. Armstrong, on the dissociation hypothesis, both water and salt are be regarded as dissociated; nevertheless the dissociation hypothesis assumes that conduction takes place only through the agency of the atoms of the dissociated salt, and not at all through that of the water. From chemical facts, *e.g.*, the partial decomposition of certain salts into base and acid by large quantities of water, it is very probable that water is to a very slight degree dissociated into H and OH.* But experiments show also that this occurs to an extent so extremely small that it will perhaps for ever be impossible to detect it by measuring the conductivity of water. Also I have essayed to show that the only fact cited in favour of a sensible conductivity of water can be satisfactorily explained without this assumption. In the same manner, different electrolytes, *e.g.*, HCl and $C_2H_3O_2H$, are very differently electrolytically dissociated by the same quantity of water, so that the one conducts very well, the other hardly sensibly, but we know representatives of all intermediate stages between these two extremes, so that there is no ground for assuming anything but a quantitative difference. Experiments on the conductivity of pure water, or of dilute salt solutions, lead to the assumption that water is not dissociated to any perceptible degree. If, therefore, as Prof. Armstrong asserts, the opinion is common among chemists, that in the case of the electrolysation of ammoniacal solutions water is (sensibly) electrolysed, then is this opinion a remnant of old views now abandoned through force of incontestable arguments?

6. In his article Prof. Armstrong makes no objection to the dissociation electrolytic hypothesis, but says: "I do not mean for one moment to assert that anything which we know of the conditions on which chemical change depends negatives beyond question the dissociation hypothesis."

7. Prof. Armstrong interprets the figures of Lenz concerning the parallelism between diffusivity and conductivity of alcoholic aqueous solutions as an "almost conclusive argument in favour of his theory." It must be remarked that there are many exceptions to this rule. Thus, *e.g.*, $MgSO_4$ and cane sugar diffuse nearly at the same rate (Graham), although in aqueous solutions $MgSO_4$ is a good conductor, while cane sugar seems not to conduct at all; consequently, the two phenomena are not of the same order, as they should be according to Prof. Armstrong's hypothesis. "The diminution in conductivity and also in diffusivity, as the amount of alcohol is increased, is most striking. If the solvent be neutral, the substitution of alcohol for water should have little influence; but if, as I suppose, the solvent be active, alcohol being far less active than water, the effect to be expected is precisely of the nature of that observed." In coming to this conclusion a very important thing is lost sight of. The conductivity depends on two circumstances, viz., the degree of electrolytic dissociation and the friction which the ions must overcome in their passage through the solution. The first circumstance must, as Prof. Armstrong asserts, have but little altered in Lenz's experiments with diluted KI and NaI; the diminution in conductivity must consequently have chiefly depended on the increase of the friction with the quantity of alcohol, which is *à priori* very probable. Evidently one must expect that the diffusivity also diminishes as the internal friction increases, and in this manner the parallelism between conductivity and diffusivity in Lenz's figures is quite explicable by means of the electrolytic dissociation hypothesis.

8. "Why, then, should it (the electromotive force) not give direction to the moving molecules, if these are still possessed of 'residual affinity,' *i.e.*, if some portion of the original charge of the atom be still unneutralised?" According to this passage I cannot understand Prof. Armstrong to mean otherwise than that the molecules will be directed by the electromotive forces, and consequently themselves move along the lines of flow. This way of viewing the question would lead one to expect the molecules to separate at the electrodes; but it is found experimentally that not molecules but ions are transported to the electrodes.

9. Prof. Armstrong finds it difficult to explain why phenylpropiolic acid $C_6H_5.C\equiv C.CO_2H$ conducts better—*i.e.*, is more dissociated, than hydrocinnamic acid, $C_6H_5.CH_2-CH_2.CO_2H$. But there are other peculiarities, which, perhaps, are very nearly connected with this circumstance, viz., the physical properties (heat of combustion, refraction of light), which indicate that the triple union in $C_6H_5.C\equiv C.CO_2H$ is less firm than the simple union in $C_6H_5.CH_2-CH_2.CO_2H$.

10. The formula proposed by Prof. Armstrong—

$$C = E/R,$$

"C being the amount of change, E the intensity of the total chemical effect," and R the resistance of the solution in which the interaction takes place, is not verified by experience. Thus, in the case of the hydrolysis of ethylic acetate by means of bases, "the intensity of the total chemical effect" (E) must be but very little influenced by the presence of neutral salts; R, on the contrary, very much. But experience shows that "the amount of change" (the velocity of interaction C) alters but very little (for strong bases) if R be increased by addition of neutral salt from 1 to about 20. In the case of ammonia C decreases extremely rapidly, when R decreases in consequence of added neutral salt. These phenomena are easily explained by the electrolytic dissociation hypothesis, the velocity of interaction being proportional to the quantity of OH in the form of ion.

The arguments brought forward by Mr. Crompton on the conductivity of sulphuric acid seem to me not very convincing in favour of the view that hydration of H_2SO_4 should condition the electrolytic conductivity.* There is no reason mentioned why the second derivative d^2k/dp^2 (where k is conductivity and p concentration of the acid in per cents) should have angular points at the places mentioned; on the contrary, the author says that he had expected to find such angular points in the dk/dp curve, but when he did not find them there he proceeded to the examination of d^2k/dp^2. The author does not take heed of the errors of experiment; a search would probably have shown that these errors in many cases are of the same magnitude as d^2k/dp^2 itself. Further, the author does not find the same hydrates as Mendelejeff ($H_2SO_4 + 24\ H_2O$ not appearing in Mendelejeff's curve, $H_2SO_4 + 6\ H_2O$ not being marked by Crompton's curve). The part of Crompton's curve between H_2SO_4 and $H_2SO_4 + 2\ H_2O$ can hardly be considered as consisting of two straight lines, as the author asserts. The artificial nature of the proposed formula is manifested by the circumstance that they give very different values of k at the limiting points where two formulæ should be applicable. Moreover, there is a very important difference between the views of Mendelejeff and of Crompton. Mendelejeff says, "Ich habe schon lange die schwachen Lösungen als die interessantesten angesehen und dieselben dem zerstreuten oder verteilten Zustande der Materie in Dampfform an die Seite gestellt. Die bemerkenswerten Untersuchungen von van 't Hoff haben gegenwärtig dafür einen vollständigen Beweis erbracht," whereas, according to Mr. Crompton, dilute solutions are characterised by their irregularities.

The above observations will, I believe, suffice to show that the objections urged against the dissociation electrolytic hypothesis are unsatisfactory, and that the arguments in favour of the residual affinity hypothesis need a more convincing corroboration than hitherto given. On the other hand, the dissociation electrolytic hypothesis has latterly acquired a

* Wied. *Annalen*, XXXIII., p. 58, and *Phil. Mag.* (5), XXIV., p. 377.

* In saying this I wish not to deny that some (but very few) hydrates (*e.g.*, $H_2SO_4 + H_2O$, as Kohlrausch has stated) exert an influence on the conductivity, but only to say that the assertions of Mr. Crompton are to a very high degree exaggerated.

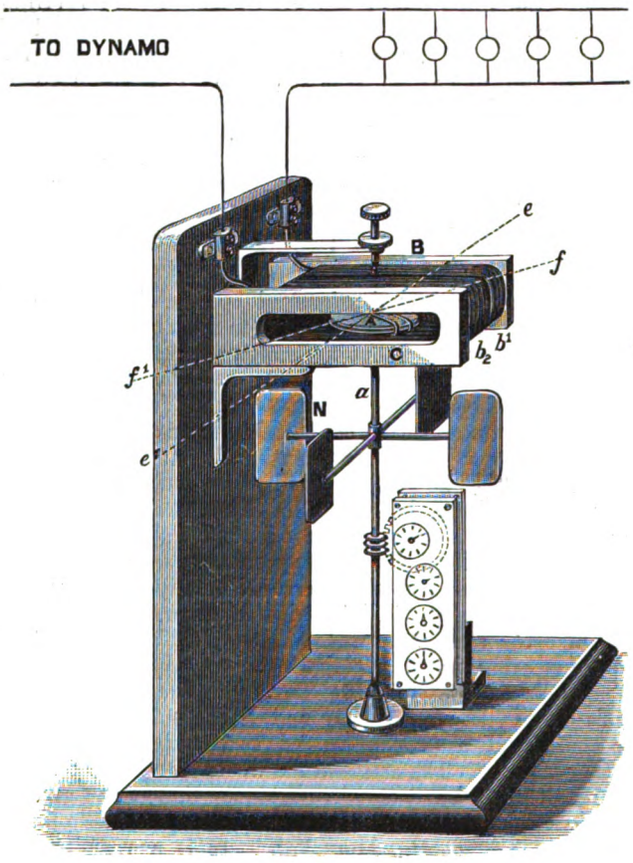
Digitized by Google

highly increased probability, as the lowering of the freezing point on addition of salts to water, and the additive properties of salt solutions, can be explained by it. In a preliminary notice Ostwald has announced that the conductivity of acids and bases can be calculated upon the basis of this hypothesis; and in a paper soon to be published in the *Zeitschrift f. Phys. Ch.* I will attempt to prove that the known facts regarding conductivity of mixtures, velocity of interaction and double decomposition between electrolytes can easily be accounted for on the same hypothesis.

Amsterdam, February, 1888.

THE SHALLENBERGER ALTERNATING-CURRENT METER.

We illustrate in the accompanying engraving a form of electric meter designed by Mr. O. B. Shallenberger, electrician of the Westinghouse Electric Company, and in which electrical energy is converted into mechanical motion, the rate of which



The Shallenberger Meter.

is directly proportional to the energy being consumed. We take our account from the *Electrical World* of New York.

The principal elements employed in the construction of the meter are—first, an armature of metal capable of rotation; second, an electric circuit, which is so arranged that when it is traversed by alternating electric currents a field of force is induced having a given polar line or axis with reference to the armature; and third, a circuit so related to the first circuit that currents are produced in such second circuit by the action of those in the first, the phases of which succeed those of the currents in the first circuit and set up for the armature a second field of force, the axis of which intersects that of the first. The armature may be built of soft iron, or of copper, or other non-magnetic metal, or it may be composed of a core of soft iron having a conducting circuit of other material surrounding.

Referring to the engraving, A represents a circular armature mounted upon a shaft, *a*, and placed within a coil, B. The coil is made in two sections, b^1, b^2, for convenience of construction, the shaft *a* passing between the two.

Alternating electric currents traversing this coil tend to establish a field of force whose polar line or axis is approximately in the direction *e e'*, at right angles to the shaft *a*. A second conductor, C, is placed in inductive relation to the conductor B and armature A. This conductor is closed upon itself. It is placed with its magnetic axis at an inclination to that of the coil B. Alternating electric currents, traversing the conductor C, establish a field of force for the armature, whose polar line or magnetic axis is approximately in the direction *f f'*—that is to say, inclined with reference to the polar line of the coil B. It is found in practice that when the coil B is traversed by alternating electric currents the armature will revolve.

In order to produce a rate of rotation of the armature proportional to the amount of energy supplied to the circuit, it is necessary that some retarding force should increase in its effect by the same law as that of the rotating effect produced by the current. If, for example, the tendency to rotation increases as the square of the current, then the retarding effect should increase as the square of the speed. Such a definite law of increase of retardation is secured by the application of fans or vanes, N, fixed to the shaft *a*. The resistance offered by the air to the rotation of these vanes affords the required retardation.

This meter is said to respond to the currents traversing the coils B in such a manner as to obtain a reliable and accurate measurement of the current, the number of revolutions performed in a given time being directly proportional to the current consumed during that time.

It is found, in practice, that the resistance of the coil B may be made very small, and the current consumed in operating the meter itself quite insignificant.

The number of ampere-hours are recorded by the registering train geared to the shaft.

We understand that this type of meter will be regularly employed by the Westinghouse Company in their central station work.

THE GAULARD-GIBBS' PATENT IN AMERICA.

The following is the judgment of the Circuit Court of the United States, District of Massachusetts, in equity, in the case of the Westinghouse Electric Company *v.* Sun Electric Company, *et al.*, which was delivered on the 7th ult. :—

This suit is brought to enjoin the defendants from infringing letters patent No. 351,589, granted October 26, 1886, to George Westinghouse, jun., assignee of Lucien Gaulard and John D. Gibbs, for improvements in methods and apparatus for the distribution and conversion of electric energy.

The case has been thoroughly and ably represented on both sides. The patent relates to that branch of the art of electric lighting known as the incandescent. The specification states that the "invention relates to the distribution of electrical energy for industrial purposes ; and it consists in an improved art or method and an organisation of apparatus, whereby the same is carried into effect, by means of which we are enabled to transmit from a central or supply station, through a main conductor, a primary electric current of comparatively small quantity, but of high potential, and at a point or points more or less distant, where the said electric energy is to be utilised, to transfer the energy residing in such primary current of high potential into one or more secondary currents of lower potential, but of greater quantity. . . . At a point where the electric current is to be utilised for any suitable purpose—as, for instance, in one or more incandescent electric lamps—we place one or more secondary generators or converters. The general principle of our secondary generator is analogous to that of the well-known inductorium, or induction coil, with this exception, that while the induction coil has heretofore usually been employed to transfer electric energy from currents of low potential and great quantity into currents of high potential and small quantity, the function of the secondary generator or converter, as applied in our invention, is precisely the reverse of this, namely, to transfer electric energy from currents of high potential to currents of low potential and increased quantity. We have constructed converters for effecting this result in a variety of forms, all of which involve the same principle. The most important and characteristic feature of our invention is that which renders it possible to make use of alternating and equal positive and negative currents of moderate quantity, but of very high potential in the primary or main line circuit, and to convert these into secondary or induced currents of much greater quantity, but of correspondingly lower potential at the place of consumption, which secondary circuits are employed to do the required work. Any required number of converters of the general construction described may have their primary circuits united with or included in the conductors leading from the primary generator. The manner of connecting such converters, whether in series, multiple arc, multiple series, or otherwise, will be understood by those skilled in the art to which our invention relates without the necessity of further explanation."

The specification then says that one arrangement is indicated in Fig. 3 of the drawings, which shows an arrangement of converters in series. Then follows this disclaimer: "We do not herein claim the connection of the converters in the line in any other arrangement than we have illustrated in the drawings." Fig. 3 of the drawings shows an arrangement of converters in series. The defendants connect their converters in what is known as the multiple arc system, which is quite different in construction and mode of operation from the series system.

There are five claims in the patent, the first being for the art or method, and the remaining four claims for the apparatus.

The first question which arises relates to the proper interpretation of the patent in view of the disclaimer. Undoubtedly, as originally drawn, the patent was intended to cover all forms of converters which transferred electric energy from currents of high potential to currents of low potential and increased quantity, whether connected in series, as indicated in Fig. 3 of the drawings, or in multiple arc or otherwise. The Patent Office refused to grant so broad a patent, and instructed the applicants that, in order to avoid an interference, they must confine the arrangement of converters to the series system, that being the arrangement shown in the article in *Engineering* of March 2, 1883, which the applicants declared contained a description of their invention. Thereupon the disclaimer was inserted. An examination of the file wrapper and contents discloses that the patent office believed this patent should be limited to the arrangement of converters in series, and that this was supposed to have been effected by the disclaimer ; otherwise an interference would have been declared. The patentees avoided such interference by inserting the disclaimer, and it is too late now to say that the disclaimer means in effect nothing. If we construe the patent to cover broadly a dynamo producing alternate currents of high potential with a single reducing converter, then the disclaimer is meaningless, because such construction would embrace converters connected in multiple arc or otherwise.

The patent states that the invention is for a system of electric distribution ; the true scope, therefore, of the invention is not confined to one converter, but to several converters arranged in a system, and, when the patentees disclaim all systems but the series, they should be held to it.

As we have said, Gaulard and Gibbs declare that the invention covered by the patent in suit is found in the article in *Engineering* of March 2nd, 1883. The defendants deny that the article describes converters which transform the current from high potential to low. Whoever may be right, it appears quite certain that the high potential of the primary, and the low potential of the secondary, or the long, thin primary wire and the short thick secondary wire, which become so important in the patent under consideration, are not specifically described or shown with clearness in the article in question. The system described in the article was a general one, and was intended to meet the conditions laid down in the English Electric Lighting Act, which provided that the "undertakers" shall not prescribe to householders and others to whom they supply the current the use of any particular kind or form of lamp. The Gaulard and Gibbs invention has a two-fold object, says the article ; firstly, it aims at rendering it practicable for undertakers to supply current at the most economical potential permitted by the terms of their provisional orders ; and, secondly, it is intended to make the user independent of the producer, and to enable him to apply the current he receives to any purpose he may please, such as arc lighting, incandescent light, the generation of power or of heat." If the article does show a converter which transforms electric energy from high potential to low, it is evident that Gaulard and Gibbs did not at this time regard this as a great discovery, or it would have been more clearly indicated. Undoubtedly the article was intended to outline a general system to supply to customers currents of high or low potential, as might be desired, by means of converters connected in series based upon the principle of the Ruhmkorff coil, but that this was to be accomplished by means of a primary current of high potential and secondary currents of low is not apparent.

Further, if the reducing converter, now made so important, was discovered by Gaulard and Gibbs in March, 1883, and constituted such a great invention, why did it not form the subjected matter of their subsequent American patent of April 29, 1884, and British patent of September 15, 1882 ?

These things go to prove that the prominence given to the reducing converter in the patent in suit was based upon something else than the article in *Engineering*. I am led to think that it was based upon the fact that, between the date of the article and the date of the patent in suit, other inventions had come to light, and that it was these improvements which induced Gaulard and Gibbs to set up the claim they make in their last patent.

In the patent granted to E. Thomson, July 14, 1885, the converters are arranged in series. The object of the invention was to provide a safety switch for the converters, but we there find described the primary or main current of high potential and the secondary current of low potential. The specification says : "The secondary coil is wound with such coarse wire, and the lamps used therewith are of such low volt potential as not in itself to produce dangerous discharges or shocks." Thomson seems to take it as a matter of course, in view of the prior state of the art, that there was no invention in reduction from high potential to low through a converter.

But the most important improvement was made by Zipernowsky and Déri in their English patent of March, 1885. This patent describes minutely a system of distribution by induction through potential-reducing converters combined in multiple arc, and it includes an alternating-current dynamo generating a current of high potential.

We see, then, that the state of the art in 1882, when the article in *Engineering* was written, and in 1886, when the patent in suit was issued, was quite different. It became very important, therefore, for Gaulard and Gibbs to obtain a patent for a single reducing converter, however it might be combined with others in a system. I think the importance given to this point in the patent an effort to expand the real invention of Gaulard and Gibbs, as contained in the article in *Engineering*, and that the patent office intended and did in effect limit the patentees to all they were fairly entitled to, namely, the arrangement of their converters in series in a system of electrical distribution.

By assuming that our interpretation of the effect of the disclamer is wrong, and that Gaulard and Gibbs are entitled under their patent to claim the exclusive right to a converter which transforms energy from high potential to low, in combination with a dynamo producing alternating currents, can so broad a claim be sustained in view of the prior state of the art ?

To uphold this position, of course Gaulard and Gibbs have to go back to the article in *Engineering* of March 2, 1883, as the date of their inventions, because this form of converter in combination with an alternating dynamo is clearly shown, as has been observed in the Thomson and Zipernowsky and Déri patents of 1885. But, admitting that the date of the invention was March 2, 1883, I have much doubt whether Gaulard and Gibbs could obtain a lawful patent for so broad a claim. The counsel for the plaintiffs in his closing argument admits that the induction coil or inductorium or converter, in its general sense, as a device used for taking off from the line at different points a portion of the electric energy, whether of the same or higher or lower potential, was well known. The article in *Engineering* states that the secondary generator or converter was based upon the same principle as the Ruhmkorff coil. In the English patent granted to Paul Jablochkoff, Nov. 9, 1877, we find described a system for producing and dividing electric lights which consisted in carrying a main alternating current round an unbroken circuit, and transferring its energy by means of induction coils to consumption circuits at the points where it was to be used. The converters are placed in series with one or more lamps in the secondary of each converter. But it is said that Jablochkoff contemplated a conversion from low to high potential, the reverse of Gaulard and Gibbs. At the same time it was well known that the converter would transfer energy from high to low, or low to high, as the primary wire was longer or shorter. Was it invention for Gaulard and Gibbs simply to reverse the coils and transfer the energy from high to low ?

In the English provisional specification of Edwards and Normandy, November 13th, 1878, the inventors propose to use either interrupted or alternating currents with a converter near every place where the light is to be produced. The specification says :—"At or near every point where it is required that a light shall be produced, we arrange a coil (or a series of coils) of insulated metallic wire or ribbon (preferably surrounding a bar or wires of soft iron), through which coil or coils the current from the principal wire first described can be passed when desired, or cut off by

Digitized by Google

means of a key or lever. Round or adjacent to each coil of insulated wire described we form one or more secondary coils of insulated metallic wire or ribbon, arranged so that the passage of the rapidly intermittent current of electricity, as described, through the primary coil or coils generates a corresponding amount of electricity in each of the secondary coils. In order to facilitate the production of the induced electricity, *and to diminish its intensity and increase its quantity*, we prefer making the coil or coils in which the electricity is induced of a number of insulated wires or ribbons made up into a bundle or rope, the ends of the wires or ribbons at each end of the bundle or rope being in metallic contact with each other, which united ends are then joined to the conductor, conveying the induced electricity." Here is found distinctly stated the principle of a reduction from high potential in the primary to low potential and increased quantity in the secondary, which Gaulard and Gibbs assert is their great discovery.

The patent to J. B. Fuller, Nov. 26, 1878, is for an improvement in induction apparatus for lighting by electricity. The invention embraces converters arranged in series like those of the patent in suit to be operated upon by an alternating current. It is not stated whether the potential is to be raised or lowered in the converters, but the drawings appear to indicate that it was to be raised.

In the English provisional specification of J. H. Johnson, Dec. 24, 1878, while the inventor contemplated the raising of the potential in his converters, yet he says "the apparatus may be connected together . . . in such manner as to augment either the tension or the quantity of the current."

Thomas A. Edison took out a patent May 28, 1883 (the application having been filed August 14, 1882), for an apparatus for translating electric currents from high to low tension. In his invention he uses a continuous current of high tension in the main circuit, and reduces it to a continuous current of low tension in the secondary circuit.

This incomplete review of the prior state of the art would seem to show that at the date of the article in *Engineering* there was no invention in a single converter which transferred energy from high to low potential, as distinguished from a conversion from low to high. It seems to have been assumed in prior patents as a matter of common knowledge that, by the laws governing the inductorium or converter, the electric force transferred could be either of the same potential or of greater or of less, as might be desired. It required something further, something that might be called invention, to solve the problem of a successful system for electric distribution. Gaulard and Gibbs undoubtedly believed that, in the article in *Engineering*, they unfolded to the world a description of a successful system. So far as their system was a new invention, and is incorporated in the patent in suit, they are entitled to be protected. But they are expressly limited by their disclaimer to the series system, and therefore the defendants who use the multiple-arc system do not infringe.

Without entering further into the defences raised, I am satisfied, for the reasons given, that the bill should be dismissed.

Bill dismissed.

SEWAGE PURIFICATION BY ELECTROLYSIS.*

BY MR. WILLIAM WEBSTER, F.C.S.

The question of the disposal of sewage has occupied the attention of engineers and chemists for many generations past, and regarded from a hygienic point of view, cannot be too thoroughly considered.

In this short Paper it is not my intention to criticise the many processes in use at the present time, as there is no doubt all are doing their best to solve the question; but I must protest against sewage farms, where sewage is allowed to percolate through the land without previous treatment.

It is quite ten years since I carried out my first experiments in electrolysis, but in those days the available electric apparatus had not attained such completeness as we now have in it. The chemical changes which take place in sewage when it is electrolysed depend chiefly on the well-known facts that water and sodium, magnesium, and other chlorides (which are always present in sewage) are split up into their constituent parts. Thus, we have at the positive pole chlorine and oxygen set free, and these elements are liberated in a nascent state, a condition in which they are intensely active, so that the organic matter in the sewage is rapidly oxydised and burnt up to innocuous compounds. So rapid is this action that I will now act on a little Crossness sewage, and produce a disinfecting liquid, which is nothing more or less than hypo-chlorous acid, the strongest oxydising agent that is known. To obtain this quickly I must separate the positive action from the negative by a porous diaphragm. At the negative pole I obtain ammonia, potass, soda, magnesia, &c. So strong is the action of oxide of chlorine that I have found no pressed carbon plates would stand its action. I am, therefore, compelled in practice to use cut carbon or coke. [Demonstration made.]

It was this fact that made me investigate the cost, and the result was, knowing that iron salts were of great use in precipitating organic matter in solution, that I experimented with iron electrodes, for the oxydising acids produced by this action being probably 100 times more active than any acids produced by chemical processes alone, it necessarily followed that the iron salt produced must have similar properties. The nascent chlorine and oxygen generated partly unite, and, with the water, form hypo-chlorous acid, the positive iron plate being attacked, and ferrous hypochlorite formed; but a portion of the hypo-chlorous acid attacks the organic matter, for it is well known that putrefying sewage has a strong affinity for oxygen.

To still further strengthen this action, I have lumps of carbon cast into the iron plates, thus securing a supply of the before-mentioned acid. The iron plates are common casts run direct from the furnace into this form instead of pigs, and are used for the positive poles, the negative plates being thin rolled sheet. The positive plates are gradually acted on by the acids produced, but the negative plates are not acted on, and will remain in the same condition for years; this is so well known that I need not enlarge upon it. I have estimated that the waste of iron at the positive pole is about 1gr. per gallon, but, of course, this entirely depends upon the electric current used. The hypo-chlorite of iron formed at the positive pole is acted on by the free ammonia, sodium, potassium, and magnesium hydrates, and the ferrous hydrated oxide precipitated. This particular oxide of iron has the property of combining with organic matter, and it is a peculiarity of this salt to take a white hue, and then by exposure to the atmosphere to become green, and ultimately an ochrey red colour.

The ferrous hydrated or protoxide of iron is so beautifully precipitated, one may say, in its most active condition by this electrolytic process, that it takes up more organic matter than if precipitated chemically, for by chemical precipitation the iron oxide carries a large part of the suspended matter in the sewage with it, but only traces of the dissolved organic matter. In the electrical process the whole of the matter suspended is carried with the oxide of iron, together with a considerable portion of the organic matter in solution, and, if necessary, the whole of the soluble organic matter can be oxydised. The precipitate itself is carried to the surface by the numerous bubbles of hydrogen issuing from the negative pole, and the effluent may be run off quite clear from below, or may be run with the precipitate into settling tanks, where the deposit will take place in from half an hour to two hours; the precipitate, being exceedingly flocculent, subsides readily. The sludge formed does not hold so much water as by chemical process, and presses without any addition of lime. The effluent is less alkaline than the natural sewage, and, if necessary, can be rendered neutral by passing through coke filters arranged in such a way that the electric current can be applied, thus further purifying the effluent and delivering it in such a state that, personally, I should have no objection in drinking it. The reason of the alkalinity being reduced is that a small quantity of free ammonia is carried off with the hydrogen gas at the negative pole, and also by the formation of hypo-chlorous acid. It is by means of this coke filter that potable water can be purified either on a large or small scale, and the treated sewage is not liable to secondary fermentation, nor does it form a precipitate when mixed with ordinary river water. The chlorides are slightly diminished in quantity, owing to the escape of nascent chlorine at the positive pole. The amount of soluble mineral matter is not increased in quantity, as in ordinary precipitating processes.

The chloride of lime of commerce is really hypo-chlorite of lime. It has been suggested that the hypo-chlorous acid may possibly be as objectionable in its after effects as the salts of lime; but this is not the case, as hypo-chlorous acid is an unstable compound, which, having delivered up its oxygen in oxydising organic matter, changes into hydrochloric acid, which neutralises the alkalinity of the sewage.

As I have already demonstrated that hypo-chlorous acid can be obtained in quantities by means of a porous cell enclosing positive pole, so likewise by enclosing the negative pole in a solution of ammonia, &c., can be obtained from the raw sewage.

I have brought with me a weak solution of the disinfecting fluid obtained from sewage twelve months ago; also a sample of an effluent eight months old. I have shown that the sewage can be purified to any extent, even to conversion into a disinfectant; it therefore only remains for me to enter into the question of cost, which I will do as briefly as possible, and it is just as well to mention that this will be partly ruled by the particular state of purity you require in your effluent.

The chief expense is the engine power. My experience up to the present time is limited to treatment of about 100 gallons of sewage at any one time; and from a large number of experiments I found it would be possible to treat this quantity with about one-third horse-power; the dynamo and engine were unsuitable for my experiments, as the dynamo was only fit for electric lighting, and the engine twenty-five years old—without a governor; I should, therefore, prefer to think the horse-power over-estimated. The time occupied in treating every 100 gallons varies from five to ten minutes. The consumption of iron was one grain per gallon; the cost of this is easily estimated when one knows the market price of

pig-iron. By kind permission of the Metropolitan Board of Works, I have erected works at my own expense at the Crossness Outfall of sufficient capacity to treat sewage at the rate of one million gallons per diem, as I have sufficient confidence in this process to risk the large outlay entailed. For this I have had an Edison-Hopkinson dynamo specially constructed, giving an output of 1,600 amperes and twenty volts.

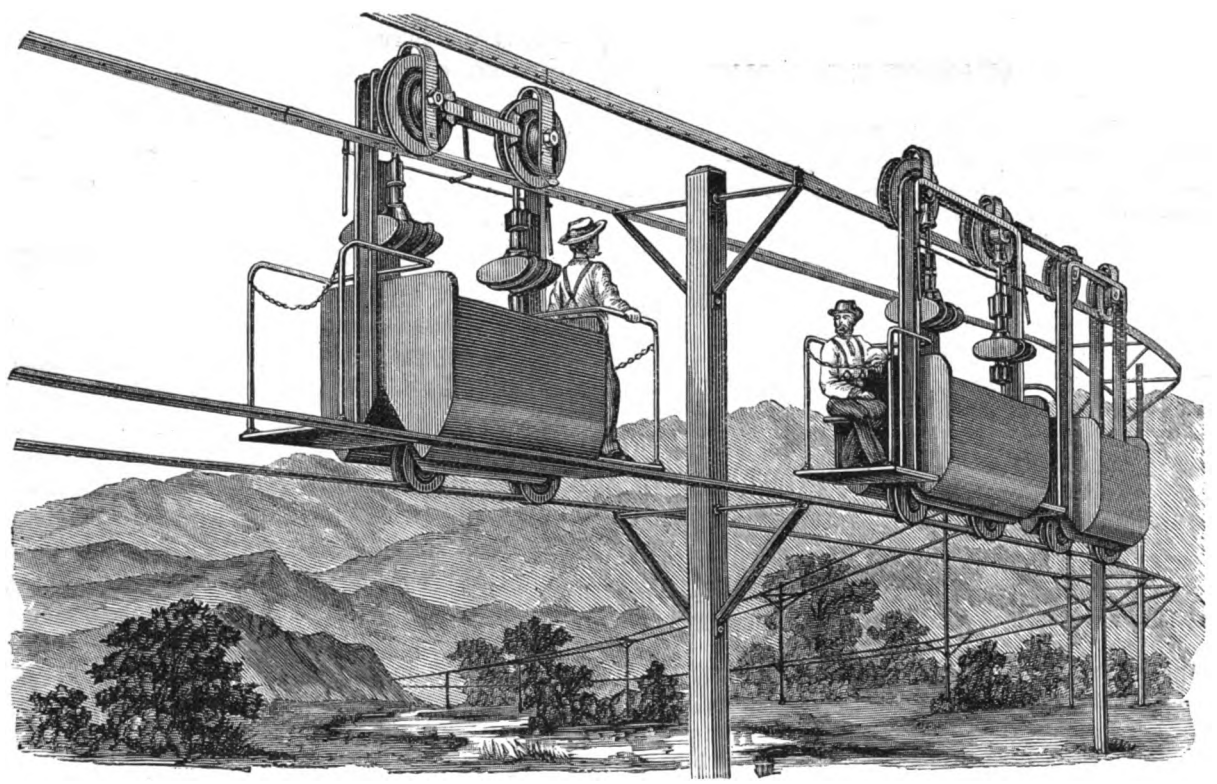
Unfortunately, the electrical portion of the works is not yet completed, or I should have hoped to have had the pleasure of inviting you to inspect them.

The question of cost resolves itself into this:—The more iron plates you introduce into the system the greater the surface, and the lower the resistance; consequently, the less horse-power required. The increase of the iron plates is only an increase of prime cost, and does not mean a greater waste of iron; this means a saving of labour, as the more iron originally used the less frequently it would require renewal.

I hope to prove that by using positive plates 1in. thick, their duration will be from five to ten years. If the proportion of one-third horse-power to 100 gallons in ten minutes holds good, as I am inclined to think it will, then 25 actual horse-power would be capable of purifying 1,080,000 gallons of sewage in twenty-four hours. I should much have liked to have gone into more minute details connected with these experimental tests, but until I have verified the present results on practical working scale, I feel it would be premature to quote figures.

The above table gives the results of a few analyses of sewage before and after treatment.

THE SPRAGUE TELPHERAGE SYSTEM.



The Sprague Electric Railway and Motor Company is now introducing a system of telpherage for mining work, and we illustrate herewith its *modus operandi*. The road or overhead track consists of two stationary steel cables, suspended one above the other between posts of wood or metal, fifty feet and upwards apart, and at such an elevation from the ground as not to interfere with surface traffic. The cars run on wheels, and are suspended between the upper and lower cables, the upper cable carrying most of the weight. By contact of the wheels with the cables the current is conveyed to an electric motor in the car, which imparts motion to the wheel by gears, &c. These cars can be of any pattern, dimensions or material required.—*Electrical World.*

TO ADVERTISERS.

"The Electrician" offers exceptional advantages to Advertisers. **It has the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application to this office.

Advertisements intended for the current issue must be handed in not later than 4 p.m. on Thursday.

TECHNICAL PRINTING.

"The Electrician" Printing and Publishing Company (Limited) *beg to inform Electricians and Electric Light Engineers that they make a specialty of Technical Printing, and have a Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electrical Catalogues and Electro-Technical Literature generally.*

The Electricians' Directory.

Royal 8vo. Cloth Boards, 3s. 6d. Boards, 3s.

At the end of December in each year is issued The Electricians' Directory and Handbook. *The Directory was established in 1883, and has now attained considerable proportions. Every care is taken to make the names and addresses of all persons engaged in the Electrical Industries absolutely accurate. Useful Tables and Electrical Formulæ are given, together with popularly-written Biographical Notices of the leading Electricians, accompanied in many cases by Portraits.*

THE DIRECTORY FOR 1889 IS IN PREPARATION.

"THE ELECTRICAL WORLD" IN THE UNITED KINGDOM.

Arrangements have been made by which "The Electrical World" of New York can be obtained from "The Electrician" Office, 1, Salisbury-court, Fleet-street, London, E.C.

The Rate of Subscription (payable in advance), including postage, is **£1. 1s. 0d.** *per annum to this Country and Abroad.*

Single Copies of "The Electrical World" can also be obtained, **price 6d. each.**

The Rates for Advertisements in "The Electrical World" of New York can be obtained on application to "The Electrician" Printing and Publishing Company, Limited, as above.

THE GROWTH OF ELECTRICAL INDUSTRIES.

For a fuller appreciation of the progress of electrical industry since the British Association last visited the City of Bath our readers may usefully turn to the Presidential Address at the same place on Wednesday, and to the Address delivered by the President of Section G yesterday. The position of electrical science and electrical industry, as exemplified at the 1864 meeting—a retrospective account of which we gave in our last issue—and their position now, could hardly have been brought into stronger contrast than they are by these two meetings, although, in point of time, barely a generation has separated them. The Papers devoted to these subjects at the former meeting might be counted on the fingers of one hand; to-day they may be reckoned by the score. And even now not half or a quarter of the fields surveyed either by Sir Frederick Bramwell or by Mr. W. H. Preece have been separately reported upon at this year's meeting. The applications of electricity to industrial purposes, to the arts, and to objects of warfare, are multiplied almost beyond recollection; and though the fashion of the hour or the pecuniary interests immediately involved fixes attention on the more conspicuous of these applications, their

Digitized by Google

intrinsic contribution to the industrial and social welfare of the nation is almost equalled, if not excelled, in the numberless and unrecognised services which electricity is everywhere rendering us, and of which Mr. PREECE has now very properly reminded us.

More than once in the course of his address the author, who may fairly claim to be a practical electrician, crosses swords with the theorist, or, more correctly, brandishes his weapon in the face of that unfortunate. Theorists, or philosophers, or physicists—for Mr. PREECE designates them in several ways—will, we fancy, be able to take care of themselves if they accept this challenge. Lord MANSFIELD once advised a newly appointed colonial judge always to deliver his judgments with boldness, but never to give his reasons. Science and practice would get along much more amicably, perhaps, if they observed this wholesome rule; the practice may be thoroughly sound though the reasons are all wrong, and, on the other hand, the reasoning may be all right but its application all amiss. We, therefore, will not here discuss the question whether electricity is "a form of matter or a form of energy," but rather content ourselves with agreeing with Mr. PREECE as to one ruling proposition which pervades the whole of his Paper, and to some extent that also of Sir F. BRAMWELL, namely, that the electrical engineer, by treating electricity as a form of something, has truly accomplished many wonderful things. And so long as he continues these achievements the world at large will trouble itself extremely little whether he acknowledges or denies his indebtedness to "the scientist, the theorist and the mathematician."

The long roll of discoveries and inventions which Mr. PREECE has enumerated is so magnificent and so comprehensive that its honours might be evenly divided without loss of self-esteem on either side. Between them, electrical science and electrical engineering have given us the electric telegraph, the telephone and the electric light. They have protected our buildings from lightning, and deprived railway travelling of its chief dangers. They have made easy the multiplication of works of art, and beautified the utensils of domestic life; the waste forces of nature are being utilised; avocations which were formerly dangerous or hurtful have been rendered safe and healthy; and industries which were an offence and a menace to society are becoming wholesome and innocuous. Of these benefits the telegraph is undoubtedly the widest in its operation, and grows wider every day in its subsidiary application to such purposes as fire alarms, bell ringing and telephony. The study of the electric light, too, besides its direct application, has opened up a wide field for the electrical transmission of power, for the welding of metals, and for painless operations in surgery. Some valuable statistics, the result of personal observation, are furnished by the author in relation to the hygienic value of the electric light. He tells us that in the Post Office Savings Bank, where gas was superseded two years ago by the new and purer illuminant, the average amount of illness among members of the staff has been diminished by about two days a year for each person—equivalent to a saving of the salary of eight clerks in that department. Besides, therefore, the advantage of better work performed by the staff, due to the improved atmospheric conditions which they enjoy, there is a saving of £266 a year, notwithstanding the acknowledged higher price of electricity compared with that of gas. As regards the mere production of the respective lights, Mr. PREECE finds that the cost for one candle light per annum of 1,000 hours is, in the case of London gas, 1s. 3d., against only 9d. for the electric glow lamp. Other considerations, however, have to be taken into account; and for supplying such places as the Post Office and the House of Commons with electricity produced on the premises, the glow lamp costs 22s. and a gas lamp 18s. per annum.

This difference in cost—compensated for, moreover, in other ways—will not deter those from using the glow lamp who study the welfare of their servants and their own best interests. On board ship the new light has gained a rapid and undisputed footing already. Not only are our warships equipped with arc and incandescent lamps, but the ocean-going passenger steamers are similarly provided; and no wonder, if, as Mr. PREECE alleges, it is on board ship that "the comfort, security, and true blessedness of the electric light is experienced." Concerning telegraphy and telephony Mr. PREECE is a still higher authority, and that part of his address which is devoted to these subjects is of exceeding interest and importance. Of the telephone he speaks in the language of an enthusiast; and no one who reads his address will have any room to suspect that the shortcomings of telephony in this country are in any way due to the Electricians of the British Post Office. Like his chief, the POSTMASTER-GENERAL, Mr. PREECE looks forward to the time when the patents of the existing owners shall expire; we shall then see what we shall see. Meanwhile, it is a painful confirmation of London's perennial complaint to learn that there are more telephonic subscribers, not only in New York, but in Stockholm, than there are in London, the largest city in the world.

When we turn to his facts and figures relating to the telegraph we are amazed and almost staggered at the immensity of its power and the rapidity of its growth. In this country alone the increase of telegraph business since the year 1870 is represented by fifty-two million messages per annum against six millions, and from being the luxury of the few the telegraph has become the servant of all. The business of the private companies, which amounted to £550,000 a year, has grown in the hands of the State to £2,000,000 a year, and the speed of transmission has increased from 100 or 150 words a minute as a rare performance, and for short distances, to 500 and 600 as a normal speed over a great number of lines, and to the geographical limits of these islands. Thirteen years ago it was thought a wonderful feat to transmit messages to Ireland through an intervening submarine cable at the rate of 80 words a minute. Recently when he was at Belfast Mr. PREECE timed messages arriving at the rate of 461 words a minute. The amount of news passing over the wires, chiefly in the night time, and appearing in the newspapers the next morning, averages 1,538,270 words per day, and this, of course, is mainly due to the speed at which they are despatched. On the question of speed Mr. PREECE is entitled to speak with some exultation. Not very long ago the American Press boasted that 500,000 words were sent out of Chicago in a single night. Mr. PREECE is like Mr. BALFOUR, he is not in a hurry to retort; he bides his time, and when it arrives he brings down a crusher. "500,000! Why, when Mr. GLADSTONE introduced his Home Rule Bill about two years and a-half ago, we sent from the central office no fewer than 1,500,000 words, and made no fuss about it." Some national pride, too, is aroused by Mr. PREECE'S reminder that of the submarine cables of the world 110,000 miles have been laid by British ships, and nearly £40,000,000 of British capital has been expended in completing that great enterprise. With such splendid proofs of the subjection into which he has brought

Digitized by Google

the powers of electricity, a modern electrician may, perhaps, be forgiven the confident affirmative with which he is now inclined to answer that dumbfoundering query addressed to Job of old: "Canst thou send lightnings that they may go, And say unto thee, 'Here we are'?"

OBITUARY.

PROF. RUDOLF JULIUS EMANUEL CLAUSIUS.

In expressing our profound regret at hearing of the death of the far-famed professor who has so long and so ably occupied the chair of Natural Philosophy at the University of Bonn we echo the sentiments of the whole scientific world, which has lost in him one of the most profound investigators; and of the students of his University, who mourn the loss of one of the most able teachers in Europe. Prof. Clausius was born on 2nd January, 1822, at Cöslin, in Pomerania. He was educated at Berlin, where he early distinguished himself in mathematics and physics. He began his career as a teacher as *privat docent* in the Univerity of Berlin, and instructor in Natural Philosophy at the School of Artillery in that city. In 1857 he accepted the Chair of Natural Philosophy at the Polytechnic School at Zurich, which he retained until 1867. In 1869 he was appointed Professor of Natural Philosophy at the University of Bonn, a post which he held until his death. His fame will chiefly rest upon his development, together with Rankine and Thomson, of the science of thermo-dynamics; but this was by no means his only important work. It was he who first established the kinetic theory of gases upon a scientific basis, and his contributions to various scientific journals, embracing more than 100 Papers, cover a very wide field. His earliest investigations were in connection with the transmission of light through the atmosphere and the blue colour of the sky, but he very soon turned his attention to the thermo-dynamical researches with which his name is chiefly associated. His treatise on the mechanical theory of heat forms a standing monument to his memory, not only as a physicist of the most profound insight, but as an expositor of singular lucidity and power. His work throughout is remarkable for the manner in which he always subordinates his mathematical analysis, generally of a comparatively simple character, to the physical problems which he is considering, so that the reader gains an insight into the subject to an extent which is by no mean common in memoirs and treatises on mathematical physics.

Among his more important electrical Papers we may mention:—"The Mechanical Equivalent of an Electric Discharge and the Heating of the Conducting Wire which accompanies it;" "Electrical Conduction in Electrolytes;" "The Effect of Temperature on Electrical Conductivity;" "A New Fundamental Law of Electro-Dynamics;" "The Different Systems of Measures for Electric and Magnetic Quantities;" "The Employment of the Electro-Dynamic Potential for the Determination of Ponderomotive and Electromotive Forces;" "The Theory of Dynamo-Electrical Machines;" "The Theory of the Transmission of Power by Dynamo-Electrical Machines." These Papers have nearly all been translated in Taylor's "Scientific Memoirs" or in the *Philosophical Magazine*, and a translation of the Paper on "The Theory of Dynamo-Electrical Machines" appeared in Vol. XII. of *The Electrician*.

Although it does not deal with electricity, we must not omit to mention his very important Paper "On the Determination of the Energy and Entropy of a Body," translated in the *Phil. Mag.*, Vol. XXXII., 4th series, 1866, as it was in this Paper that the important conception of the entropy of a body was first propounded.

In 1877 Prof. Clausius published a small but important work on the "Potential Function and the Potential." In 1868, he was elected a foreign member of the Royal Society, and 11 years later he was the recipient of the Copley medal, the blue ribbon of the Society. He was decorated with numerous German orders, and he received the Iron Cross from the German Government and the ribbon of the Legion of Honour from that of France for his services as a caretaker of the wounded in the Franco-German War, for which he volunteered.

GENERAL LORD ALFRED PAGET, C.B.

The lamented death of General Lord Alfred Paget, which took place on board his yacht, the "Violet," near Inverness on the 25th ult., will recall to many of our readers the very earliest days of the electric telegraph, when its development as a commercial undertaking depended largely on the encouragement and support of men like the deceased nobleman. He was one of the original Directors of the Electric Telegraph Company, incorporated in 1846, under the able chairmanship of Mr. John Lewis Ricardo. Lord Alfred's interest in telegraphy never flagged; and at the time of his death he was a Director of the Eastern Telegraph Company, as well as of several other companies. Although in his seventy-third year, having been born in June, 1816, Lord Alfred Paget was enjoying good health, and his death, after a very short illness, was the result of an accidental chill caught while shooting on the moors. The remains of the deceased nobleman were brought to his residence, Upper Lodge, Bushey Park, and were interred in the family grave in Hampton parish churchyard, on Wednesday, the 29th ult. The funeral was attended by a large concourse of noblemen and gentlemen, amongst whom were Col. the Hon. Wm. Carrington, representing Her Majesty the Queen, and Major-General Ellis, who represented the Prince of Wales, the Eastern Telegraph Company being represented by Mr. J. D. Pender, Mr. G. Draper, Mr. W. T. Ansell, and others. The Vicar of Hampton conducted the service, which was partly choral, assisted by the Rev. Sholto D. Campbell Douglas, of Inverness, who had attended his lordship in his last illness. Lord Alfred Paget was married in 1847 to Miss Cecilia Wyndham, who survives him, and by whom he had a family of fourteen children. He was a General in the Army, Chief Equerry and Clerk Marshal of the Royal Household, and Member of Parliament for Lichfield from 1837 to 1865.

IMPROVEMENTS IN THE TELEPHONE SYSTEM OF GLASGOW AND THE WEST OF SCOTLAND.

By D. Sinclair, Engineer, National Telephone Company.

(Continued from page 531.)

A distinct feature in our telephone work is the change that has been made from the use of electric batteries to that of magneto-electric generators for ringing purposes. There is a very great economy effected by the use of generators, and in every way they are much more suitable than batteries. A magneto will work for years without any attention whatever, and it has power to signal through a resistance of from 12,000 ohms to 16,000 ohms, this being more than is required in practice.

The switch-board in all telephone exchanges is a very important part of the system, and many changes have been made in trying to arrive at a really satisfactory switch-board. Glasgow was started with the ordinary "Bell" board, and the "Universal" switch-board of the style known as Edison's. After some experience these gave place to "Williams'" boards, and for small exchanges of from 100 to 200 wires they are very satisfactory, but for larger exchanges the best boards are decidedly the "Multiple" switch-boards.

Were I to enter into all the details showing this, I should far exceed the limits of a Paper of this kind, but I will mention a few of the main points.

First. The principal and best feature of the multiple switch-board is that every operator has complete control over the number of wires she attends to, with power to join them to any other wire in the exchange without the intervention of any other operator.

Digitized by Google

Second. The perfection with which the manufacturing details are carried out.

Third. The fact that it has capacity for carrying a greater number of wires in a smaller space than any other switch-board.

Fourth. An operator can attend to a greater number of subscribers than with any other switch-board.

The manner in which the wires are arranged so as to give each operator control over the whole is shown in Fig. 5, where the tables are numbered from 1 to 5.

The wire coming into the exchange from the test-box (say No. 1 wire) goes to a jack with that number on No. 1 table, and out to a jack with the same number on No. 2 table, going

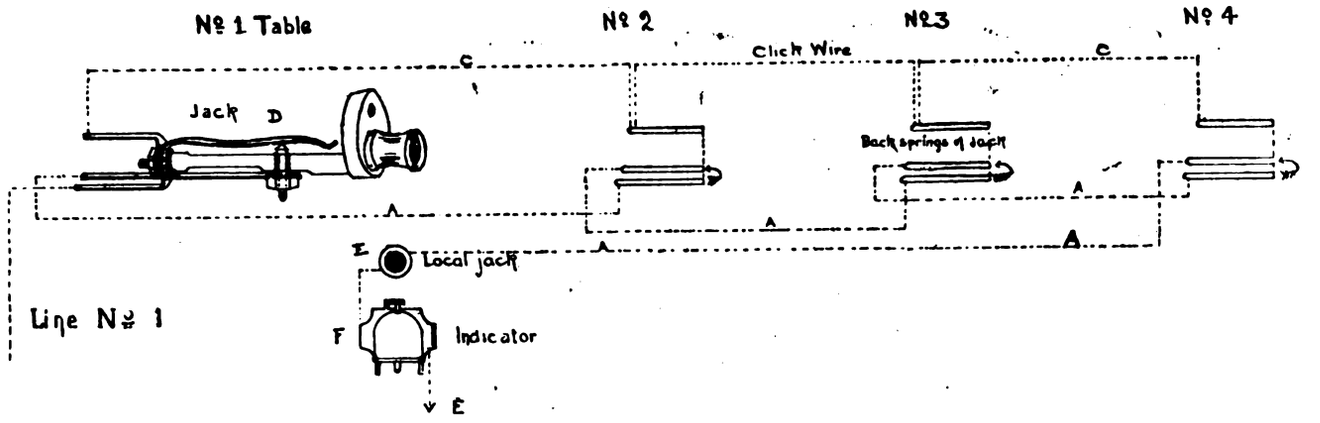

FIG. 5.—CONNECTIONS OF "MULTIPLE" SWITCH-BOARD.

A A shows line of subscriber No. 1 going to No. 1 jack on No. 1 table, then to No. 1 jack on each table in the room, returning to local jack E on No. 1 table, then through indicator F to earth. C C.—Click wire. By touching front of jack with plug the operator can tell whether a line is engaged or not. D.—Complete jack, showing insulated parts. Every subscriber's line follows a similar course through the whole of the tables.

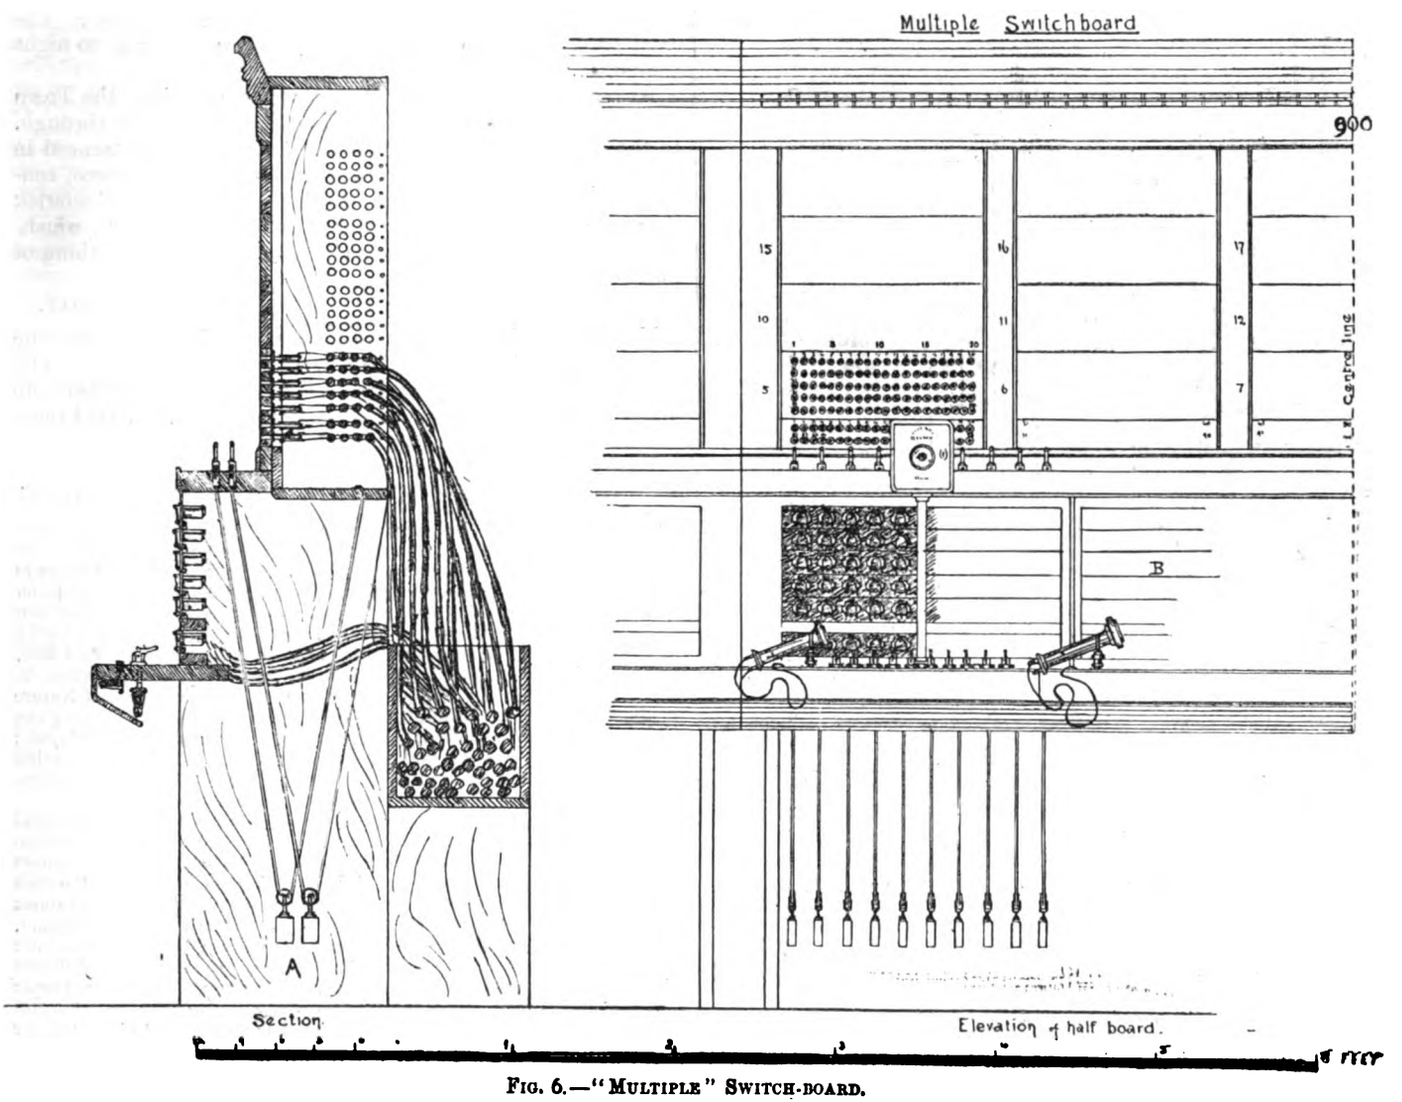

FIG. 6.—"MULTIPLE" SWITCH-BOARD.

A, section of board; B, elevation of half board.

We have this multiple system at work in our central exchange in Glasgow, where there are 10 boards of 200 lines each, or 2,000 lines in all.

thus in and out through every table in the room. Four tables only are shown in the figure. Finally it returns to No. 1 table, where it makes connection with its "local jack,"

Digitized by Google

and through an indicator to earth. All the wires on this No. 1 table, which are 200 in number, follow the same course. Another set of 200 wires starts from the same table, passes round the room in the same way, and is taken from the last table to earth through the local jack on table 2. This system of every wire commencing at No. 1 table, going to all the other tables, and finishing at that on which its number exists, is carried on throughout, and is necessary to give the facility just mentioned of any operator having within her reach all the wires in the exchange.

Let us suppose that No. 1 subscriber rings the exchange and asks to be connected with No. 600. It would not do for the operator to connect 600 without first ascertaining that that wire was not already engaged. Provision is made on the "multiple" system for this being done by means of a test wire, without in any way interfering with the wire if engaged, and the user has no knowledge that the test is being made. The operator just touches the front of the jack with her connecting plug; if engaged a smart click occurs in her telephone, and she at once replies to No. 1 that "600 is engaged." If not engaged there is no click, and she inserts the plug and the connection is immediately completed.

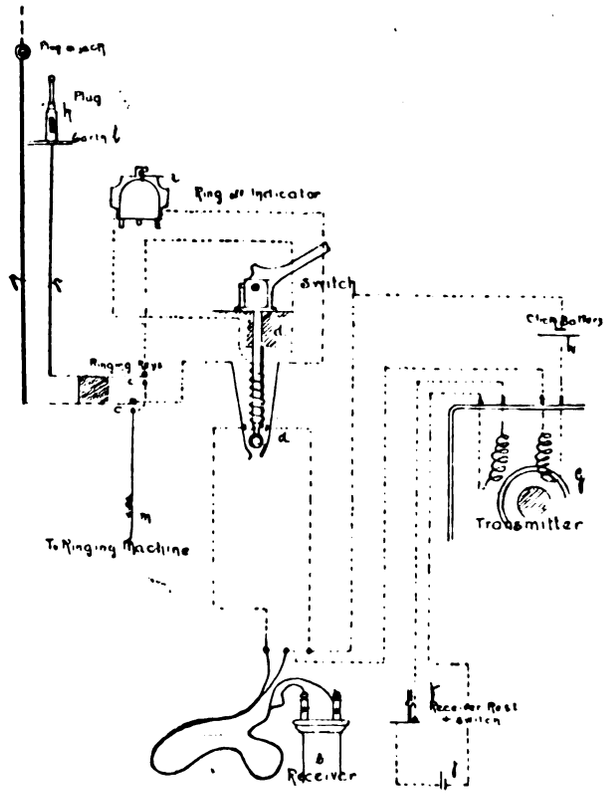

FIG. 6A.

C, connections, showing subscriber speaking to operator; *a*, plug inserted in jack; *b b*, connecting cords; *c c*, ringing keys; *d*, switch for cutting in or out operator's instrument; *e*, operator's receiver; *f*, receiver rest and local battery cut-out; *g*, operators transmitter; *h*, click battery; *i*, ring-off indicator; *j*, local battery; *k*, plug resting on earth strip *l*; *m*, ringing machine.

The indicators of both lines thus connected are cut out of circuit, and an indicator placed in the connecting cord circuit serves to show further requirements from either, until the plugs are withdrawn and both wires are back into normal positions.

Fig. 5 shows the connection of this click system with the ordinary line jack. Figs. 6 and 6A show front and sectional views and further details of the connections.

It must be added that these facilities are not given without a very considerable amount of wire, jacks, and work in setting up. In speaking of an exchange like this one in Glasgow, fitted up for 2,000 subscribers, I hope that we can look at it as a small exchange compared with what we expect in the future; but as all things are great or small by comparison only, it will be admitted that even fitting up an exchange of this size is a heavy undertaking, when it is said that we had to cut, fix, and solder on, then test, no less than 107,000 wires, making a total length of 132 miles in the exchange.

(To be continued.)

THE BRITISH ASSOCIATION MEETING AT BATH, 1888.

(FROM OUR CORRESPONDENT.)

BATH, WEDNESDAY.

The second meeting held by the British Association at Bath opened to-day under very favourable auspices, even the weather proving fine for a few hours. The local arrangements appear to have been admirably made. The sectional meetings are somewhat far apart, but this, however, was unavoidable, and is amply atoned for by the suitability of the rooms selected. Some £3,600 has been subscribed by the people of Bath; a large corrugated iron building has been erected as a reception room, where the members of the Association will find every telegraphic, telephonic and postal facility, as well as ticket, luggage and inquiry offices. The seventeen excursions are already being rapidly entered for. They comprise visits to Berkeley Castle, Bristol, Stonehenge, Wells, and Glastonbury, and last, but not least, the Severn Tunnel. The chief local attraction is the flower show, which was to-night brilliantly illuminated by the electric light.

At one o'clock Sir Henry Roscoe took the chair at the Town Hall, where the usual opening formalities were gone through. In the evening the meetings of the Association commenced in the Drill Hall. Sir Henry Roscoe, after a brief speech, concluded by resigning the chair to his successor, Sir Frederick Bramwell, who then delivered his inaugural address, which, although of a very interesting character, contained nothing of special interest to electricians.

THURSDAY.

Nearly the whole of the sections met this morning for the transaction of business. They were largely attended. The total number of tickets issued is 1,794. The weather continues fine. In the Mechanical Section (G) Mr. W. H. Preece delivered the following address:—

MR. PREECE'S PRESIDENTIAL ADDRESS IN SECTION G

"Canst thou send lightnings that they may go, And say unto thee 'Here we are,'" were pregnant words addressed to Job unknown centuries ago. They express the first recorded idea in history of the potentiality of electricity to minister to the wants of mankind. From Job to Franklin is a long swing in the pendulum of time. It was not until that American philosopher brought down atmospheric electricity by his kite-string in 1747, and showed that we could lead it where we willed, that we were able to answer the question addressed to the ancient patriarch. Nearly another century elapsed before this mysterious power of Nature was fairly conquered. It has been during this generation, and during the life of the British Association, that electricity has been usefully employed; and it is because I have taken a subordinate position in inaugurating nearly all of its practical applications, that I venture to make the developments of them the text of my address to this section.

People are singularly callous in matters affecting their own personal safety, they will not believe in mysteries, and they ridicule or condemn that which they do not understand. The Church itself set its face against Franklin's "impious" theories, and he was laughed to scorn by Europe's scientific sons; and even now, though commissions composed of the ablest men of the land have sat and reported on Franklin's work in England, France, and nearly every civilised nation, the public generally remains not only ignorant of the use of lightning conductors, but absolutely indifferent to their erection, and if they are erected, certainly careless of their proper maintenance. I found in a church not very far from here the conductor leaded into a tombstone, and in a neighbouring cathedral the conductor only a few inches in the ground, so that I could draw it out with my hand. Although I called the attention of the proper authorities to the absolute danger of the state of affairs, they remained in the same condition for years.

Wren's beautiful steeple in Fleet-street, St. Bride's, was well nigh destroyed by lightning in 1764. A lightning rod was fixed, but so imperfectly that it was again struck. In July last (1887) it was damaged because the conductor had been neglected, and had lost efficiency.

As long as points remain points, as long as conductors remain conductors, as long as the rods make proper connection with the earth, lightning

Digitized by Google

protectors will protect; but if points are allowed to be fused or to corrode away, if bad joints or faulty connections are allowed to remain, if bad earths or no earths exist, protectors cease to protect, and they will become sources of danger. Lightning conductors, if properly erected, duly maintained, and periodically inspected, are an absolute source of safety; but if erected by the village blacksmith, maintained by the economical churchwarden, and never inspected at all, a loud report will some day be heard, and the beautiful steeple will convert the churchyard into a new geological formation.

We have not yet acquired that mental confidence in the accuracy of the laws that guide our procedure in protecting buildings from the effects of atmospheric electrical discharges which characterises most of the practical applications of electricity. Some of our cherished principles have only very recently received a rough shaking from the lips of Prof. Oliver Lodge, F.R.S., who, however, has supported his brilliant experiments by rather fanciful speculation, and whose revolutionary conclusions are scarcely the logical deduction from his novel premises. The whole subject is going to be thoroughly discussed at this meeting.

We are now obtaining much valuable information about the nature of lightning from photography. We learn that it does not, as a rule, take that zigzag course conventionally used to represent a flash on canvas. Its course is much more erratic and sinuous, its construction more complicated, and pictures have been obtained of *dark* flashes whose *raison d'être* has not yet been satisfactorily accounted for. The network of telegraph wires all over the country is peculiarly subject to the effects of atmospheric electricity, but we have completely mastered the vagaries of lightning discharges in our apparatus and cables. Accidents are now very few and far between.

The art of transmitting intelligence to a distance beyond the reach of the ear and the eye by the instantaneous effects of electricity had been the dream of the philosopher for nearly a century, when in 1837 it was rendered a practical success by the commercial and far-sighted energy of Cooke and the scientific knowledge and inventive genius of Wheatstone. The metallic arc of Galvani (1790) and the developments of Volta (1796) had been so far improved that currents could be generated of any strength, the law of Ohm (1828) had shown how they could be transmitted to any distances, the deflection of the magnetic needle by Oersted in 1819, and the formation of an electro-magnet by Ampère and Sturgeon, and the attraction of its armature had indicated how those currents could be rendered visible as well as audible.

Cooke and Wheatstone in 1837 utilised the deflection of the needle to the right and the left to form an alphabet. Morse used the attraction of the armature of an electro-magnet to raise a metal style to impress or emboss moving paper with visible dots and dashes. Steinheil imprinted dots in ink on the different sides of a line on paper, and also struck two bells of different sound to affect the ear. Bréguet reproduced in miniature the actual movements of the semaphore, then so much in use in France, while others rendered practical the favourite idea of moving an indicator around a dial, on which the alphabet and the numerals were printed, and causing it to dwell against the symbol to be read—the A B C instrument of Wheatstone in England, and of Siemens in Germany. Wheatstone conceived the notion of printing the actual letters of the alphabet in bold Roman type on paper—a plan which was made a perfect success by Hughes in 1854.

At the present moment the needle system of Cooke and Wheatstone, as well as the A B C dial telegraph, are very largely used in England on our railways and in our smaller post offices. The Morse recorder and the Hughes type printer are universally used on the Continent, while in America the dot and dash alphabet of Morse is impressed on the consciousness through the ear by the sound of the moving armature striking against the stops that limit its motion. In our larger and busier offices the Morse sounder and the bell system, as perfected by Bright, are largely used, while the press of this country is supplied with news which is recorded on paper by ink dots and dashes by means of the automatic apparatus at a speed that is almost fabulous.

Sir William Thomson's mirror—the most delicate form of the needle system—where the vibratory motions of an imponderable ray of light convey words to the reader, and his recorder where the wavy motion of a line of ink spirted on paper by the frictionless repulsion of electricity performs the same function, are exclusively employed on our long submarine cables.

Bakewell in 1848 showed how it was possible to reproduce facsimiles of handwriting and of drawing at a distance, and in 1879 E. A. Cowper reproduced one's own handwriting, the moving pen at one station so controlling the currents flowing on the line wire that they caused a similar pen to make similar motions at the other distant station. Neither of these plans, the former beautifully developed by Caselli and D'Arlincourt, and the latter improved by Robertson and Elisha Gray, has yet reached the practical stage.

The perfection of telegraphy has been attained by that chief marvel of this electrical age—the speaking telephone of Graham Bell. The reproduction of the human voice at a distance, restricted only by geographical limits, seems to have reached the confines of human ingenuity; and though wild enthusiasts have dreamt of reproducing objects abroad visible to the naked eye at home, no one at the present moment can say that such a thing is possible, although in face of the wonders that have been done no one dare say that is impossible.

The commercial business of telegraphy, when our thoughts and wishes, orders and wants, could be transmitted for money, was inaugurated in this country by the establishment of the Electric Telegraph Company in 1846, and until 1870 it remained in the hands of private enterprise, when it was purchased by the Government, and placed under the sole control of the Postmaster-General. It has been the fashion to decry the terms of purchase of the various undertakings then at work by those who have not understood the question, and by those who, being politically opposed to the Government in power at the time, saw all their acts, not only through a glass darkly, but through a reversing lens. A business producing £550,000 per annum was bought at twenty years' purchase, and that business has now increased to £2,000,000 per annum. 6,000,000 messages per annum have increased to 53,400,000. In August, 1870, the largest number of messages per week was 234,000. Last month it reached 1,276,000.

Every head post office has been made a telegraph office, every village of any size has its wire; messages which used to cost 12s. 6d. are now sent for 6d.; a tariff which was vexatious from its unfair variation is now uniform over the United Kingdom, and no one can justly complain of error or delay in the transmission of their messages. Silly complaints are sometimes inserted in the press, of errors which the most elementary knowledge of the Morse alphabet would detect, and little credit is given to the fact that the most perfect telegraph is subject to strange disturbances from terrestrial and atmospheric causes which admit sources of error beyond the control of the telegraphist. A flash of lightning in America may cause an extra dot in Europe and *mine* may become *wine*. An earthquake in Japan may send a dash through France and *life* would become *wife*. A wild goose flying against a telegraph wire might drive it into momentary contact with another wire and *sight* might become *night*. Everyone should know his Morse alphabet, and people should learn how to write. Nine-tenths of the errors made are due to the execrable caligraphy of the present day. As a matter of fact, in ninety-nine cases out of a hundred the telegraphist delivers to the editor of a newspaper "copy" far more accurate than the first proof submitted by the printer of his own leader. The quantity of news transmitted is enormous, an average of 1,538,270 words are delivered per day. The recent convention in Chicago when the Republican party of the United States nominated their candidate for the presidentship created so much business that every American paper has chronicled this big thing as unique. 500,000 words were sent on one night; but we in England, when Mr. Gladstone introduced his celebrated Home Rule Bill on April 8th, 1886, sent from the Central Telegraph Office in London 1,500,000 words.

The growth of business has led to vast improvement in the carrying capacity of the wires. Cooke and Wheatstone required five wires for their first needle instrument to work at the rate of four words per minute. One wire can now convey six messages at ten times the speed. The first Morse apparatus could work at about five words a minute; we now transmit news at the rate of 600 words a minute. Even in 1875 it was thought wonderful to transmit messages to Ireland at 80 words a minute. When I was recently in Belfast I timed messages coming at the rate of 461 words a minute. Duplex working—that is, two messages travelling on the same wire at the same time in opposite directions, the invention of Gintl, of Vienna—is now the normal mode of working, Edison's quadruplex is common, and the Delany system of multiplex working is gradually being introduced by which six messages are indiscriminately sent in either direction on one wire. The telegraphic system of England has been brought to the highest pitch of perfection. We have neither neglected the inventions of other countries, nor have we been chary of exercising inventive skill ourselves, and we have received our full meed of that reward which is always freely bestowed on a British Government official—neglect and abuse.

All parts of the civilised world are now united by submarine cables. *The Times* every morning has despatches from every quarter of the globe, giving the news of the previous day. 110,000 miles of cable have been laid by British ships, and nearly £40,000,000 of British capital has been expended by private enterprise in completing this grand undertaking. A fleet of 37 ships is maintained in various oceans to lay new cables and to repair breaks and faults—faults that arise, among other causes, from chafing on coral reefs, ships' anchors, the onslaught of insects, and earthquakes. The two cables connecting Australia and Java were recently simultaneously broken by an earthquake.

The politician, unmindful of the works of the engineer, is apt to apply to the credit of his own proceedings the growing prosperity of the world. The engineer, however, feels that steam and electricity in his hands have done more to economise labour, to cheapen life, to increase wealth, to promote international friendship, to alleviate suffering, to ward off war, to encourage peace, than all the legislation and all the verbosity of the politician.

The railways of this country are entirely dependent for the conduct of their traffic on the telegraph, and the security of their passengers is mainly due to the working of the block system. A railway, say between London and Bath, is broken up into certain short sections, and only one train is allowed on one section at one time. The presence, motion, and departure of trains is announced and controlled by electric signals, and the out-door signals are governed by these electric signals. There are few more interesting places to visit than a well-equipped signal-box on one of our main railways. The signalman is able to survey the lines all around and about him by aid of his electric signals; he can talk by telegraph or by telephone to his neighbours and his station master; he learns of the motion of the trains he is marshalling by the different sounds of electric bells; he controls his out-door signals by the deflection of needles, or the movement of miniature semaphores; he learns the true working of his distant signals by their electrical repetition; machinery governs and locks every motion he makes, so that he cannot make a mistake. The safety of railway travelling is indicated by the fact that while in the five years ended 1878 thirty-five people were killed annually from causes beyond their own control, in the five years ended 1887 the average has been reduced to sixteen. One person is killed in 35,000,000 journeys made by train. Wherever we are dependent on human agency we are subject to human error, and a serious accident very recently at Hampton Wick has shown how the most perfect machinery may be rendered valueless to protect life when perversity, thoughtlessness or criminality enter as factors in the case.

Digitized by Google

At the meeting of the Association in Plymouth in 1877, I was able for the first time in this country to show the telephone at work. Since then its use has advanced with giant strides. There are probably a million instruments at work now throughout the civilised world. Its development has been regularly chronicled at our meetings. As far as the receiving part of the apparatus is concerned, it remains precisely the same as that which I brought over from America in 1877; but the transmitter, since the discovery of the microphone by Hughes in 1878, has been entirely remodelled. Edison's carbon transmitter was a great step in advance; and the modern transmitters of Moseley, Berliner, D'Arsonval, De Jongh, leave little to be desired. The disturbances due to induction have been entirely eliminated, and the laws regulating the distance to which speech is possible are so well known, that the specification of the circuit required to connect the Land's End with John O'Groats by telephone is a simple question of calculation. A circuit has been erected between Paris and Marseilles, 600 miles apart, with two copper wires of 6½ gauge weighing 540lb. per mile, and conversation is easily maintained between those important cities at the cost of three francs for three minutes. One scarcely knows which fact is the more astounding—the distance at which the human voice can be reproduced, or the ridiculously simple apparatus that performs the reproduction. But more marvellous than either is the extreme sensitiveness of the instrument itself, for the energy contained in one heat unit (gramme-water-degree) would, according to Pellat, maintain a continuous sound for 10,000 years.

The influence which electric currents exert on neighbouring wires extends to enormous distances, and communication between trains, and ships in motion, between armies inside and outside besieged cities, between islands and the main land, has become possible without the aid of wires at all, by the induction which is exerted through space itself. On the Lehigh Valley Railway, in the United States, such a system of telegraphing without wires is in actual daily use.

The conduct of telephonic business in England is still in the hands of those who hold the patents, and who maintain a most rigid monopoly. These patents have only a short period to run, and when they expire we may expect to find that England will not occupy the very retired position she holds now as a telephone country. Stockholm has more subscribers than London; there are 15,000 subscribers in and about New York, while the number in London is only 4,851.

Electric lighting has become popular, not alone from the beauty of the light itself, but from its great hygienic qualities in maintaining the purity and coolness of the air we breathe. The electric light need not be more brilliant than gas, but it must be more healthy. It need not be cooler than a wax candle, but it must be brighter, steadier, and more pleasant to the eye. In fact, it can be rendered the most perfect artificial illuminant at our disposal, for it can illumine a room without being seen directly by the eye; it can be made absolutely steady and uniform without irritating the retina; it does not poison the air by carbonic acid and carbonic oxide, or dirty the decorations by depositing unconsumed carbon; it does not destroy books or articles of vertu and art by forming water which absorbs sulphur acids; and it does not unduly heat the room.

In the Post Office Central Savings Bank in London it has been found, after two years' experience of electric lighting, that the average amount of absences from illness has been diminished by about two days a year for each person on the staff. This is equivalent to a gain to the service of the time of about eight clerks in that department alone. Taking the cost at the "overtime" rate only this would mean a saving in salaries of about £640 a year. The cost of the installation of the electric light was £3,349 and the annual cost of working £700 per annum, say a total annual cost of £1,034. The cost of the gas consumed for lighting purposes was about £700 a year, so that on the whole there was a direct saving of something like £266 a year to the Government, besides the material advantage of the better work of the staff resulting from the improved atmospheric conditions under which their work is done.

The production of light by any means implies the consumption of energy, and this can be measured in *watts*, or the rate at which this energy is consumed. A watt is $\frac{1}{746}$ part of a *horse-power*. It is a very convenient and sensible unit of power, and will in time replace the meaningless horse-power.

The relative heat generation of these illuminants may be estimated from these figures. Though the electric light was discovered by Davy in 1810, it was not until 1844 that it was introduced into our scientific laboratories by Foucault; it was not until 1878 that Jablochkoff and Brush showed how to light up our streets effectually and practically; it was not until 1881 that Edison and Swan showed how our homes could be illuminated softly and perfectly. Unpreparedness for such a revolution produced a perfect panic among gas proprietors; inexperience in the use of powerful electric currents resulted in frequent failure and danger; speculation in financial bubbles transferred much gold from the pockets of the weak to the coffers of the unscrupulous; hasty legislation in 1882 restricted the operations of the cautious and the wise; and the prejudice arising from all these causes has, perhaps fortunately, delayed the general introduction of electricity; but now legislation has been improved, experience has been gained, confidence is being restored, and in this beautiful town of Bath fifty streets are about to be lighted, and we see everywhere around and about us in our English homes the pure glow lamp replacing filthy gas and stinking oil. The economical distribution of the electric current over large areas is annually receiving a fresh impetus. The expensive systems defined in the Act of Parliament of 1882 have entirely disappeared. Hopkinson in England and Edison in America showed how a third wire reduced the weight of copper needed by 66 per cent. Gaulard and Gibbs in 1882 showed how the conversion of alternate currents of high electromotive force to currents of low electromotive force by simple induction coils would enable a mere telegraph wire to convey sufficient electricity to light a distant neighbourhood economically and efficiently. Lane-Fox in 1879 showed how the same thing could be done by secondary batteries; and Planté, Faure, Sellon, and Parker have done much to prove how batteries can be made to solve the problem of storage; while King and Edmunds have shown how the distribution by secondary batteries can be done as economically as by secondary generators. The Grosvenor Gallery Company in London have proved the practicability of the secondary generator principle by nightly supplying 24,000 glow lamps scattered over a very wide area of London. The glow-lamp of Edison, which in 1881 required 5 watts per candle, has been so far improved that it now consumes but 2½ watts per candle. The dynamo which in the same year weighed 50,000lb., absorbed 150 horse-power, and cost £4,000 for 1,000 lamps, now weighs 14,000lb., absorbs 110 horse-power, and cost £500 for the same production of external energy; in other words, its commercial output has been increased nearly six times, while its prime cost has been diminished eight times.

The steam engine has received equal attention. The economy of the electric light when steam is used depends almost entirely on the consumption of coal. With slow-speed low-pressure engines one kilowatt (1,000 watts, 1⅓ horse-power) may consume 12lb. of coal per hour; in high-speed high-pressure triple-expansion-condensing engines it need not consume more than 1lb. of coal per hour. Willans and Robinson have actually delivered from a dynamo one kilowatt by the consumption of 2lb. of coal per hour, or by the condensation of 20lb. of steam.

There is a great tendency to use small economical direct-acting engines in place of large expensive engines, which waste power in countershafting and belts. Between the energy developed in the furnace in the form of heat, and that distributed in our rooms in the form of light, there have been too many points of waste in the intermediate operations. These have now been eliminated or reduced. Electricity can now be produced by steam at 3d. per kilowatt per hour. The kilowatt hour is the Board of Trade unit as defined by the Act of 1882, for which the consumer of electric energy has to pay. Its production by gas engines costs 6d. per kilowatt-hour, while by primary batteries it costs 3s. per kilowatt-hour. The Grosvenor Gallery Company supply currents at 7¼d. per kilowatt-hour; a 20 candle-power lamp consuming 3 watts per candle, and burning 1,200 hours per annum, expends 82,000 watt-hours or 82 kilowatt-hours, and it costs, at 7¼d. per unit, 50s. per annum. If the electricity be produced on the premises, as is the case in the Post Office, in the House of Commons, and in many large places, it would cost 20s. 6d. per annum. I have found from a general average under the same circumstances and for the same light in the General Post Office in London that an electric glow lamp costs 22s. and a gas lamp 18s. per annum. The actual cost of the production of one candle light per annum of 1,000 hours is as follows:—

	s.	d.
Sperm candles	8	6
Gas (London)	1	3
Oil (petroleum)	0	8
Electricity, glow	0	9
,, arc	0	1½

The greatest development of the electric light has taken place on board ship. Our Admiralty have been foremost in this work. All our warships are gradually receiving their equipment. Our ocean-going passenger ships are also now so illumined, and perhaps it is here that the comfort, security, and true blessedness of the electric light is experienced.

Railway trains are also being rapidly fitted up. The express trains to Brighton have for a long time been so lighted, and now several northern railways, notably, the Midland, are following suit. Our rocky coasts and prominent landfalls are also having their lighthouses fitted with brilliant arc lamps, the last being St. Katherine's point on the Isle of Wight, where 60,000 candles throw their bright beams over the English Channel, causing many an anxious mariner to proceed on his way rejoicing.

Fontaine showed in Vienna, in 1873, that a dynamo was reversible; that is, if rotated by the energy of a moving machine it would produce electric currents, or if rotated by electric currents it would move machinery. An electric current is one form of energy. If we have at one place the energy of falling water we can by means of a turbine and a dynamo convert a certain portion of the energy of this falling water into an electric current. We transmit this current through proper conductors to any other place we like, and we can again by means of a motor convert the energy of the current into mechanical energy to do work by moving machinery, drawing tramcars or in any other way. We can in this way transmit and utilise 50 per cent. of the energy of the falling water wherever we like. The waste forces of Nature are thus within our reach. The waterfalls of Wales may be utilised in London; the torrents of the Highlands may work the tramways of Edinburgh; the wasted horse-power of Niagara may light up New York. The falls of Bushmills actually do work the tramway from Portrush to the Giant's Causeway, and those of Bessbrook the line from Newry to Bessbrook. Lord Armstrong lights his house at Craigside by a waterfall in his grounds.

The practicability of the transmission of energy by currents is assured, and the economy of doing this is a mere matter of calculation. It is a question of the relative cost of the transmission of fuel in bulk, or of the transmission of energy by wire. Coal can be delivered in London for 12s.

Digitized by Google

per ton. The mere cost of the upkeep of a wire between Wales and London to deliver the same amount of energy would exceed this sum tenfold. For long distances the transmission of energy is at present out of the question. There can be no doubt, however, that for many purposes within limited areas the transmission of energy by electricity would be very economical and effective. Pumps are worked in the mines of the Forest of Dean, cranes are moved in the works of Easton and Anderson at Erith, lifts are raised in Banks in London; water is pumped up from wells to cisterns in the house of Sir Francis Truscott, near East Grinstead: ventilation is effected and temperature lowered in collieries; goods, minerals and fuel can be transmitted by telpherage.

The transmission of power by electricity is thus within the range of practice. It can be distributed during the day by the same mains which supply currents for light by night. Small industries, such as printing, watch-making, tailoring, boot-making, can be cheaply supplied with power. It is thus brought into direct competition with the distribution of power by steam as in America, or by air-pressure as in Paris, or by high-pressure water as in London; and the relative advantages and economies of each system are simple questions of calculation. When that evil day arrives that our supply of natural fuel ceases, then we may look to electricity to bring to our aid the waste energies of Nature—the heat of the sun, the tidal wave of the ocean, the flowing river, the roaring falls, and the raging storm.

There is a mode of transport which is likely to create a revolution in the method of working tramways. A tramcar carries a set of accumulators which supplies a current to work a motor geared to a pair of wheels of the car. The weight, price, day's work, and life of the accumulator is curiously the same as the weight, price, day's work, and life of horseflesh; but the cost of maintenance, the liability to accident, and the chances of failure are much less. Although very great improvements in batteries have been made, and they are now really practical things, sufficient experience in tramcar working has not yet been obtained to say that we have reached the proper accumulator. Nor have we yet acquired the best motor and mode of gearing; but very active experiments are being carried out in various countries, and nothing can prevent their ultimate success.

The property, which the electric current possesses, of doing work upon the chemical constitution of bodies so as to break up certain liquid compounds into their constituent parts, and marshal these disunited molecules in regular order according to a definite law upon the surfaces of metals in contact with the liquid where the current enters and exists, has led to immense industries in electro-metallurgy and electro-plating. The extent of this industry may be gathered from the fact that there are 172 electro-platers in Sheffield and 99 in Birmingham. The term electro-metallurgy was originally applied to the electro-deposition of a thin layer of one metal on another; but this is now known as electro-plating.

In 1839 Jacobi in St. Petersburg and Spencer in Liverpool laid the foundations of all we know of these interesting arts. Copper was deposited by them so as to obtain exact reproductions of coins, medals, and engraved plates. The first patents in this country and in France were taken out by Messrs. Elkington, of Birmingham, who still occupy the foremost position in the country.

The fine metals (gold and silver) are deposited in thin layers on coarser metals, such as German silver, in immense quantities. Christofle, of Paris, deposits annually six tons of silver upon articles of use and of art, and if the surfaces so electro-plated were spread out continuously they would cover 140 acres.

The whole of the copper plate used in Southampton for the production of our splendid Ordnance survey maps are deposited by current on matrices taken from the original engraved plates, which are thus never injured or worn, are always ready for addition or correction, while the copies may be multiplied at pleasure and renewed at will.

Nickel-plating, by which the readily oxidisable metals like iron are coated with a thin layer of the more durable material nickel, is becoming a great industry; the trappings of harness, the exposed parts of machinery, the fittings of cycles and carriages and innumerable articles of daily use are being rendered not only more durable but more beautiful.

The electro-deposition of iron, as devised by Jacobi and Klein, in the hands of Prof. Roberts-Austen, F.R.S., is giving very interesting results. The dies for the coins which were struck at our Mint on the occasion of the Jubilee of the Queen were modelled in plaster, reproduced in intaglio by the electro-deposition of copper, and on these copper moulds hard excellent iron in layers of nearly $\frac{1}{10}$th of an inch was deposited.

The exact processes of measurement, which have led to such vast improvement in our telegraphic systems, have scarcely yet penetrated into this field of electrical industry, and little is known at present of the exact relations of current and electromotive force with respect to surfaces of contact, rate of deposit and resistance of liquids. Captain Sankey, R.E., of the Ordnance Survey Department, has done some useful work in this direction.

The extraction of metals from their ores by deposition has received wide application in the case of copper. In 1871 Elkington proposed to precipitate copper electrolytically from the fused sulphide of copper and iron known to the copper smelter as "regulus." Thin copper plates were arranged to receive the deposited copper while the foreign metals, including gold and silver, fell to the bottom of the solution, the process being specially applicable, it was supposed, to regulus containing small quantities of the precious metals.

The electrical purification of copper from impure "blister copper" or "blade copper" has also made great progress, and special dynamos are now made which will, with an expenditure of 100 horse-power, precipitate 18 tons of copper per week. The impure metal is made to form the anode in a bath of sulphate of copper, the metal being deposited in the pure form on a thin copper cathode. It was not very long ago considered very economical to absorb ·85 horse-power in depositing one pound of copper per hour, but now the same work can be done with ·3 horse-power. Mr. Parker, of Wolverhampton, has done good work in this direction, and his dynamos in Messrs. Bolton's works have revolutionised this process. Both at Swansea and Widnes immense quantities of copper, in spite of the restrictive operations of the copper syndicate, are being produced by electro-deposition. Copper steam pipes for boilers are now being built up of great firmness, fine texture, and considerable strength, by Mr. Elmore, at Cockermouth, by electro-deposition on a rotating mandrel in a tank of copper. By this process one ton of copper requires only a little more than one ton of coal to raise the requisite steam to complete the operation.

It has been shown that the electrolytic separation of silver from gold by similar methods is perfectly practicable. The value of the material to be dealt with may be gathered from the fact, communicated to the "Gold and Silver Commission" now sitting, that nearly 90,000,000 ounces of silver are annually produced, and the greater portion of this amount contains sufficient gold to render refining remunerative. Although the old acid process of "parting" gold and silver remains practically undisturbed, there seems no reason to doubt that in the future electricity will render us good service in this direction, as it has already in the purification of copper.

There is not much actual progress to report in the extraction of gold from its ores by electrical agency. The conversion of gold into chloride of gold by the direct, or indirect, action of chlorine is employed on a very large scale in [Grass Valley] California and elsewhere. This fact has led to well-directed efforts to obtain by electrolytic action, chlorine which should attack finely divided gold suspended (with the crushed ore) in the solution from which the chlorine was generated, the gold, so converted into soluble chloride, then being deposited on a cathode. The process would seem to be hopeful; but is not as yet a serious rival to the ordinary chlorination method.

In the amalgamation of gold ores much is expected from the possibility of keeping clean, by the aid of hydrogen set free by the electric current, the surfaces of amalgamated plates.

It is well known that the late Sir William Siemens considered that the electric arc might render good service in the fusion of metals with high melting points, and he actually succeeded in melting 96 ounces of platinum in ten minutes with his electrical furnace. The experiments were interrupted by his untimely death; but in the hands of Messrs. Cowles the electric arc produced by 5,000 amperes and 500 horse-power is being employed on a very large scale for the isolation of aluminium (from corundum), which is immediately alloyed *(in situ)* with copper or iron, in the presence of which it is separated.

The heating power of large currents has been used by Elihu Thomson in the United States, and by Benardos in Russia, to weld metals, and it is said to weld steel without affecting its hardness. It has even been proposed to weld together in one continuous metallic mass the rails of our railways, so as to dispense entirely with joints.

The production of chlorine for bleaching and of iodine for pharmaceutical purposes, the economical production of oxygen, are also processes now dependent on the electrolytic effect of the electric current.

It is almost impossible to enumerate the various general purposes to which electricity is applied to minister to our wants and to add to our comforts. Everyone appreciates the silent efficiency of the trembling electric bell, while all will sooner or later derive comfort from the perennially self-winding electric clock. Correct mean time is distributed throughout the length and breadth of the land by currents derived from Greenwich Observatory. Warehouses and shops are fitted with automatic contact pieces, which on any undue increase of temperature due to fire create an alarm in the nearest fire station; and at the corner of most streets a post is found with a face of glass, which on being broken enables the passer-by or the watchful and active policeman to call a fire-engine to the exact spot of danger. Our sewers are likely to find in its active chemical agency a power to neutralise offensive gases, and to purify poisonous and dangerous fluids. The germs of diseases are attacked and destroyed in their very lairs. The physician and the surgeon trust to it to alleviate pain, to cure disease, to effect organic changes beyond the reach of drugs. The photographer finds in the brilliant rays of the arc lamp a sun which enables him to pursue his lucrative business at night, or during the dark and dismal hours of a black November fog of London.

We learn from the instructive and interesting advertising columns of our newspapers that "electricity is life," and we may perhaps read in the more historical portion of the same paper that by a recent decision of the New York Parliament, "electricity is death." It is proposed to replace hanging by the more painless and sudden application of a powerful electrical charge; but those who have assisted at this hasty legislation would have done well to have assured themselves of the practical efficacy of the proposed process. I have seen the difficulty of killing even a rabbit with the most powerful induction coil ever made, and I know those who escaped and recovered from the stroke of a lightning discharge.

The fact that the energy of a current of electricity either when it flashes across an air space, or when it is forced through high resistance assumes the form of heat of very high temperature led early to its employment for firing charges of gunpowder; and for many civil, military, and naval purposes it has become an invaluable and essential agent. Wrecks like that of the Royal George at Spithead were blown up and destroyed; the faces of cliffs and quarries are thrown down; the galleries of mines and tunnels are excavated; obstructions to navigation like the famous Hell Gate, near New York, have been removed; time guns to distribute correct time are fired by currents from Greenwich at 1 p.m. In the operations for war, both for attack and defence, submarine mining has become the most important branch of the profession of a soldier and a sailor. Big guns, whether singly or in broadside, are fired; and torpedoes, when an enemy's ship unwittingly is placed over them, are exploded by currents of electricity.

An immense amount of research has been devoted to design the best form of fuse, and the best form of generator of electricity to use to explode

Digitized by Google

them. Gun tubes for firing consist of a short piece of very fine wire embedded in some easily fusible compound, while the best form of fuse is that known as the Abel fuse, which is composed of a small, compact mass of copper phosphide, copper sulphide, and potassium chlorate. The practice in the use of generators is very various. Some, like the Austrians, lean to the high-tension effects of static electricity; others prefer magneto machines; others use the dynamo; while we in England cling with much fondness to the trustworthy battery. Since the electric light has also become such a valuable adjunct to war purposes, it is probable that secondary batteries will become of immense service. The strong inductive effects of atmospheric electricity are a source of great danger. Many accidental explosions of fuses have occurred. An experimental cable with a fuse at one end was laid below low-water mark along the banks of the Thames at Woolwich. The fuse was exploded during a heavy thunderstorm. The knowledge of the causes of a danger is a sure means for the production of its removal, or of its reduction to a minimum. Low-tension fuses and metallic circuits reduce the evils of lightning, but have not removed them. Should war unhappily break out again in Europe, submarine mining will play a very serious part, and, paradoxical as it may appear—as has been suggested by the French ambassador, M. Waddington—its very destructiveness may ultimately prove it to be a powerful element of peace.

It seems incredible that, having utilised this great power of nature to such a wide and general extent, we should be still in a state of mental fog as to the answer to be given to the simple question—What is electricity? The engineer and the physicist are completely at variance on this point. The engineer regards electricity, like heat, light, and sound, as a definite form of energy, something that he can generate and destroy, something that he can play with and utilise, something that he can measure and apply. The physicist—at least some physicists, for it is difficult to find any two physicists that completely agree with each other—regard electricity as a peculiar form of matter pervading all space as well as all substances, together with the luminiferous ether which it permeates like a jelly or a sponge. Conductors, according to this theory, are holes or pipes in this jelly, and electrical generators are pumps that transfer this hypothetical matter from one place to another. Other physicists, following Edlund, regard the ether and electricity as identical, and some, the disciples of Helmholtz, consider it as an integral constituent of nature, each molecule of matter having its own definite charge, which determines its attraction and its repulsion. All attempts to revive the Franklinian, or material theory of electricity, have, however, to be so loaded with assumptions, and so weighted with contradictions, that they completely fail to remove electricity from the region of the mysterious. It is already extremely difficult to conceive the existence of the ether itself as an infinitely thin, highly elastic medium, filling all space employed only as the vehicle of those undulatory motions that give us light and radiant heat. The material theory of electricity requires us to add to this another incomprehensible medium embedded or entangled in this ether, which is not only a medium for motion, but which is itself moved. The practical man, with his eye and his mind trained by the stern realities of daily experience, on a scale vast compared with that of the little world of the laboratory, revolts from such wild hypotheses, such unnecessary and inconceivable conceptions, such a travesty of the beautiful simplicity of nature.

He has a clear conception of electricity as something which has a distinct objective existence, which he can manufacture and sell, and something which the unphilosophic and ordinary member of society can buy and use. The physicist asserts dogmatically: "Electricity may possibly be a form of matter—it is not a form of energy." The engineer says distinctly: "Electricity is a form of energy—it is not a form of matter; it obeys the two great developments of the present generation—the mechanical theory of heat and the doctrine of the conservation of energy." There must be some cause for this strange difference of views. It is clear that the physicist and the engineer do not apply the term electricity to the same thing. The engineer's electricity is a real form of energy; the speculative philosopher's electricity is a vague subjective unreality which is only a mere factor of energy and is not energy itself. This factor, like force, gravity, life, must, at any rate for the present, remain unknowable. It is not known what force is; neither do we know what is matter or gravity. The metaphysician is even doubtful as regards time and space. Our knowledge of these things commences with a definition. The human mind is so unimpressionable, or language is so poor, that writers often cannot agree even on a definition. The definition of energy is capacity for doing work. We practical men are quite content to start from this fiducial line, and to affirm that our electricity is a something which has a capacity for doing work; it is a peculiar form of energy. The physicist may speculate as much as he pleases on the other side of this line. He may take the factors of energy, and mentally play with them to his heart's content; but he must not rob the engineer of his term *electricity*. It is a pity that we cannot settle our difference by changing the term. Physicists might leave the term *electricity* to the form of energy, which is an objective reality, and which the ordinary mortal understands; while engineers would be quite content if speculative physicists and enthusiastic mathematicians would call their subjective unreality, their imaginary electrical matter, by some other term. If it be necessary to mentally create some imaginary matter to fulfil the assumptions and abstractions of their mathematical realisations, let them call it *coulombism* or *electron*, and not appropriate the engineer's generic and comprehensive term electricity. The engineer finds the motions of existing matter and of the ether quite sufficient to meet all his requirements, and to account for all those phenomena which are called electrical.

It seems paradoxical to assert that two unrealities can form a reality, or that two subjective ideas can become an objective one; but it must be remembered that in all electrical phenomena that which makes them real and objective is derived from without. The motion that renders an electrical phenomenon evident is imparted to it from some other form of energy. The doctrine of the conservation of energy asserts that energy is never destroyed, it is only transformed—work must be done to render it evident. No single electrical effect can be adduced which is not the result of work done, and is not the equivalent of energy absorbed. The engineer's notion of work—something done against resistance; and of power—the rate at which this change of condition is effected—are the keystones to the conception of the character of those great sources of power in nature whose direction to the uses and convenience of man is the immediate profession of those who generally assemble together in Section G of the British Association to discuss the "practical application of the most important principles of natural philosophy which has, in a considerable degree, realised the anticipations of Bacon and changed the aspect and state of affairs in the whole world."

I cannot pretend to have given a survey of all the practical applications of electricity; I have but briefly indicated the present area covered by the new and rapidly-growing industry. 5,000,000 people upon the globe are now dependent on the electric current for their daily bread; scarcely a week passes without some fresh practical application of its principles, and we seem to be only on the shore of that sea of economy and beneficence which expands with every new discovery of the properties of electricity, and spreads already beyond the mental grasp of any one single worker.

MATHEMATICAL AND PHYSICAL SECTION (A).

PROFESSOR G. F. FITZGERALD'S ADDRESS.

The British Association in Bath, and especially we here in Section A, have to deplore a very great loss. We confidently anticipated profit and pleasure from the presence in this chair of one of the leading spirits of English science, Dr. Schuster. We deplore the loss and we deplore the cause of it. It is always sad when want of strength makes the independent dependent, and it is doubly sad when a life's work is thereby delayed; and to selfish humanity it is trebly sad when, as in this case, we ourselves are involved in the loss. And our loss is great. Dr. Schuster has been investigating some very important questions. He has been studying electric discharges in gases, and he has been investigating the probably allied question of the variations of terrestrial magnetism. We anticipated his matured pronouncements upon these subjects, and also the advantage of his very wide general information upon physical questions, and the benefit of his judicial mind while presiding here.

As to myself, his substitute, I cannot express how much gratified I feel at the distinguished honour done me in asking me to preside. It has been one of the ambitions of my life to be worthy of it, and I will do my best to deserve your confidence; man can do no more, and upon such a subject "the less said the soonest mended."

I suppose most former occupants of this chair have looked over the addresses of their predecessors to see what sort of a thing was expected from them. I find that very few had the courage to deliver no address. Most have devoted themselves to broad general questions, such as the relations of mathematics to physics, or more generally deductive to inductive science. On the other hand, several have dealt each with his own speciality. On looking back over these addresses my attention was specially arrested by the first two past presidents of this section, whose bodily presence we cannot have here. They were presidents of Section A in consecutive years. In 1874 Provost Jellett occupied this chair, and in 1875 Prof. Balfour Stewart occupied it. Both have gone from us since the last meeting of this Association. Each gave a characteristic address. The Provost, with the clearness and brilliancy that distinguished his great intellect, plunged through the deep and broad questions surrounding the mechanism of the universe, and with impassioned earnestness claimed on behalf of science the right to prosecute its investigations until it attains, if it ever does attain, to a mechanical explanation of all things. This intrepid honesty to carry to their utmost the principles of whose truth he was convinced, the utter abhorence of the shadow of double dealing with truth, was eminently characteristic of one whom all, but especially we of Trinity College, Dublin, will long miss as a lofty example of the highest intellectual keenness and honesty, and mourn as the truest-hearted friend, full of sympathy and Christian charity. In 1875 Prof. Stewart gave us a striking example of the other class of address in a splendid exposition of the subject he did so much to advance, namely, solar physics. He brought together from the two great storehouses of his information and speculation a brilliant store, and displayed them here for the advancement of science. Him, too, all science mourns. Though, from want of personal acquaintance, I am unequal to the task of bringing before you his many abilities and great character, you can each compose a fitting epitaph for this well-known great one of British science. In this connection I am only expressing what we all feel when I say how well timed was the Royal bounty recently extended to his widow. At the same time the niggardly recognition of science by the public is a disgrace to the enlightenment of the nineteenth century. What chancellor or general, with his tens of thousands, has done that for his country and mankind that Faraday, Darwin, and Pasteur have done? The "public" now are but the children of those who murdered Socrates, tolerated the persecution of Galileo, and deserted Columbus.

In a presidential address on the borderlands of the known delivered from this chair the great Clerk Maxwell spoke of as an undecided question whether electro-magnetic phenomena are due to a direct action at a distance or are due to the action of an intervening medium. The year 1888 will be ever memorable as the year in which this great question has been experimentally decided by Hertz in Germany and, I hope, by others in England. It has been decided in favour of the hypothesis that these actions take place by means of an intervening medium. Although there is nothing new about the question, and although most workers at it have

Digitized by Google

long been practically satisfied that electro-magnetic actions are due to an intervening medium, I have thought it worth while to try and explain to others who may not have considered the problem what the problem is and how it has been solved. A presidential address such as this is not for specialists; it is for the whole section; and I would not have thought of dealing with this subject only that its immediate consequences reach to all the bounds of physical science and are of interest to all its students.

We are all familiar with this, that when we do not know all about something there are generally a variety of explanations of what we do know. Whether there is anything of which there are in reality a variety of explanations is a deep question which some have connected with the Freedom of the Will, but which I am not concerned with here. A notable example of the possibility of a variety of explanations for us is recorded in connection with an incident said to have occurred in the neighbouring town of Clifton, where a remarkable meteorological phenomenon, as it appeared to an observing scientist, was explained by others as a bulls-eye lantern in the hands of Mr. Pickwick. Another kind of example is the old explanation of water rising in a pump, that "Nature abhors a vacuum," as compared with the modern one. Nowadays, when we know as little about anything, we say, "It is the property of electricity to attract." This is really little or no advance on the old form, and is merely a way of stating that we know a fact but not its explanation. There are plenty of cases still where a variety of explanations is possible. For example, we know of no *experimentum crucis* to decide whether the people I see around me are conscious or are only automata. There are other questions which have existed, but which have been experimentally decided. The most celebrated of these are the questions between the caloric and kinetic theories of heat, and between the emission and adulatory theories of light. The classical experiments by which the case has been decided in favour of the kinetic theory of heat and the undulatory theory of light are some of the most important experiments that have ever been performed. When it was shown that heat disappeared whenever work appeared, and *vice versâ*, and so the caloric hypothesis was disproved; when it was shown that light was propagated more slowly in a dense medium than in a rare, the sciences of light and heat were revolutionised. Not but that most who had studied the subject had given their adhesion to the true theory before it was finally decided in general estimation. In fact, Rumford and Davy's experiments on heat, and Young and Fresnell's experiments on light had really decided these questions long before the erroneous views were finally abandoned. I hope that science will not be so slow in accepting the results of experiment in respect of electro-magnetism as it was in the case of light and heat, and that no Carnot will throw back science by giving plausible explanations on a wrong hypothesis. Rowland's experiment proving an electro-magnetic action between electric charges depending on their absolute and not relative velocities has already proved the existence of a medium relative to which the motion must take place, but the connection is rather metaphysical and is too indirect to attract general attention. The importance of the striking experiments was that they put the language of the wrong hypothesis out of fashion. Elementary text-books that halted between two opinions, and, after the manner of text-books, leant towards that enunciated in preceding text-books, had all perforce to give prominence to the true theory, and the whole rising generation began their researches from a firm and true standpoint. I anticipated the same results to follow Hertz's experimental demonstration of a medium by which electro-magnetic actions are produced. Text-books which have gradually been invoking lines of force in some respects to the aid of learners and in others to their bewilderment, will now fearlessly discourse of the stresses in the ether that cause electric and magnetic force. The younger generation will see clearly in electro-magnetic phenomena the working of the all-pervading ether, and this will give them a firm and true standpoint for further advances.

And now I want to spend a short time in explaining to you how the question has been decided. An illustrative example may make the question itself clearer, and so lead you to understand the answer better. In colloquial language we say that balloons, hot air, &c., rise because they are light. In old times this was stated more explicitly, and therefore much more clearly. It was said that they possessed a quality called "levity." "Levity" was opposed to "heaviness." Heaviness made things tend downwards, levity made things tend upwards. It was a sort of action at a distance. At least it would have required such a hypothesis if it had survived until it was known that heaviness was due to the action of the earth. I expect levity would have been attributed to the direct action of heaven. It was comparatively recently in the history of mankind that the rising of hot air, flames, &c., was attributed to the air. Everybody knew that there was air, but it was not supposed that the upward motion of flames was due to it. We now know that this and the rising of balloons are due to the difference of pressure at different levels in the air. In a similar way we have long known that there is an ether, an all-pervading medium, occupying all known space. Its existence is a necessary consequence of the undulatory theory of light. People who think a little, but not much, sometimes ask me "Why do you believe in the ether? What's the good of it?" I ask them, "What becomes of light for the eight minutes after it has left the sun before it reaches the earth?" When they consider that they observe how necessary the ether is. If light took no time to come from the sun there would be no need of the ether. That it is a vibratory phenomenon, that it is affected by matter it acts through—these could be explained by action at a distance very well. The phenomena of interference would, however, require such complicated and curious laws of action at a distance as practically to put such a hypothesis out of court or else be purely mathematical expressions for wave propagation; in fact, anything except propagation in time is explicable by action at a distance. It is the same in the case of electro-magnetic actions. There were two hypotheses as to the causes of electro-magnetic actions. One attributed electric attraction to a property of a thing called electricity, to attract at a distance, the other attributed it to a pull exerted by means of the ether, somewhat in the way that air pushes balloons up. We do not know what the structure of the ether is by means of which it can pull, but neither do we know what the structure of a piece of India-rubber is by means of which it can pull, and we might as well ignore the India-rubber, though we know a lot about the laws of its action, because we do not know its structure, as to ignore the ether because we do not know its structure. Anyway, what was wanted was an experiment to decide between the hypothesis of direct action at a distance and of action by means of a medium. At the time that Clerk Maxwell delivered his address no experiment was known that could decide between the two hypotheses. Specific inductive capacity, the action of intervening matter, the delay in telegraphing, the time propagation of electro-magnetic actions by means of conducting material—these were known, but he knew that they could be explained by means of action at a distance, and had been so explained. Waves in a conductor do not necessarily postulate action through a medium such as the ether. When we are dealing with a conductor and a thing called electricity running over its surface, we are, of course, postulating a medium on or in the conductor, but not outside it, which is the special point at issue. Clerk Maxwell *believed* that just as the same air that transmits sound is able by differences of pressure—*i.e.*, by means of its energy per unit volume—to move bodies immersed in it, so the same ether that transmits light causes electrified bodies to move by means of its energy per unit volume. He believed this, but there was no experiment known then to decide between this hypothesis and that of direct action at a distance. As I have endeavoured to impress upon you, no *experimentum crucis* between the hypotheses is possible except an experiment proving propagation in time either directly, or indirectly by an experiment exhibiting phenomena like those of the interference of light. A theorist may speak of propagation of actions in time without talking of a medium. This is all very well in mathematical formulæ, but, as in the case of light, we must consider what becomes of it after it has left the sun and before it reaches the earth, so every hypothesis assuming action in time really postulates a medium whether we talk about it or not. There are some difficulties surrounding the complete interpretation of some of Hertz's experiments. The conditions are complicated, but I confidently expect that they will lead to a decision on most of the outstanding questions on the theory of electro-magnetic action. However, there is no doubt that he has observed the interference of electro-magnetic waves quite analogous to those of light, and that he has proved that electro-magnetic actions are propagated in air with the velocity of light. By a beautiful device Hertz has produced rapidly alternating currents of such frequency that their wave-length is only about two metres. I may pause for a minute to call your attention to what that means. These waves are propagated three hundred thousand kilometres in a second. If they vibrated three hundred thousand times a second the waves would be each a kilometre long. This rate of vibration is much higher than the highest audible note, and yet the waves are much too long to be manageable. We want a vibration about a thousand times as fast again with waves about a metre long. Hertz produced such vibrations, vibrating more than a hundred milion times a second. That is, there are as many vibrations in one second as there are seconds—in a day? No, far more. In a week? No, more even than that. The pendulum of a clock ticking seconds would have to vibrate for four months before it would vibrate as often as one of Hertz's vibrators vibrates in one second. And how did he detect the vibrations and their interference? He could not see them; they are much too slow for that; they should go about a million times as fast again to be visible. He could not hear them; they are much too quick for that. If they went a million times more slowly they would be well heard. He made use of the principle of resonance. You all understand how by a succession of well-timed small impulses a large vibration may be set up, it explains many things, from speech to spectrum analysis. It is related that a former Marquis of Waterford used the principle to overturn lamp-posts; his ambition soared above knocker-wrenching. So that it is a principle known to others besides scientific men. Hertz constructed a circuit whose period of vibration for electric currents was the same as that of his generating vibrator, and he was able to see sparks, due to the induced vibration, leaping across a small air space in this resonant circuit. The well-timed electrical impulses broke down the air-resistance just as those of my Lord of Waterford broke down the lamp-post. The combination of a vibrating generating circuit with a resonant-receiving circuit is one that I spoke of at the meeting of the British Association at Southport as one by which this very question might be studied. At the time I did not see any feasible way of detecting the induced resonance; I did not anticipate that it could produce sparks. By its means, however, Hertz has been able to observe the interference between waves incident on a wall and the reflected waves. He placed his generating vibrator several wave-lengths away from a wall, and placed the receiving resonant circuit between the generator and the wall, and in this air-space he was able to observe that at some points there were hardly any induced sparks, but at other and greater distances from his generator they reappeared to disappear again in regular succession at equal intervals between his generator and the wall. It is exactly the same phenomenon as what are known as Lloyd's bands in optics, which are due to the interference between a direct and a reflected wave. It follows hence that, just as Young's and Fresnell's researches on the Interference of Light prove the undulatory theory of optics, so Hertz's experiment proves the ethereal theory of electro-magnetism. It is a splendid result. Henceforth I hope no learner will fail to be impressed with the theory—hypothesis no longer—that electro-magnetic actions are due to a medium pervading all known space, and that it is the same medium as the one by which light is propagated, that non-conductors can and probably always do, as Prof. Poynting has taught us, transmit electro-magnetic energy. By means of variable currents energy *is* propagated into space with the velocity of light. The rotation of the earth is being

Digitized by Google

slowly stopped by the diurnal rotation of its magnetic poles. This seems a hopeful direction in which to look for an explanation of the secular precession of terrestrial magnetism. It is quite different from Edlund's curious hypothesis that free space is a perfect conductor. If this were true, there would be a pair of great antipodes outside the air, and terrestrial magnetism would not be much like what it is, and I think the earth would have stopped rotating long ago. With alternating currents we *do* propagate energy through non-conductors. It seems almost as if our future telegraph cables would be pipes. Just as the long sound waves in speaking tubes go round corners, so these electro-magnetic waves go round corners if they are not too sharp. Prof. Lodge will probably have something to tell us on this point in connection with lightning conductors. The silvered glass bars used by surgeons to conduct light are exactly what I am describing. They are a glass, a non-conducting, and therefore transparent, bar surrounded by a conducting, and therefore opaque, silver sheath, and they transmit the rapidly alternating currents we call light. There would not be the same difficulty in utilising the energy of these electro magnetic waves as in utilising radiant heat. Having all the vibrations of the same period we might utilise Hertz's resonating circuits, and in any case the second law of thermodynamics would not trouble us when we could practically attain to the absolute zero of these, as compared with heat, long period vibrations.

We seem to be approaching a theory as to the structure of the ether. There are difficulties from diffusion in the simple theory that it is a fluid full of motion, a sort of vortex sponge. There were similar difficulties in the wave theory of light owing to wave propagation round corners, and there is as great a difficulty in the jelly theory of the ether arising from the freedom of motion of matter through it. It may be found that there is diffusion or it may be found that there are polarised distributions of fluid kinetic energy which are not unstable when the surfaces are fixed; more than one such is known. Osborne Reynolds has pointed out another, though in my opinion less hopeful, direction in which to look for a theory of the ether. Hard particles are abominations. Perhaps the impenetrability of a vortex would suffice. Oliver Lodge speaks confidently of a sort of chemical union of two opposite kinds of elements forming the ether. The opposite sides of a vortex ring might perchance suit, or maybe the ether, after all, is but an atmosphere of some infra-hydrogen element; these two latter hypotheses may both come to the same thing. Anyway we are learning daily what sort of properties the ether must have. It must be the means of propagation of light; it must be the means by which electric and magnetic forces exist; it should explain chemical actions and, if possible, gravity.

On the vortex-sponge theory of the ether there is no real difficulty by reason of complexity why it should not explain chemical actions. In fact, there is every reason to expect that very much more complex actions would take place at distances comparable with the size of the vortices than at the distances at which we study the simple phenomena of electromagnetism. Indeed, if vortices can make a small piece of a strong elastic solid we can make watches and build steam engines and any amount of complex machinery, so that complexity can be no essential difficulty. Similarly the instantaneous propagation of gravity, if it exists, is not an essential difficulty, for vortices each occupy all space, and they act on one another simultaneously everywhere. The theory that material atoms are simple vortex rings in a perfect liquid otherwise unmoving is insufficient, but with the innumerable possibilities of fluid motion it seems almost impossible but that an explanation of the properties of the universe will be found in this conception. Anything purporting to be an explanation founded on such ideas as "an inherent property of matter to attract," or building up big elastic solids out of little ones, is not of the nature of an ultimate explanation at all; it can only be a temporary stopping place. There are metaphysical grounds, too, for reducing matter to motion and potential to kinetic energy.

These ideas are not new, but it is well to enunciate them from time to time, and a presidential address in Section A is a fitting time. Besides all this it has become the fashion to indulge in quaint cosmical theories, and to dilate upon them before learned societies and in learned journals. I would suggest, as one who has been bogged in this quagmire, that a successor in this chair might well devote himself to a review of the cosmical theories propounded within the last few years. The opportunities for piquant criticism would be splendid.

Returning to the sure ground of experimental research, let us for a moment contemplate what is betokened by this theory that in electromagnetic engines we are using as our mechanism the ether, the medium that fills all known space. It was a great step in human progress when man learnt to make material machines, when he used the elasticity of his bow and the rigidity of his arrow to provide food and defeat his enemies. It was a great advance when he learnt to use the chemical action of fire; when he learnt to use water to float his boats and air to drive them; when he used artificial selection to provide himself with food and domestic animals. For two hundred years he has made heat his slave to drive his machinery. Fire, water, earth, and air have long been his slaves, but it is only within the last few years that man has won the battle lost by the giants of old, has snatched the thunderbolt from Jove himself, and enslaved the all-pervading ether.

The Indo-European Telegraph.—The second cable of the Indian Government, broken between Bushire and Jask, in the Persian Gulf, on the 13th ult., was repaired on the 1st inst., thus re establishing duplicate communication with Australia, China, and India, &c., by the Indo-European line. The delay caused by the breakage has been entirely worked off.

LETTERS FOR LEARNERS AND UN-PROFESSIONAL READERS.

BY H. D. WILKINSON.

CHAPTER IX.—*Magnetic Fields.*

(Continued from page 533.)

SECTION II.—ELECTRO-MAGNETIC FIELDS.

127. *Preliminary.*—The telegraph systems of Morse and Wheatstone, with their relay and translating apparatus, electric bells and telephone exchange annunciators, systems for the synchronising of clocks, and a large proportion of the industrial applications of electricity, depend for their action upon that great discovery made by Arago and Davy nearly seventy years ago, viz, that pieces of iron, steel, and other magnetic metals become magnetised when an electric current is passed through a coil of insulated wire surrounding them. A magnet so formed is termed an *electro-magnet.* Incidentally here we may remark that metals which are said to be *magnetic* are not necessarily magnetised, the terms magnetic and non-magnetic indicating simply whether they are or are not *capable of being magnetised.* The two important principles of the electro-magnet may be thus stated :—

1. Reversal of the direction of current round the iron causes a reversal of its magnetic polarity.

2. Cessation of the current causes almost complete disappearance of magnetic polarity in the case of soft annealed iron.

To this might be added the important aid now available for the manufacture of powerful steel magnets magnetised electromagnetically with the aid of currents now obtainable from dynamos and accumulators.

Considering the first principle—viz., that of reversal—it is found experimentally that if the current circulates in a clockwise direction round the iron core the end of the same nearest to the observer is a south pole, and *vice versâ.* This will be seen to be the case in the two Figs. 102 and 103, although the direction in which the wire is wound on is different in the two cases.

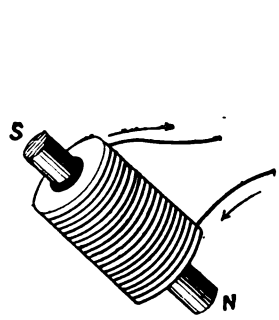

FIG. 102.

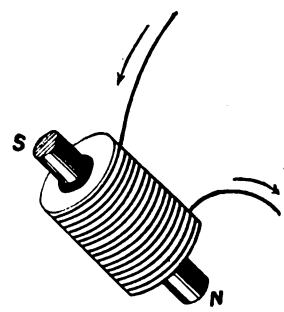

FIG. 103.

The winding of the coil or helix in Fig. 102 is called right-handed, the wire being wound on in a clockwise direction; while that in Fig. 103 is left-handed; and it will be seen that, in order to produce the same magnetic polarity in each, the current must be passed through in opposite directions in each as regards the ends of the coils. The current then circulates round each core the same way, producing the same poles in each. Reversing the current in either of these reverses the polarity.

An iron-filing diagram, taken with the electro-magnet of an ordinary telegraph "sounder," is shown in Fig. 104, a current being passed through the coils. The current was adjusted till the electro-magnet just supported the weight of the armature. Here we have precisely the same delineation of field as in the previous cases of permanent magnets. The two upright cores of soft iron are screwed to the horizontal iron keeper or "yoke" (Y).

The magnetic circuit is indicated by the dotted lines through the two cores and the yoke in Fig. 105, where it will be seen

Digitized by Google

that this circuit completes itself through the air between the two poles by the curved lines of force, one typical line being shown in the figure. The direction assumed for these lines has already been explained (para. 104), and is marked by arrow heads in the figure. Now, when there is an iron "armature" in proximity to the poles of the electro-magnet, most of the

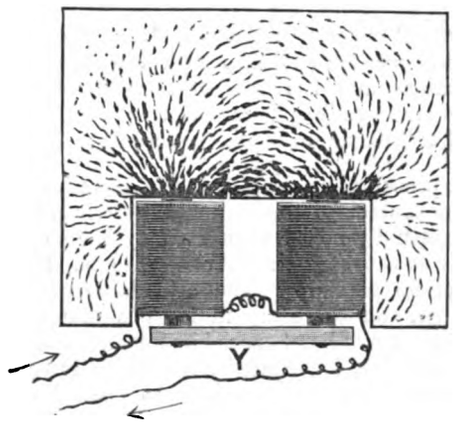

FIG. 104.

lines of force are deflected, or turned from their original direction, and pass through the armature (Fig. 106). Noticing the direction in which these lines pass through the interior of the armature it will be clear (para. 104) that the latter becomes magnetised, its poles, *s n*, being as shown. Attraction must, therefore follow, and the armature is drawn towards the poles, N S, against the force of the counteracting spring. Every

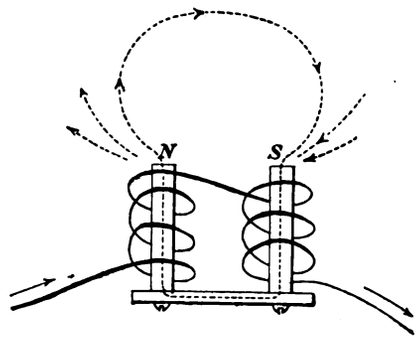

FIG. 105.

time the electrical circuit is completed by means of a "key" (*see* Fig. 34) this attraction occurs, and ceases when the circuit is broken, by means of which, with the Morse code of signals made up of dots and dashes, signals can be sent from one end of a line to the other, and read by sound, or by the ink-writer, as the case may be.

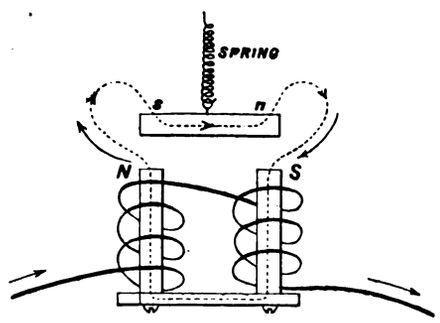

FIG. 106.

If we take an iron-filing diagram of the field when the armature is held away from the poles, or placed far enough away not to yield to the attraction (Fig. 107), the deflection of the lines of force through the armature is made evident; the position of the armature being seen by the absence of any filings, since the latter only take up the position of the curves of force through the air. We have here between the armature and the poles of the electro-magnet what is termed "magnetic induction"—that is, the magnetism of the armature is "induced" in it by the action of the poles of the electro-magnet; or we may look at it another way, viz., the armature

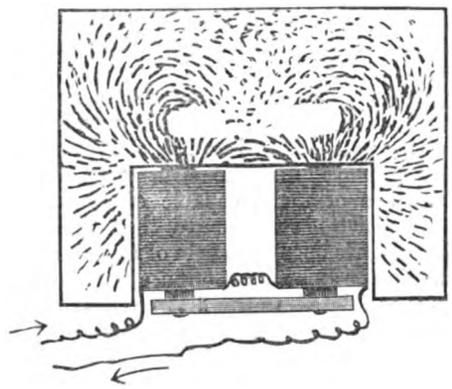

FIG. 107.

is placed in a magnetic field, and immediately becomes a magnet itself by "induction" from the field.

It will be seen by the figures (105 and 106) that the current must pass round the two cores of the electro-magnet in the opposite direction to produce opposite poles at the upper end of the cores. The winding for this is easy to remember by considering the two cores as put end to end where they join the yoke, so as to make one bar; the winding is then a simple helix wound continuously along the bar, in order to produce opposite poles at the extremities.

In the rapid transmission of signals it is very important to overcome, as far as possible, the *time* taken by the electro-magnet to become magnetised and demagnetised. To overcome this retarding effect of the coils, which is a property depending on their self-induction, the two coils are wound in multiple arc (paras. 41 and 61), as shown in Fig. 108, for the fast-speed Wheatstone receivers. More will be said upon this point when self-induction is considered.

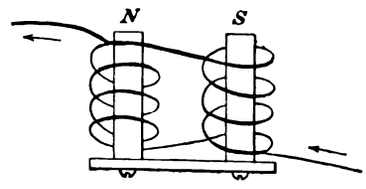

FIG. 108.

If the cores were not connected together by the yoke, the poles of the electro-magnet would be much feebler, because there would then be two air gaps to be bridged over by the lines of force instead of one. Further, if a complete circuit of iron were formed by bridging over both upper and lower pairs of core ends by yokes, there would be many more lines of force created through the interiors of the cores, but there would be practically no external field. An external field is, however, required in the case of a "sounder" to cause attraction of its armature, and therefore the only air gap left is that immediately beneath it. The rule is, let there be a magnetic circuit of iron everywhere except in the particular position where external magnetic action is required.

(*To be continued.*)

Bridlington Quay.—At a Local Board meeting on Tuesday the question of lighting the Sea Wall Parade with electric light was brought forward, and a resolution passed instructing the committee to ascertain upon what terms it could be done.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *August 25th*, 1888.

Last week I sent to you a description of the new meter which is patented by Prof. Forbes, which is a variation of his well-known mill wheel coulomb meter. This week I note that another patent has been issued on a like meter, designed for electric current, by Mr. O. B. Shallenberger, the electrician of the Westinghouse Company. This meter is simple in construction, and depends upon a quite novel principle. As described in the patent issued to Mr. Shallenberger, the principal elements employed in the construction of the meter are :—First, an armature of metal capable of rotation; second, an electric circuit, which is so arranged that when it is traversed by alternating electric currents a field of force is induced, having a given polar line or axis with reference to the armature; and third, a circuit so related to the first circuit that currents are produced in such second circuit by the action of those in the first, the phases of which succeed those of the currents in the first circuit, and set up for the armature a second field of force, the axis of which intersects that of the first. The armature may be built of soft iron, or of copper or other non-magnetic metal, or it may be composed of a core of soft iron, having a conducting circuit of other material surrounding. The meter is said to respond to the currents traversing the coils in such a manner as to obtain a reliable and accurate measurement of the current, the number of revolutions performed in a given time being directly proportional to the current consumed during that time. By the arrangement of circuits in this fashion the fields of force set up between the coils of the armature are such as to cause an attraction between them which sets the armature in rotation when the alternating currents pass through the coils. The shaft to which the armature, which is in the form of a disc, is attached, carries vanes which retard the motion of the armature in the same ratio as the tendency to rotation increases—that is, as the square of the speed, being thus in exact relation to the square of the current. I learn that this form of meter has been in successful operation at the Westinghouse factory, and that it will soon be put out on central station work.

A circular has been distributed in this country, which is causing no small amount of comment among the patent attorneys and electric light people. It purports to come from Shippey Brothers (Limited), of London, England. The circular states that a convention of patent experts was held recently at Washington to discuss certain questions in connection with incandescent lamp manufacture, and that the said convention gave an award to the firm which conferred upon it the monopoly of the manufacture of incandescent lamps of 100 candle-power and upwards. It is also stated that the convention gave a certificate as to the priority of invention to the same people for fancy striped and coloured lamps for decorative lighting. Everybody wants to know what it all means. I have still to meet an electrical expert who attended the said convention, and I have still to learn of any firm that took steps to call the said convention together. The circular states that the Shippey firm do not intend to manufacture lamps, but will maintain their rights under patents referred to, and will grant licenses on royalty the French, Belgian, and American patents being for sale. Why anybody in England or anywhere else abroad should imagine for a moment that such a convention, if it were held, could adjudicate on the value of patents, I am utterly at a loss to understand. It would seem as if an explanation from Shippey Brothers was in order.

The American Association for the Advancement of Science is holding its annual meeting at Cleveland from the 15th to the 22nd of this month. Reports from Cleveland would indicate that a very enjoyable and profitable meeting has been held during the present week. Over 300 members were in attendance, and the influx to the city of other visitors has, of course, been large. Some Papers of interest to electricians have been read, and others will probably follow. One of the most interesting is that by Prof. A. A. Michelson, of the Case School of Applied Science at Cleveland, "On the Desirability of Utilising Light Waves in Establishing Standards of Measurement." Another Paper of interest was that by Prof. E. L. Nichols and Mr. W. S. Franklin "On Experiments as to the Direction and Velocity of Electric Currents." A valuable Paper with practical bearing was that by Mr. C. J. H. Woodbury "On the Protection of Watches from Magnetism," and Mr. Woodbury pointed out that with the rapidly extending use of dynamos and the general introduction of motors, especially on street railways, watches that were unaffected by magnetism had become an absolute necessity.

Extensive preparations are now being made for the meeting in this city next week of the National Electric Light Association. It is generally hoped that we may have cool weather, as attendance at the sessions will otherwise be deprived of a good deal of its pleasure. The attendance promises to be unusually large, and there are indications that some of the Papers to be read will be of special importance and value. Dr. Schuyler S. Wheeler, for example, the energetic young expert of the Board of Electrical Control, is to present a Paper on "Electrical Conductors" in New York City; and Mr. W. Lee Church, whose excellent Paper on the advantages of small high-speed engines in stations instead of large low-speed engines attracted so much favourable notice at home and abroad a few months ago, will present another Paper on the topic "Electrical Steam Engineering." Other Papers are promised on special features of motor work and on the measurement of alternating currents for commercial purposes. This meeting will be immediately followed at the same place by the annual gathering of the National Telephone Exchange Corporation. This body, by the very nature of things, and unlike the Electric Light Association, has no tendency to rapid increase of membership, but still it maintains its organisation and affords the telephone men an opportunity to get together to discuss questions of special interest.

I note that the *Electrical World* this week issues a special supplement, entitled "A Day with Edison at Schenectady," describing a visit made to the Edison machinery works at that place. An interesting description of the works is given, supplemented by a large number of fine illustrations, which convey even more vividly than words an idea of the magnitude of the operations there carried on. It appears that the works employ from 700 to 800 men all the year round, and that it is nothing unusual to have in hand 200 or 300 dynamos, and 300 or 400 motors at the same time.

CORRESPONDENCE.

MR. KAPP'S REPORT ON THE LINEFF SYSTEM OF ELECTRIC TRACTION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your reprint of my report on the Lineff system of electric traction there is a typographical error on page 544. The pressure at which current is supplied to the cars should be 280 and not 230 volts, as will be evident from the fact that I have fixed the working pressure at the station at 300 volts, and the loss of pressure along the line at 20 volts.—Yours, &c.,

Wimbledon, August 31, 1888. GISBERT KAPP.

UNIPOLAR INDUCTION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In my letter on this subject in last week's *Electrician*, third line, for "incompatible" please read *as* compatible. This error, for which bad caligraphy is responsible, completely mars the meaning of the first paragraph.—Yours, &c.,

Staveley, 31st August, 1888. R. SNOWDON.

Digitized by Google

TO THE EDITOR OF THE ELECTRICIAN.

SIR: As Mr. Snowdon's letter (after correcting the misprint of incompatible for compatible in its first paragraph) contains no addition to the discussion beyond his statement that he has "shown" what, as a matter of fact, he has simply asserted, it is unnecessary for me to trespass further on your space, as your readers will have no difficulty in assigning their proper weight to Mr. Snowdon's "proofs."—Yours, &c.,

G. W. DE TUNZELMANN.

THE RECHNIEWSKI ALTERNATE-CURRENT MOTOR.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your issue of Aug. 24 you illustrate a machine designed by Mr. W. C. Rechniewski, stated to be manufactured by us. We must beg, however, to correct one or two mistakes. The machine illustrated was not constructed by us, but was built in France, and is, indeed, very French in constructive design. Further, the machine was not designed or constructed primarily with a view of working as an alternate-current motor, but as a dynamo, the view being that the use of a Pacinotti armature, together with a laminated field and poles, would give the advantages of the low magnetic resistance of the former, with the absence of Foucault currents in the poles, which generally arise from the use of this form of armature.

In the machine in question, however, which was submitted to us to test, the poles were bored with a greater clearance at the tips than in the centre, and as this form of boring (which we used in dynamos constructed in the latter end of 1885, and which has more recently been patented by Dr. Hopkinson for an analagous purpose) is quite sufficient to practically eliminate Foucault heating, the advantage of the laminated field is not apparent. Furthermore, however suitable for small dynamos, such a construction is, in our opinion, hardly solid enough for heavy machines. Of its performance as a motor we cannot speak very favourably. In our opinion the objection stated in your "Editorial Notes" on the currents induced in a coil short-circuited by the brush is fatal to the practical use of this form of motor, as with no load on it is possible to put an alternating current through it which, whilst insufficient to start it, is sufficient quickly to burn a coil out.

Even when running the same cause gives rise to very destructive sparking.—Yours, &c.,

W. T. GOOLDEN AND CO.

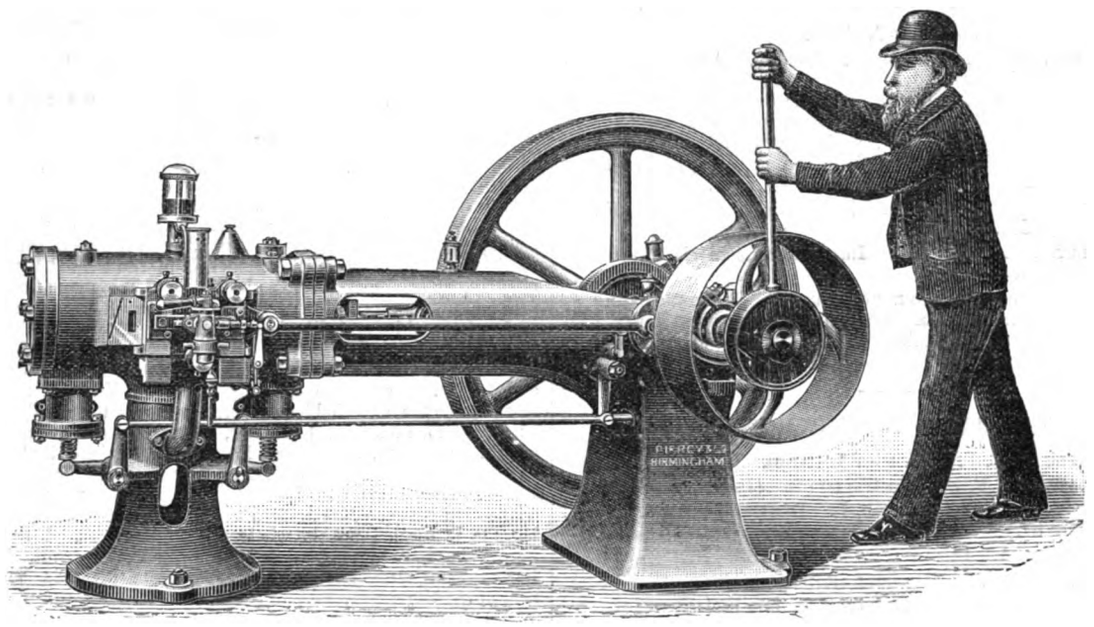
Halifax, Aug. 24, 1888.

LEA'S HAND STARTER FOR GAS ENGINES.

Lea's "Hand Starter" is designed to enable one man to do the work of two in starting a gas engine, and obviates the risk of accident attending the common practice of pulling round the fly-wheel. The attendant can start the engine without going inside the fence or handrail around the engine.

The apparatus, as will be seen in the figure, forms a smooth circular terminal at the end of the crank shaft, and is thus incapable of catching clothing, and even when the engine is running at full speed a slight pressure of the hand will arrest the motion of the body of the apparatus.

To use the starter, after lighting the igniting burner of the gas engine, the attendant places a bar or lever in one of the holes of the starter, as shown in the engraving, and works it up and down like a pump handle, thereby turning the crank shaft. When the engine begins to work the attendant ceases to work the bar, and withdraws it at leisure. The bar can be put in and taken out while the engine is at full speed.



Lea's Hand Starter for Gas Engines.

The attendant can turn the crank shaft, but the crank shaft cannot turn the attendant.

COMPANIES' MEETINGS & REPORTS.

Lancashire and Cheshire Telephonic Exchange Company (Limited).

The seventh annual meeting of this Company was held on Tuesday, in the Town Hall, Manchester, Mr. Alderman Joseph Thompson (the Chairman) presiding. The Directors' report was taken as read.

The Chairman moved that the report and statement of accounts be received and adopted, and that a balance dividend for the year at the rate of 7 per cent. per annum, less income-tax, be declared and paid forthwith. Referring to the death of the late Chairman, Mr. Charles Moseley, he said Mr. Moseley was most active in his work, and most kind and genial. The Directors requested him (Mr. Thompson) to take the place of Mr. Moseley. He could not but feel the great difference there was between himself and their late Chairman, who had studied the whole subject of telephony, was conversant with it, and was indefatigable in his exertions. He and his colleagues had given a great deal of time during the past year to the affairs of the Company, and he hoped the shareholders would be satisfied with the result of their labours. They would find from the report that the allocated income in 1888 was £89,797. 5s. 10d., and in 1887 it was £82,490. 14s. 6d., showing an increase of £7,306. 11s. 4d. The income in 1887 showed an increase over that of 1886 of £9,982. 1s. 4d. The service of trunk wires and call offices brought in an increase of £4,000 in 1885, and had steadily increased until now it was double what it was three years ago. The figures were—for 1885, £4,000; 1886, £5,000; 1887, £6,500; 1888, £8,000. This was most satisfactory, but it was only an indication of the great possibilities of the future. This £8,000 of income would represent the enormous number of 320,000 sixpenny telegrams. This showed one of two things—either that there had been a great disturbance of the telegraphic service in consequence of the institution of telephones, or, what was more probable, that the telephones had been an immense benefit to the commercial interests of the district. But they might also look at it in another way. It not only represented a saving of sixpence upon every message, but it allowed three minutes' conversation instead of twelve words. The number of subscribers' calls had continued to increase at the rate of about half a million a year. The aggregate number of messages sent in one year over the wires of the company was 12 millions, and these were carried at the rate of about one penny per communication, which showed what a very valuable instrument the telephone was in the hands of commercial people. There had been an increase of 1,609 miles in the length of wire in use. In 1888 they had 8,737 miles. Last year they had 7,128 miles. The company at first had some hesitation as to whether they should go beyond the large towns, or whether they should include in their system the smaller towns, and more especially whether they should connect these smaller towns with each other. After very careful consideration they decided that it was their duty, though it might not at the moment seem to be to their interest, to put as many towns as possible in communication one with the other. The Directors felt that they had obtained a very valuable concession which had practically become a monopoly, and that, having the privilege of serving towns like Manchester, Liverpool, and Blackburn, there was a certain claim on the part of the public that they should afford communication with those smaller towns. The Directors now felt that within certain limits it was very desirable in many respects to cover the country to as large an extent as possible. There was an almost boundless field open to them. They already had many towns connected with their system, but the Directors had felt that it was desirable to go even beyond their own system, and to get communication with other systems, more especially with the National Telephone Company. The main object the Directors had in this movement was, of course, to enable their subscribers to have as free communication as possible. But they also had another object in view. They felt that when their patents expired the position of the Company would be greatly strengthened if its system and the system of kindred companies covered the whole of the United Kingdom. Consequently, by arrangement with the National Telephone Company, telephonic communication had been set up between all the towns on the system of the Lancashire and Cheshire Telephonic Exchange Company and the principal towns in Yorkshire. Messages between any of the Lancashire and Cheshire towns were charged 6d. per conversation for three minutes, and for 1s. conversation could be had with Yorkshire. Since the last meeting of the shareholders several towns had been added to the trunk wire system, including Lancaster, Colne, Nelson, Brierfield, Leigh, Tyldesley, Longridge, Ribchester, Macclesfield and Bollington. Wires were in progress of erection to link up Ramsbottom, Tottington, Clitheroe, Bacup, Altrincham and Bowdon. They were very hopeful that the connection between Macclesfield and Bollington would prove very useful, because it opened up the whole of the Potteries. If sufficient support were offered, it was intended to extend the trunk line system to Barrow, for already several Manchester firms had sought this connection. Ulverston, Chester, Congleton, Wrexham, and other North Wales towns were to be included, and once the trunk system reached Wrexham they would be within a few miles of Oswestry, which was the district of the Western Counties Company, who had promised to run wires to meet them at their boundary at Oswestry whenever they were ready. This would bring the district of the Lancashire and Cheshire Telephonic Exchange Company in touch with Shrewsbury and other important towns on the Western Company's territory. The Directors had had inquiries as to whether Manchester and London could not be connected, and that subject was receiving consideration. It must be remembered, however, that it did not rest with the Lancashire and Cheshire Company so much as with the United and the National Company. He might, however, say that a wire had been run part of the way, and it was very probable that before long Manchester and Liverpool would be in direct communication with Birmingham and London. They had also had inquiries for connection with Glasgow, and if they got their system in North Lancashire, with Cumberland and Westmoreland thoroughly established, there was no reason why they should not go still further, and become connected with Glasgow. This subject also would have the careful consideration of the Directors, but a year or two might elapse before the whole programme was carried out. Judging from what had already been accomplished in a little more than three years, it was evidently only a question of time for still more to be done. He hoped the work of the Directors would have the approval of the shareholders, and that they would be encouraged to make still further progress. He desired next to refer to the switch-board arrangement at the central offices. The subscribers had felt that there were delays in obtaining communication. This, in the system formerly in vogue, was unavoidable. It was found from the experience of Liverpool and other places that by the adoption of the new American system a great improvement might be made, and at a very considerable expense the Directors had carried out the American plan. The new system was much quicker than the old. The old system was very good for small centres, but it became very tedious and caused much delay in large centres. By the new system they had been enabled to concentrate their work, and thereby they effected a considerable saving of time. An immense amount of labour was involved in concentrating all the wires into one switch-room, and bringing the new boards into operation, but, with the exception of a few days at Whitsuntide, the Manchester service was very little disturbed by the change. There had been a decrease of about £1,200 in the expenditure on maintenance. It was only right to say that this was not due to any neglect of work, nor did it indicate that there was an excessive expenditure in the two previous years. The wires that were originally laid were iron. These had gradually worn out, and had been renewed by copper

Digitized by Google

wires. This was a great advantage, because the copper wires had a greater conductive power, and were also much thinner, and were consequently not such a disfigurement in the sky. They could be run much better in cables, and did not look so hideous as the huge iron wires used to. The condition of the plant was very good. As regarded general expense, there was every year a steady increase, but this was inevitable. He now desired to refer to their connection with the United Company. They obtained a license from that company to work in the Lancashire and Cheshire district. They were subject to them under certain conditions. The Lancashire and Cheshire Company had to pay a royalty to the United Company, and the United Company had a right to sit on the Board, audit the accounts, and say whether or not there should be a fresh issue of capital. The Lancashire Company had to get their instruments through the United Company, and it would scarcely be wondered that sometimes there was a difference of opinion between the company's Board and the London authorities. He was glad to be able to say, however, that the relations between the two were now most friendly, and that certain matters of dispute which had existed for several years were now happily settled. The patent for the instruments would shortly expire, and when that time arrived it was quite possible that there might be something like opposition, or an attempt at opposition. The directors had long felt that the old adage, "Union is strength," was true of property as of other things. That feeling also pervaded the minds of the directors of the United Company and the subsidiary companies, and the result of conferences between the directors of the several companies was that there was a possibility of their all becoming amalgamated. Already the accounts of the various companies had been placed in the hands of a first-class firm of accountants, Messrs. Griffiths, of London, and these gentlemen were trying to bring these accounts into something like harmony. When their reports were presented an earnest attempt would be made to bring about amalgamation. Whenever that should happen it would be the duty as well as the pleasure of the Directors to call the shareholders together and lay the matter before them. With a greatly increasing business it was of course necessary to have more money, but pending the settlement of the question of amalgamation it was thought undesirable to ask for a fresh issue of stock, and as a matter of fact the Directors had not required more money. Now he had to refer to the relations of the Company with the Post Office Department. These, though friendly, were not in a certain sense satisfactory. They did not quarrel with one another, but the Directors thought that the Post Office put certain restrictions on their actions which ought to be removed, and they had tried to get them removed. In February last the directors of several telephone companies had an interview with the Postmaster-General, and laid their case before him. It was thought that the Postmaster-General would make some concessions, but, he was sorry to say, up to this time they had had no answer to their appeal. The Post Office had put a restrictive hand upon the proceedings of t lephone companies. He thought it would be greatly to the interest of the commercial community if that hand was very greatly relaxed. The grievances of the telephone companies were these: Fir t, the royalty charged by the Post Office, the view of the companies being that this charge, which was an indirect form of taxation, should be removed. Even if the telephone somewhat affected the income of the Telegraph Department, what did that matter? They got increased celerity, cheapness, and convenience. The Government ought to give the telephone companies a free hand or else take them over altogether, as they did the telegraph companies. If the Government would forego their royalties on telephones the amount thus saved by the companies could be put to the credit of the subscribers, and the commercial class would thereby greatly benefit. But he was sorry to say the General Post Office did not try to benefit commerce. It seemed most arbitrary for the Government to levy a royalty and to tie the hands of the companies with licenses and restrictions upon the transmission of news. At the present time the Lancashire and Cheshire Company provided a telegram service in Manchester, Liverpool, and Blackburn; but the revenue which they derived in the shape of commission was very far short of clearing the rental charged to them by the Government for the use of the telegram wires between the three exchanges and the three post offices. Their contention was that the Post Office Department ought to provide the telegram service free of charge, both in its own interests and in the interests of public convenience. The Lancashire and Cheshire Company had been asked to provide a telegram service to subscribers in other towns than Manchester, Liverpool, and Blackburn, but the charges made by the Post Office Department prevented them from doing so. In the United States the telegraph companies, so far from charging the telephone companies for rental of wires for the telegram service, paid the telephone companies a commission on the business received by telephone. He thought it not unreasonable to expect the English Postal Department to meet the telephone companies liberally in the matter. They simply asked for free wires. To illustrate the position of the telephone companies in England he would give them the result of one year's working of the telegram service; 10,005 messages, representing a money value of £466. 19s. 9½., were sent along their wires to the post offices of Manchester, Liverpool, and Blackburn. The Lancashire and Cheshire Company charged their subscribers a commission of £41. 15s. 0½d., but the postal authorities charged the Lancashire and Cheshire Company £310 for the use of the wires, which caused a total loss to the Company of £268. 4s. 11½d. for the year, without counting the clerical labour, the stamps, and the cost of collecting the telegrams and money of their subscribers. He thought they might claim some consideration from the Postal Department by reason of the fact that their wires saved a large amount in porterage, as something like 6,000 telegrams were delivered from the three post offices direct to the subscribers of the Lancashire and Cheshire Company without the intervention of the messengers. The Company had put up the wires to the Post Office at their own cost. He thought that the telephone system ought to be connected with the Postal Telegraph Office, so that the time of the public might be saved. It was of the utmost importance that they should have call offices conveniently placed so that the public could use them. He considered it would be a great public advantage to have call offices established in every post office. In some countries this was done, and call offices also existed in railway stations. He thought the experiment ought to be tried in England, but the Telegraph Department would not allow telephone call offices to be placed in their post offices. The Postal Department had also prohibited the telephone companies supplying news messages, such as the results of elections and of cricket matches, and the cotton reports. This showed that the convenience of commerce was not considered as it ought to be. The Post Office, indeed, was more anxious to maintain a huge monopoly than to accommodate the public. It had been his experience in telephony that the greater the freedom of action the greater the volume of business, and they had a right to ask the Department to remove the restrictions they now placed upon the use of the telephone.

Mr. ELI HEYWORTH, the Deputy-Chairman, seconded the adoption of the report, and the motion was carried.

Mr. Heyworth and Mr. C. S. Agnew were re-elected Directors, and Mr. C. R. Trevor (of the firm of Pilling and Trevor) was re-appointed one of the auditors.

A vote of thanks was passed to the Chairman, and this brought the proceedings to a close.

Manchester Edison-Swan Company (Limited).

The sixth ordinary general meeting of this Company was held on Monday last, at the Memorial Hall, Manchester. In the absence of Mr. V. K. Armitage, Chairman of the Company, Sir J. C. Lee took the chair.

Mr. JOHN E. SHARPLES, the secretary, read the following report of the Directors:—The net profit, including last year's balance, amounts to £1,781. 15s. 3d., which it is proposed to appropriate as follows: To payment of dividend at 5 per cent per annum, £1,000; to reserve fund, £500; balance to be carried forward, £282. In accordance with special resolutions, passed on 5th September, 1887, and confirmed on 3rd October, 1887, the name of the Company has been changed from the Manchester and District Edison Electric Light Company to Manchester Edison-Swan Company (Limited), and a reduction of the capital has been effected by cancelling capital which has been lost, to the extent of £1 per share upon each of the 20,000 "A" shares issued, and by reducing the nominal amount of all the "A" shares in the Company's capital from £10 to £9 per share. The Company's stock and plant have now been depreciated to their present market value and all losses written off, thus leaving the assets of the Company in a sound condition, because enabling the Directors to place £809. 18s. to a depreciation fund for future contingencies. The work of the past year has, on the whole, been satisfactory, showing an increase of business with a decrease in the expenses, and the Directors think the result cannot fail to be encouraging to the shareholders. The Directors, as in previous years, do not propose to ask any remuneration for their services; but if the work of the Company continues to be successful the attention of the shareholders will be drawn to this matter at a future meeting. Since the last general meeting the Directors have to deplore the loss by death of their esteemed colleague, Mr. Charles Moseley. Mr. J. R. Williamson, the Company's manager, has been elected to fill this vacancy on the Board, and the shareholders are asked to confirm his appointment as Director. Mr. Edward Cross retires in accordance with the Company's Articles of Association. He is, however, eligible, and offers himself for re-election.

In moving the adoption of the report, the CHAIRMAN said that in accordance with the decision arrived at in September last the capital of the Company had been reduced by £1 per share. The money had actually been lost, and it was thought well, as explained by the Chairman a year ago, to look the circumstances boldly in the face, and write off the necessary amount; so that now the figures in the balance sheet only represented actual values, except, of course, the £13,000 paid for patent rights, the present value of which is difficult to determine. The report in the hands of the shareholders showed a balance of £1,781. 15s. 3d. in favour of the Company. Out of that balance it was proposed to pay a dividend of 5 per cent., which would absorb about £1,000, to place £500 to reserve fund, and to carry forward £281. 15s. 3d. to the next account. The orders received during the year would have been more numerous than they had ever been but for the difficulty in carrying the wires either over or under the streets. If the Corporation gave them permission to cross the streets, business could be done on much more advantageous terms than at present.

Mr. J. R. WILLIAMSON, who seconded the motion, said that the Act of 1882, instead of facilitating the progress of the electric light, as it was intended to do, had done the very reverse. The electric lighting companies had had their hands tied ever since. During the present year, however, action had been taken, with the result that the objectionable clauses had been altered, and no doubt a great impetus would be given to electric lighting. Large lighting stations would be established all over the country within a few years, and he expected the company would participate in much of this work. He was glad to say that the business done showed an improvement over that of any previous year, and further, as the expenses of the company had been reduced, the result was so far satisfactory that the Directors recommended a dividend of 5 per cent.

Mr. N. SHELMERDINE said that in view of the probable increase in the business of the Company, he thought it was desirable to keep their ready money and trade with it rather than declare a dividend.

The CHAIRMAN replied that the Directors had very carefully considered the matter, and they thought the shareholders should share in any advantages that had been gained by careful trading. There was now every prospect of the Company becoming a dividend-paying company.

Digitized by Google

The motion was then put to the meeting, and the report and balance-sheet adopted and approved.

On the motion of the CHAIRMAN, seconded by Mr. GRIMSHAW, a dividend of 5 per cent. was declared, and it was resolved to use the remainder of the balance in the manner recommended by the Directors.

On the motion of the CHAIRMAN, seconded by Mr. ERNEST CREWDSON, Mr. Edward Cross was re-elected a Director, and the appointment of Mr. J. R. Williamson as managing director was confirmed. The auditors were re-elected, and a vote of thanks was accorded to the Directors for their past services.

The Chatham, Rochester and District Electric Lighting Company.

The second ordinary general meeting of the Chatham, Rochester and District Electric Lighting Company (Limited) was held at the Sun Hotel, Chatham, on Tuesday evening, the Mayor of Rochester (Councillor F. Wingent) presiding.

The SECRETARY (Mr. J. J. Acworth) having read the notice convening the meeting, the Directors' report was read, as follows:—

"As we do not propose to transact any business this evening, we feel bound to explain the object of now calling you together. No. 18 of the Company's Articles of Association prescribes that general meetings shall be held at least once in every year, as may be prescribed by the Company in general meeting, and if no other time and place be prescribed, a general meeting shall be held on the first Monday in July in every year, at such time and place as the Directors may appoint. Your Directors being anxious, if possible, to get the works in operation before calling the shareholders together, did not convene this meeting on the day appointed by the Company's Articles. Having, however, met with several delays, which could neither be seen or averted, it was thought best to hold their meeting without any further delay, although it will be now necessary to adjourn it for the transaction of business, which cannot be brought forward at the present time. At our first general meeting, which was held last November, we told you that 667 shares only had been taken up. This, of course, was insufficient for the purposes which your Directors had in view; but we are now glad to be able to inform you that since then the whole of the shares have been applied for and allotted. The first and one of the most important questions which had to be considered after the holding of the last general meeting was that of selecting a suitable site for erecting a central station. Much time, care and consideration were given to this matter. Advertisements were inserted in the three local papers inviting offers of land. The site which was eventually selected as being the best, you are doubtless all aware, was a portion of the Victualling Office, Rochester, the sub-lease of which, together with a couple of offices, has been secured upon satisfactory terms. On securing the latter, the registered office of the Company was removed from 22, High-street, to the Victualling Office, Rochester. Having obtained possession of the wharf, plans for the central station were prepared, and the work of making foundations and erecting buildings was set in hand with as little delay as possible. The most serious part of this business was making the necessary foundations to receive the machinery. It has, however, been done well, at a rather heavy cost. The buildings are now practically complete, the engines and boilers are fixed in place, and have been run to-day for the first time, and the dynamo electric machinery is now being erected, and will be in working order before the end of the present week. As might have been expected, considerable difficulty has been experienced in getting our mains run up and down the street, although the Corporation of Rochester and the Local Boards of Chatham and Gillingham have given us permission to cross the streets with our wires. We are, however, glad to say that the Chatham circuit is now rapidly approaching completion, and we believe that by the middle of next week it will be so; we shall then be prepared to take on customers for lighting. Taking all things into consideration, we believe we have considerable cause for encouragement since we last met. The Liverpool Electric Lighting Company has declared a dividend of 7½ per cent.; Taunton 5 per cent, and Hastings 3 per cent. In the latter case the dividend would have been much larger had not the company been severely handicapped by circumstances which occurred years ago. From this it will be seen that electric lighting has now become a paying business, and the fact is so well recognised that a wonderful activity is now evinced in every branch of electrical work; in proof of this, we can advance no better example afforded by the Woodhouse and Rawson Company, which declared an interim dividend of 12½ per cent., besides which a sufficient sum was carried forward to a reserve fund, which would have raised the dividends to 40 per cent. As the merits of electric lighting are becoming more fully recognised and also public confidence in the financial soundness of the same, it is not surprising to find that many towns are adopting the electric light, or else taking steps for so doing, such as London, Edinburgh, Dublin, Bradford, Birmingham, Liverpool, Glasgow, Southampton, Cheltenham, Leamington, Bath, Bournemouth, Poole, Weston-super-Mare, Ilfracombe, Exeter, Queenstown, Waterford, &c., &c."

On the motion of Mr. E. SMITH, seconded by Mr. S. J. HART, it was unanimously resolved that the meeting be adjourned to November 20th, 1888.

Pilsen-Joel and General Electric Light and Power Company (Limited).

An extraordinary general meeting of this Company was held at the Cannon-street Hotel on the 20th ult., under the presidency of Sir Rawson W. Rawson, K.C.B.

The notice convening the meeting having been read,

The CHAIRMAN said the sole object of the meeting was to confirm the resolution which was passed at the previous meeting to proceed to voluntary liquidation. That was with the prospect of carrying out an agreement which had been entered into between the Directors and Mr. Gwynne, with the sanction of a large maiority of the shareholders. Since the previous meeting, however, circumstances had occurred which had entirely altered the state of affairs. Mr. Fyfe, who had taken an active part in the affairs of the Company, not always nor generally with very happy results—and he (the Chairman) was quite sure that it would not be with happy results on this occasion—had sought and obtained an injunction restraining the Directors from carrying out the agreement. The judge did not go into particulars and did not pronounce a definite opinion upon the statements made by Mr. Fyfe or the counter-statements presented by the Directors; but he was under the impression that most important questions were raised, one being whether there could be such a resolution as that upon which the agreement in question was entered upon. He doubted whether the shareholders even were in a position to come to a resolution in a general meeting, such as the last, to sell the whole of the business of the Company. Upon that ground he decided to issue an interlocutory injunction restraining them from carrying out the agreement until the question could be argued in Court. This was merely a motion for a restraining injunction: it was not a motion to deal with the question at all, but merely to stop the proceedings until the question could be decided. Mr. Fyfe's grounds appeared to be three: the inability either of the Directors or of the shareholders to proceed in the manner in which they did proceed, that was to vote a sale and then proceed to liquidation. There was no doubt that the liquidator, if and when appointed, would have power to carry out a sale of that description, but the judge was under the impression, although it was contested by counsel, that there was a doubt whether any such power existed in the case of the Directors and shareholders. The Directors were now called upon to take action under these circumstances. Their sole desire had been, was, and would be, to carry out the wishes of the majority of the shareholders, to consult the interests of all, whether in the majority or the minority, and to wind up the affairs of the Company, which it seemed were not likely to be carried on in a satisfactory way under present circumstances, to the best possible advantage. They had not yet had time to consider what action should be taken. But one very important action had already been taken which, at all events, would satisfy the shareholders that neither Mr. Gwynne nor the Directors had the least desire to force the contract upon any portion of the shareholders who did not consider that it was just and equitable. Mr. Gwynne had offered in the most handsome manner to cancel the agreement, with the undertaking that he would not claim an indemnity for any loss or damages which such cancelment would entail upon him. The Directors had agreed to the cancellation, but whether that was a benefit to the shareholders or not was questionable. Mr. Fyfe and the Directors held very opposite views as to the value of the property for selling purposes. There had been plenty of opportunity during the preceding three months of ascertaining the value of the property. The Directors were satisfied that Mr. Gwynne's offer, by which he took upon himself all the liabilities and risks of the concern, was as good a one as they were likely to obtain. But, as they told Mr. Fyfe when he expressed a contrary opinion at the last committee meeting which he attended, if a better offer presented itself they would be only too happy to entertain it. No such offer had been presented, and no signs of any such offer being likely to be presented were apparent. The Directors were desirous of averting from the shareholders the certain waste of their funds which would be caused by the litigation that now lay before them, and the litigation which might follow under any circumstances in connection with the opposition raised by Mr. Fyfe and those who supported him. But since the previous week, when the case was heard, they had had insufficient means and opportunity for entering upon the consideration of the best course to be adopted with the view of meeting the wishes and consulting the interests of all the shareholders, because it must be borne in mind that whilst one portion of the shareholders were unwilling to advance any more money for the carrying on of the affairs of the Company, another body, holding three-fourths of the capital, were disposed to carry on the business under efficient management. Under these circumstances the Directors were of opinion that it was not desirable at that meeting to take action for confirming the resolution for the liquidation of the Company. They might find that such a course was the best to adopt eventually, but they would have to look into their financial position very carefully. He would remind them that when they reduced the call from 5s. to 3s. in the early part of the year, it was with the desire of calling up no more money than was requisite to meet the liabilities and to carry on the affairs until some such action as was taken at the last meeting could be taken for deciding the future of the Company. But now they were almost in the month of September, and there must be some weeks' delay before they could take renewed action. No time, he could assure them, would be lost; but there was quite a possibility that it would be necessary to call up more money to carry on until a decision could be come to. That, of course, was one of the consequences of the action taken by Mr. Fyfe. He regretted it exceedingly, for he thought the litigation might have been avoided. It was not the intention of the Board to move the confirmation of the resolution, and therefore the resolution would drop. The business of that meeting was therefore at an end.

Discussion ensued as to the best course to be now adopted. There were suggestions that 2s. per share should be called up and the Directors instructed to proceed with the business, but there were objectors to this, and eventually it was understood that the present position of inactivity would be maintained for a further period of two months, during which

Digitized by Google

the Board would cast about for a definite policy, and Mr. Fyfe would pursue his endeavours to bring forward, or induce some one else to bring forward, the "better offer" of which he had spoken.

NEW COMPANIES REGISTERED.

BARNET AND DISTRICT ELECTRIC SUPPLY COMPANY (LIMITED).—This company was registered on the 25th ult., with a capital of £5,000, divided into 490 Ordinary shares of £10 each, and 190 Founders' shares of £1 each, to adopt and carry into effect an agreement bearing date the 27th of July, 1888, and made between Henry Francis Joel of the one part and Walter Bramall, as a trustee for the company, of the other part, for the purchase of all the rights, benefits, and advantages of Henry Francis Joel, under a contract with the Barnet Local Board, for the lighting of the district by electricity, and the supply of electricity to shops, private houses and other buildings. The first subscribers are :—

	Shares.
*J. Ross, 1, Basinghall-street, London, E.C., merchant	10
W. M. Porter, Fairlawn, Northaw, Potters's Bar, N., merchant	10
J. Ewart, 46, Longridge-road, S.W.	10
*J. Palmer, jun., 50, Finsbury-square, E.C., merchant	10
*H. F. Joel, 31, Wilson-street, E.C., electrical engineer	10
*W. Mossop, Bycullah-park, Enfield	10
A. Morley, 1, Rocliffe-street, Islington, N., electrical engineer	10

The holders of the Ordinary shares are to receive in each year a preferential dividend of 7½ per cent. on the paid-up capital, and one moiety of the surplus profits after this payment in each year shall belong to the Founders' shares, and the remaining moiety shall be divided amongst the Ordinary shareholders. The qualification shall be the holding of shares of the nominal value of £100 in the capital of the company. Each director shall receive £10 per annum as remuneration for his services, and an additional sum of £50 is payable to the managing director.

BEDFORD ELECTRIC LIGHT COMPANY (LIMITED).—Registered by Richard Jordan, 120, Chancery-lane, W.C., with a capital of £15,000 in shares of £1 each. Object: to enter into contracts for electric lighting, either alone or in conjunction with other means, and for the supply of electric energy for power or transmission, and for fixing, maintaining, sealing, hiring, or otherwise dealing with transformers, wires, lamps, primary, secondary, or storage batteries, and all other electrical appliances and equipments with any corporation or person, and to supply or manufacture, purchase or hire, take in, exchange or otherwise acquire, sell and supply all machinery, motors, generators, lamp materials, or appliances in connection with the production, transmission, storage, and use by any means and any purpose of light and heat, and electric, magnetic or other force. The first subscribers are :—

	Shares.
Sir H. Mance, Menora, Newnham-road, Bedford	1
T. Jessopp, St. Paul's-square, Bedford	1
R. B. Stafford, Cauldwell House, Bedford	1
W. B. Jessopp, 3, St. Paul's-square, Bedford	1
O. T. Christie, Hoddesdon, Herts	1
T. Spencer, Ashburnham-road, Bedford	1
D. Bower, Springfield House, near Bedford	1

The number of directors shall not be less than three, and the first directors shall be appointed by the signatories to the Memorandum of Association. The qualification of every director shall consist of his being the registered holder of 100 shares in the company. By way of remuneration for their services the directors shall be paid a yearly sum of £250, to be divided as the directors may determine.

REES MINERS' PATENT SAFETY ELECTRIC LAMP COMPANY (LIMITED).—This company was registered on the 25th ult., with a capital of £50,000, in shares of £5 each, of which Nos. 1 to 50 (inclusive) are Founders' shares, to acquire under an agreement to be made between John Price Rees of the one part and Thomas M. Field, as trustee for the company, of the other part, certain letters patent for the United Kingdom and elsewhere of the Rees Miners' Patent Safety Electric Lamp and the Rees Double Liquid Primary Battery, and all future improvements, and any extensions of the same, to carry on the business of electricians, electrical engineers, and workers, and dealers, in electrical motive power and light. The first subscribers are :—

	Shares.
G. Holdsworth, Cremorne Wharf, Chelsea, metal manufacturer	1
T. M. Field, 41, Earl's Court-square, S.W.	1
H. Gerard, C.E., 31, Crondall-road, Fulham, S.W.	1
J. P. Rees, 1, Trinity-place, Trinity-street, Southwark, S.E., electrician	1
J. D. Ayres, 6, Old Jewry, E.C., agent	1
T. Baker, 422, Mansion House-chambers, E.C., surveyor	1
G. S. Anderson, 52, Queen Victoria-street, E.C., merchant	1

There is not to be less than three nor more than seven directors, in addition to any managing director or directors; qualification of a director, other than the first directors, shall be the holding of £500 in shares or stock of the company. The first directors are to be appointed by the subscribers; the remuneration to the directors for their services shall be the sum of £1,000 per annum, to be divided amongst them as they may determine.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended August 31, 1888, amounted to £4,805.

DIRECT SPANISH TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the month of August, 1888, amounted to £1,643, against £1,614 in the corresponding period of last year, showing an increase of £29.

EASTERN EXTENSION, AUSTRALASIA, AND CHINA TELEGRAPH COMPANY.—The traffic receipts of this company for the month of August, 1888, amounted to £38,103, against £36,274 in the corresponding period of 1887. Increase, £1,829.

EASTERN TELEGRAPH COMPANY.—The traffic receipts of this company for the month of August, 1888, amounted to £43,703, and to £43,609 in the corresponding period of 1887.

GREAT NORTHERN TELEGRAPH COMPANY.—Traffic returns: Receipts in August, 1888, £23,200; 1st January to 31st August, 1888, £179,200; corresponding months, 1887, £174,120; ditto, 1886, £169,960.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended August 31st, 1888, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company (Limited), were £3,991.

WEST COAST OF AMERICA TELEGRAPH COMPANY.—The traffic receipts of this company for the month ended August 31st, 1888, amounted to £5,450.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The estimated receipts of this company for the half month ended 31st August, 1888, were £2,469, as compared with £2,059 in 1887. May receipts, estimated at £5,793, realised £5,830.

THE TRUSTEES, EXECUTORS & SECURITIES' INSURANCE CORPORATION (Limited).

CAPITAL, £2,000,000.

FIRST ISSUE OF £1,000,000 FULLY SUBSCRIBED. PAID UP, £300,000. UNCALLED, £700,000.

BOARD OF DIRECTORS.

The Right Hon. Sir H. J. SELWIN-IBBETSON, P.C., Bart., M.P., *Chairman.*
LORD CLAUD J. HAMILTON, *Deputy Chairman.*

Hon. EVELYN ASHLEY.
J. SPENCER BALFOUR, Esq.
MICHAEL BIDDULPH, Esq., M.P.
W. P. BOUVERIE, Esq.
ARTHUR CLARKE, Esq.
Sir WILLIAM FORWOOD.
EDWARD LAWRENCE, Esq.
ERNEST NOEL, Esq.
Sir JOHN PENDER, K.C.M.G.
J. DENISON PENDER, Esq.
The Right Hon. LORD SUDELEY, P.C., F.R.S.
LEOPOLD SALOMONS, Esq.
JOHN C. SALT, Esq.
C. A. WHITMORE, Esq., M.P.

Offices—**WINCHESTER HOUSE, OLD BROAD STREET. LONDON, E.C.**

The principal objects of the Corporation are:—

1. Performing the duties of Trustee, Executor and Administrator.
2. The Insurance of Bonds, Shares and all other Securities lodged with the Corporation against risks of all kinds.
3. The Issue of Warrants and Certificates against Securities deposited, and making and procuring advances on such Warrants.

The Office of Trustee or Executor is to private persons usually a thankless post, involving much anxiety, time and money, and frequently leads to serious actual loss; whilst death, illness and change of residence necessitate frequent fresh appointments, and consequent expense to the parties interested. The Corporation undertakes all the duties of Executor, Trustee or Administrator for reasonable remuneration proportioned to the work and responsibility in each case.

The Corporation insures existing Trustees and Executors against all risks attending those positions, where the business is conducted by the Solicitors to their Trusts under the supervision of the Corporation, it not being the desire of the Corporation to interfere in any way with the duties of the family solicitor.

The Corporation acts as Trustees for the Debenture Holders in Public Companies.

For terms, &c., application should be made to the General Manager at the Company's Office.

GEORGE PEARSON, *General Manager and Secretary.*

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL SCIENCE, INDUSTRY AND ENGINEERING.

No. 539.—Vol. XXI. FRIDAY, SEPTEMBER 14, 1888. Price 4d.

NOTES.

We do not propose this week to comment upon the Papers read in the sections at the meeting of the British Association which has just been brought to a conclusion, but next week we shall publish a detailed review of the results of the meeting, as regards electrical science, from the pen of Dr. Oliver Lodge. We therefore content ourselves with the remark that, in spite of some falling off in the numerical attendance, the meeting has been full of interest to electricians from beginning to end. The attraction has, however, chiefly centred in Section A (Mathematics and Physics), where the presence of Prof. Fitzgerald, Sir William Thomson, Lord Rayleigh, Prof. Rowland, and Dr. Oliver Lodge, has sustained an unflagging interest in the proceedings. The absence of an electrical section has been to some extent atoned for by the division of Section A into two portions, one of which was labelled "Mathematics," and the other "Electricity and Light." Since we seem now to be rapidly approaching the time when optics will be recognised as a mere branch of electro-magnetism, this arrangement may already be considered the equivalent of a purely electrical section.

In Section G (Mechanical Science) only one day was devoted to the application of electricity, and the Papers read, although interesting enough in their way, were scarcely of first-rate importance; nor did they, as a whole, possess the charm of novelty. Almost the only exception to this latter statement is to be found in Mr. Lowrie's Paper on the method of measuring alternating currents which is employed at Eastbourne, and Mr. Edmunds' very remarkable device for distributing electricity from secondary batteries. These two Papers, together with Prof. Forbes' Paper on "Electric Lighting in America," were discussed together, and we shall give the Papers and discussion next week.

In requesting Prof. W. E. Ayrton to repeat his lecture "On The Electric Transmission of Energy," the inhabitants of Bath have paid the Professor a very marked compliment, as this is the very first occasion in the history of the Association in which such a thing has happened; that the compliment is a well deserved one, all who were present on the first occasion would bear unanimous testimony. The remarkable manner in which Prof. Ayrton managed to steer between the Scylla of Technicality and the Charybdis of Inaccuracy excited the admiration of all who were conversant with the subject; whilst the dry humour of his style and the happy fertility of his local allusions simply brought down the house. Mr. Pickwick and his memorable adventures in Bath have, of course, afforded an unfailing resource for the witticisms of the lecturers at this meeting. We think that the inhabitants of Bath are to be much congratulated on the opportunity a second time afforded them of obtaining a sound, if elementary acquaintance, with one of the most interesting and most important problems of the day in so remarkably pleasant a form.

One observation of Prof. Ayrton's—our American friends would call it a Pointer—deserves, we think, to go down to posterity as the most concise explanation hitherto advanced of the different aspect, from an engineering point of view, presented by a study of Europe and of America in the closing years of the Nineteenth Century. There are two possible definitions of Inertia, says Prof. Ayrton; in this country it is defined as resistance to motion, and in America as resistance to standing still.

As was to be expected, the British Association, so far as it condescended to notice the subject of capital punishment by electricity, stamped it with emphatic disapproval. An assembly of English gentlemen who respect their profession could hardly do less.

The discussion on lightning conductors by Sections A and G of the British Association conjointly, which took place on Tuesday last, was of a most interesting character, and we shall give it in full next week. It was opened by Mr. W. H. Preece and continued by several engineers and leading physicists.

Lord Armstrong's recent article on "The Vague Cry for Technical Education" is answered in this month's *Nineteenth Century* by Sir Lyon Playfair, who is greatly exercised because so high an authority as Lord Armstrong has thrown cold water on the programme of the "Central Association for the Promotion of Technical Education." The question between these two disputants and the schools they severally represent seems to us to be one mainly of practical expediency; and a perusal of Dr. Playfair's Paper by no means convinces us of his competency to judge a matter of that sort. Lord Armstrong, like most captains of industry, knows exactly what he wants and how to get it; but he is rather afraid of getting more than he wants, which he probably would do if Sir Lyon Playfair had his own way. To put the matter bluntly, Lord Armstrong approves of technical and even scientific training only when and

Digitized by Google

where they *are* needed; Sir LYON PLAYFAIR would scatter these accomplishments broadcast in case they *may be* needed. Sir LYON asserts that their value is proved by the prevalent demand for them among the artisan classes. It is rather soon to speak so confidently; we suspect meanwhile that the chief value of technical training in the estimation of the artisan is that it will help him to better his condition—in other words, to rise above his fellow workers. The case of 39,000 workmen being thrown out of employment by the invention of a new method of making steel does not help the argument, unless Sir LYON PLAYFAIR wishes us to believe that these men would have been kept in work had they understood the process as well as BESSEMER.

ONE other remark we should like to make on Sir LYON PLAYFAIR'S article. Here, as elsewhere, he is peculiarly given to contrasting the educated and uneducated workman, by applying the term "brute" and "animal" to the latter, just as though the exercise of man's physical energies reduced him to the level of a horse. This same Dr. PLAYFAIR once called the skilled telegraphist, who was not also an accomplished electrician, an "ambidextrous monkey." All such comparisons are not merely inaccurate, they are highly inexpedient until we have entirely displaced manual labour by the aid of machinery; and when that time arrives the artisan will be nearer akin to an automaton than to any known animal, and will need technical education about as little. Probably neither Lord ARMSTRONG nor Sir LYON PLAYFAIR speaks his whole mind in discussing this question of technical education. The learned doctor hopes to create an unlimited supply of WATTS, STEPHENSONS, ARKWRIGHTS, CARTWRIGHTS and BESSEMERS, by giving the multitude technical education, whilst his practical opponent apprehends that there would be nobody left to work their inventions if we succeeded, and everybody left discontented if we failed.

IN another column will be found a paragraph on "The Manufacture of Light," extracted from Dr. LODGE'S valuable Papers on "Modern Views of Electricity," now appearing in *Nature*. Many of us have vaguely longed to know the secret of the direct production of light unaccompanied by heat, by the glow-worm, the fire-fly, and some still lower forms of animal life. Dr. LODGE has put these vague longings into articulate form. At present there does not seem much prospect of attaining the desired end, but if our gradually-increasing knowledge of the internal nature of molecules should ever lead to a practical method of producing light vibrations directly, unaccompanied to any great extent by heat vibrations, it will constitute one of the greatest boons that scientific investigation has ever conferred upon man.

DR. VAN DER WEYDE read a Paper last week before the Electric Light Convention in New York, dealing with Mr. BROWN'S recent experiments upon the internal resistance of dogs. The learned doctor is, of course, perfectly right in taking exception to Mr. BROWN'S method of connecting his voltmeter in series with his ammeter, and, as he very truly remarks, the readings so obtained would tend to be lower than the true value of the voltage. This leads us to suppose that the dogs, which were alleged to have succumbed to 300 volts or less, in reality fell victims to much higher potential differences. Dr. VAN DER WEYDE, indeed, goes into a most ingenious calculation (based upon the output of the dynamo employed to excite the field of the alternator), from which he deduces as a probable value of the E.M.F. no less than 82,063 volts. Of course, as Dr. WEYDE himself remarks, "this is an exaggerated estimate," but it is sufficient, he thinks, "to show the worthlessness of all the figures as given by Mr. BROWN." An abstract of this remarkable Paper will be found further on in this issue.

AT the conclusion of Dr. VAN DER WEYDE'S Paper, Dr. OTTO MOSES moved a series of resolutions, which were unanimously adopted, as follows:—

Whereas, The National Electric Light Association read with some uneasiness the persistent effort of rival interests to educate the public to a distrust of high potential electric currents, and

Whereas, They would protest with all energy against recent efforts to pit against each other continuous and alternating current systems of electrical distribution, which efforts have as their covert purpose the destruction of the harmony of action now existing between them, and

Whereas, This association for mutual protection recognises distinctly the danger of unfair legislation such as has distroyed the electric lighting interest of Great Britain; therefore be it

Resolved, That the National Electric Light Association emphatically declares that it is beyond doubt possible to produce and distribute high-tension currents for public use without any more danger or difficulty than attends the distribution of gas and water in our dwellings; and further be it

Resolved, That they would impress all legislators with the fact that success in the electric light and power business is based chiefly upon economy in the size of conductors, and that to utilise this fact high-tension currents were adopted in the first stages of development of electric lighting, and have been used ever since and will continue to be used; and, further, be it

Resolved, That it is our conviction that there is no difference in the danger attending the use of continuous or alternating currents, and that both may be so transformed before being used as to render them a perfectly harmless and tractable means of distributing electric power for use in cities.

MOST extraordinary accounts are being received in this country from New York with reference to the performances of the electric sugar refining invention of the late Prof. FRIEND; and the shares of the company have consequently risen to a quite alarming figure during the past week. We can offer no opinion as to the invention itself, as we know little more about it than the people who are planting their money upon it. But we have a decided opinion that a secret of the kind which this is represented to be cannot long be kept, and that the public may easily be deluded into paying too high a price for it, even if it answer all the expectations at present entertained of it.

Leeds.—The new reading room in connection with the Leeds Municipal Buildings was opened last week. It is lit by 112 incandescent lamps.

The Java-Macassar Cable.—Preparations are being made in Batavia for laying a direct submarine cable from Java to the port of Macassar.

Restoration of Communication with the East. — The Eastern Telegraph Company notify the restoration by their cables of telegraphic communication with India and the Far East.

Digitized by Google

St. Helena.—From a Blue Book, just published, relating to St. Helena, we learn that no lightning has visited that island since 1878, and storms are unknown.

Dunfermline.—The villages of Aberdour, Cowdenheath, and Burntisland, in West Fife, have been connected with the Dunfermline centre of the National Telephone Company.

Pisek.—The electric lighting of Pisek (Bohemia) was inaugurated on the occasion of the Emperor of Austria's visit to the town in connection with the army manœuvres.

Proctor's Mechanical Stoker.—We have received from the makers a copy of reports from firms using this mechanical stoker, which appears to be coming into extensive use.

University College, Dundee.—We have received the calendar of this college for 1888-89, the sixth session of the college. An engineering and mechanical laboratory has been added since last session, and also a department for instruction in the processes of dyeing and bleaching.

Bristol.—The contract for the erection of electrical controlling apparatus and signals, in connection with the machinery in a new granary built by the Docks Committee of the Council of the City of Bristol, has been secured by Messrs. King, Mendham and Co, electrical engineers, of that city.

House-to-House Electric Light Supply Company.—We are informed that this company has accepted the tender of Messrs. Peto Brothers for the erection of their first Central Electric Lighting Station at West Brompton. It is stated that the building will be completed by the middle of November.

Death of Mr. R. A. Proctor.—We regret to learn that Mr. R. A. Proctor, well known as a writer on popular astronomy, and as the editor of the popular scientific magazine entitled *Knowledge*, died at New York on Wednesday from yellow fever, contracted recently in Florida. Mr. Proctor was in his fifty-first year.

Postal Telegraph Servants in France.—Great discontent is reported to exist among the telegraph and postal clerks all over France at the way in which promotion is made. A meeting to discuss grievances was held on Tuesday night at the Salle Eliot in Paris, and it was decided to at once get up a monster petition.

Sir John Pender, K.C.M.G.—Sir John Pender had a private audience of the Sultan on Saturday, and received from His Majesty the Grand Cordon of the Medjidieh. Sir John, with his guests, the Dean of Westminster, Sir G. Elliott, Sir Robert Herbert, and Mr. James Pender, are on a visit to Constantinople on board his yacht.

India-rubber.—From Rangoon *The Times* correspondent announces the decision of the Indian Government to abolish the india-rubber monopoly and throw open the trade to all who are willing to pay a license. It is added that the abolition of this and other monopolies in Upper Burmah will greatly assist the commercial development of the country.

Castleford.—At the last ordinary meeting of the Castleford Local Board, in consequence of the gas company having positively declined to make any reduction in the price of gas supplied to the Board, it was resolved, on the recommendation of the Finance Committee, "That the clerk make inquiries as to the feasibility and cost of providing a substitute for gas."

Winter Sessions.—The 1888-89 Session of the Royal College of Science of Dublin has commenced, and the 1888-89 Session of University College, Bristol, begins on 10th October. Full particulars will be found in our advertisement columns. The winter session of the Charterhouse Science and Art Schools and Literary Institute will commence on October 1st.

Sir James Anderson.—Messrs. W. H. Beynon, fine art publishers, of St. Albans Lodge, Cheltenham, have just issued (for private circulation) a portrait of Sir James Anderson, F.R.G.S., F.G.S., &c., as a companion to that of Sir John Pender, executed by the same firm in 1883. The portrait is on a large panel of a deep rich tint, the high lights being picked out with white. The likeness, we are able to say, is an excellent one.

Manganese Steel for Resistance Coils.—Manganese steel is being employed by Dr. E. Hopkinson in the construction of resistance coils. The resistance of this material is 75 microhms per cubic centimetre at 15° C., and the temperature coefficient is 0·00136 per degree Centigrade, as compared with ·005 for ordinary iron, while its magnetic permeability (see *The Electrician*, March 9, 1888, and March 30, 1888) is also exceedingly small, being only about $\frac{1}{6000}$ that of iron.

Cutting Glass by Electrically Heated Wire.—We are informed that several American glass factories now cut the large cylinders of window glass by encircling the cylinder with a fine wire, which is then heated to redness by an electric current, and a drop of water being allowed to fall upon the hot glass a perfectly clean cut is obtained. The old method was to draw out a fibre of white hot semi-molten glass from the furnace by means of tongs, and to wrap it round the cylinder.

Electric Lighting at the British Association.—The electric lighting in connection with the meeting of the British Association at Bath was carried out by Messrs. Laing, Wharton and Down. A Thomson-Houston 6-unit constant-current dynamo was employed to light the 13 arc lamps, which burnt remarkably well. The Sidney Gardens were also illuminated nightly by Mr. Massingham, with 30 Thomson-Houston arc lamps. The current was brought from a temporary plant occupying the site where the central lighting station is to be placed. The arrangements were excellent, and the light left nothing to be desired in the way of steadiness and brilliancy.

Fleetwood.—The committee recently appointed at a meeting of Fleetwood ratepayers to inquire into the methods and cost of lighting in other towns have had several meetings to consider proposals from electric lighting and other companies; and when the sanction of the Board of Commissioners has been obtained the committee will proceed to towns to which they have been invited, to examine modern systems of lighting. The inducements to adopt the electric light are said to be locally very strong, and it is probable that for street illumination the committee may recommend the formation of a company to undertake the lighting of the town by electricity.

Electrical Search Lights.—It appears from the interesting account of the naval manœuvres which appears in the current *Fortnightly Review* that, although frequently serviceable in warding off the attacks of torpedo boats, the electric search lights failed to detect the escape of the "Warspite," "Iris," and "Severn" from Bantry Bay on the night of August 3, although several times levelled at them. The reasons for this failure seem to have been—first, the intense gloominess of the night, attended by a soft white haze; but chiefly, perhaps, because of the escaping vessels being carefully blackened all over, and rendered indistinguishable on the dark water.

Dundee Telephonic Fire Alarm.—A fire took place at Messrs. Bryden's premises in Dundee on Wednesday, 29th August. It was the first at which the firemen were called by the new electric bell arrangement recently fitted by the National Telephone Company at the Central Police Office. The apparatus was found perfectly satisfactory, and the men

Digitized by Google

were summoned to the police office and turned out in a remarkably short space of time. On an alarm of fire being received by telephone or otherwise at the police office, the attendant has only to pull out a pin, and bells are immediately rung loundly for nearly one minute at every fireman's house in the town. This arrangement has been introduced by the National Telephone Company in several other towns.

A New Portable Battery Cell.—A handy form of single liquid cell has been devised by Mr. Barber Starkey, of Kilry Lodge, Alyth, N.B. It consists, says *Industries*, of a cylindrical vessel in two halves, which are screwed together. The interior is separated by a perforated plate of insulating material, which supports the electrodes. The latter project into the lower compartment, which contains the electrolyte when the cell is in use; but upon turning the vessel upside down the electrode projects upwards, whilst the electrolyte escapes into the other compartment through the perforations in the diaphragm, and the cell is thus put out of use. To facilitate the turning over, the cylinder is provided with trunnions, and suspended from a handle by which the apparatus can be readily carried about.

Electric Lighting in the City.—At a meeting of the City Commissioners of Sewers, held at the Guildhall on Tuesday, the Clerk presented a communication from the East Strand and District Electric Light and Power Company, asking for the Commissioners' consent to the application they are about to make to the Board of Trade for a Provisional Order or license to supply electricity in the portion of the city from Farringdon-street and New Bridge-street, westward. On the motion of Mr. J. V. Moore, it was referred to the Streets Committee for consideration and report. An application from the London Electric Supply Corporation for the Commissioners' consent to a license being granted to them by the Board of Trade for the supply of electricity within the city was similarly referred.

Voltametric Control of Ammeters.—In testing the correctness of ammeters, M. Latschinow measures the time which a given number of amperes take to evolve one cubic centimetre of hydrogen in the voltameter. The accompanying table gives the number of minutes which one ampere takes to liberate one cubic centimetre of hydrogen at different temperatures. It is thus only necessary to pass the current for a certain time through the ammeter and voltameter, and then to correct for pressure.

Temperature. Degree.	Time. m.	s.	Temperature. Degree.	Time. m.	s.
15	13	21·4	..... 20	13	2·0
16	13	17·6	..... 21	12	58·0
17	13	13·7	..... 22	12	54·1
18	13	9·9	..... 23	12	50·0
19	13	6·0	..... 24	12	46·0

The Hartmann and Braun Ammeters.—The firm of Hartmann and Braun are now making a new form of ammeter and voltmeter, in which residual magnetism is reduced to a minimum. The instrument consists of a solenoid, in the interior of which there are soft iron semi-cylindrical segments, placed at regular intervals. In these intervals there are movable segments attached to the axle of the pointer, and projecting slightly beyond the fixed segments. When a current is passed through the instrument, the movable segments are drawn towards the strongest part of the field; that is to say, towards the prolongation of the fixed segments. The controlling force is gravity. It is claimed for this arrangement that while the field produced is practically as strong as if there were a solid core within the solenoid, yet, owing to the comparatively small size of the segments, there is but little residual magnetism.

Antwerp.—The electric light station belonging to the Antwerp goods depôt was burnt down on the night of the 15th and 16th August, and electrical plant to the value of £1,000 was destroyed. The fire was caused by an overheated chimney setting the woodwork of the building alight. The installation comprised three Gramme dynamos, two small Siemens dynamos, 48 Jablochkoff arc lamps, and the necessary steam plant. The railway company naturally expected a prolonged stoppage of the electric light. However, thanks to the energy of M. Gruss, electrician in charge, and of M. Bandsept, engineer to the Société d'Eclairage du Centre, which owns the station, 24 arcs were running on the evening of the 18th, and at the present moment the whole 48 lamps are working as regularly as before the fire. Such a rapid piece of work naturally entailed great labour and expense, and reflects the highest credit on all concerned.

Target Practice by the Electric Light.—According to the *Wezer Zeitung*, the German military authorities have lately been trying the electric light with a view of testing its utility in siege operations. The night was very dark, and the marksmen were 400 metres from the target, the light being 200 metres behind the shooting party. Two experiments were made. The marksmen were first placed within the region of light so that their sights were well defined; under these conditions 90 per cent. of the shots struck the targets about the height of a man's breast. The marksmen were then placed in the dark, and told to fire on to the lit-up targets; the shooting proved somewhat inferior. The plant consisted of an 18 horse-power engine, and a dynamo placed on a cart. The projectors can be 200 metres away from the dynamo, if circumstances require it. The apparatus is only intended to be used in attacking and defending fortified places.

Paris.—The installation of electric light recently provided for the Théâtre du Gymnase comprises 2 Belleville boilers, 2 Lecouteux and Garnier engines, 2 Thury dynamos, and 883 Khotinsky incandescent lamps of various candle-power. The engine and dynamo room is somewhat small, having a superficial area of less than 300 square feet. The engines are of the high-speed, non-condensing, variable expansion type. The dynamos are shunt-wound and have an output of 200 amperes and 70 volts at 350 revolutions; they are driven direct by means of a Raffard flexible coupling. The lamps are run off accumulators of the Schenek-Farbaky pattern. The accumulators are divided into two groups of 56 cells, each group of cells being arranged 2 in parallel and 28 in series. These cells weigh 250 kilos each, the lead weighing 200 kilos. As they have a capacity of 1,400 ampere-hours, their output amounts to 7 ampere-hours per kilogramme of lead, or 5·6 ampere-hours per kilogramme of dead weight.

Electric Light Statistics for Belgium.—Some interesting statistics relating to the present position of electric lighting in Belgium have been compiled by M. Wybauw. Belgium possesses, it appears, 302 isolated installations, with a grand total of 1,907 arc lamps and 21,248 incandescent lamps. Brussels has 38 installations, comprising 29 arcs and 4,281 incandescents. Antwerp comes next with 22 installations, which comprise 194 arcs and 1,320 incandescents. Liège has 20 installations, with 176 arcs and 662 incandescents. Accumulators are employed only in some half-a-dozen cases. Central stations are almost out of the question in Belgium, owing to the fact that all the large towns except Brussels have very stringent contracts with the gas companies. In 1885 a central lighting station was started at Antwerp, but was promptly closed by the legal proceedings of the gas company. Two or three small affairs, scarcely entitled to be called central lighting stations, are the only things of the kind to be seen in Belgium.

Eastbourne.—At a meeting last week of the Eastbourne Town Council the resolution of the Lighting and General Purposes Committee, recommending the discontinuance of the electric light, came up for consideration. Councillor Chambers believed that he would be representing the views of a great many members of the council when he said that he had heard with great regret of the possible loss of the electric light. He maintained that it had been a great success from an illuminating point of view, and it had been a great success from an Eastbourne point of view as raising the character of the town, and therefore it would be a retrograde step for them to lose the electric lamps if by any reasonable negotiations they could retain them. He would move that further negotiations be made with the Eastbourne Electric Light Company, inviting them to suggest some alternative terms, such as extinguishing the lights at 10:30 p.m. After some discussion the amendment was put, three voting for it and ten against. The whole of the report was then adopted.

Brazilian Telegraph and Telephone Statistics.—According to a Ministerial statement published by the *Rio News*, the extension of the Government telegraph lines measures 10,633 kilometres with 18,364 kilometres of wire and 170 stations. The submarine cables in connection with the land lines are about 48 kilometres. The Director-General estimates at over 1,000,000 milreis annually the loss to the Government lines through the competition of the Western and Brazilian cables. Reference is made to the probable improvement in the receipts of the Government lines when the D. Pedro II. Telegraph Company commences operations. The Minister states that he proposes establishing telephonic communication in connection with telegraphic. This had already been tried at Maccio with success, the receipts from subscribers more than paying the first cost of establishment, and leaving something for repairs. It is thought that the trifling increase of expense will be more than counterbalanced by the facility with which private individuals may be able to communicate with telegraphic stations, and thus an increase of revenue be secured.

The Zone of Maximum Intensity in Arc Lighting.—According to the report upon arc lights of the committee charged with the photometric tests of lamps shown at the last Antwerp Exhibition, if S = the mean spherical luminous intensity, H = the horizontal luminous intensity, and M = the maximum luminous intensity, there exists between these three quantities the relation $S = \frac{H}{2} + \frac{M}{4}$. This empiric formula gives in most cases values which do not differ materially from those determined by exact calculation. The mean intensities of luminosity in each of the two hemispheres are fairly represented by $\frac{H}{4}$ for the superior hemisphere, and by $\frac{H+M}{4}$ for the inferior hemisphere. The zone of maximum intensity of light is the surface of a cone having the arc for its apex, and generated by a plane, one edge of which coincides with the vertical axis of the two carbons, and the other edge making with this line an angle of about 50°. It is to be understood, of course, that this zone of maximum luminous intensity is limited to the lower area of the conical figure thus described. This determination applies more particularly to arc lamps supplied by continuous currents.

The Electrical Distribution of Time.—The lecture on "The Electrical Distribution of Time," delivered before the Franklin Institute, by Commander Allan D. Brown, U.S.N., Assistant Superintendent Naval Observatory, January 13th, 1888, and published in the *Journal* of the Institute, has been republished in pamphlet form. Commander Brown traces the electrical distribution of time as far back as 1816 to a telegraph dependent upon timepieces for its working, which was invented by Ronalds. We agree with the *Engineer* that this is rather far-fetched. Ronalds used two clocks, on the dial of which the letters of the alphabet took the place of hours. In front of the dial stood a pithball electrometer. The clocks were started at the same moment with the hand pointing to the letter A, and then as the clock of the transmitter pointed to the letter he wished to use, the clock at the receiving end pointed to the same letter. The sender put down a key, which, by the aid of a current, caused the pithballs to fly apart, and thus indicated to the receiver what letter proved part of the message. All this had nothing to do with the telegraphic distribution of time signals in the modern sense of the words.

Exports of Telegraphic Wires.—A comparison of the export return for August with those of previous years is again unfavourable, though some improvement is shown on the shipments of July. According to the Board of Trade returns issued on Friday last, the aggregate shipments to August 31 last of "metals and articles manufactured therefrom, except machinery," in which category telegraphic wire, &c., is included, were valued at £25,066,672, as against £22,552,097 in the first eight months of 1887—an increase of £2,514,575. This large increase is one of the most satisfactory features of the returns, and has been referred to as one of the best indications of our improving export trade. Telegraphic material, however, does not participate in the improvement, as will be seen in the comparative table below, and the fact is more noteworthy considering the considerable advance in the price of copper :—

Exports of Telegraphic Wires and Apparatus connected therewith.

	1886.	1887.	1888.
First quarter	£124,074	£131,879	£88,077
Second „	354,331	56,933	156,136
Six months	£478,405	£188,812	£244,213
July	219,463	195,950	21,571
August	154,789	114,162	110,323
Eight months	£852,657	£498,924	£376,107

The Corrosion of Lead Pipes.—The extensive use of lead-coated wires renders the question of the corrosion of lead when exposed to atmospheric and other influences of importance to electricians. Prof. Carnelly and Mr. Frew, of University College, Dundee, have arrived at the conclusion that in lead pipes carrying water corrosion is much greater when the pipes are exposed to the air. The corrosive action of water is diminished to about one-fourth, and that of slaked lime to one-fifth, when air is excluded. The corrosive action of blue clay and aluminium hydrate is, however, increased somewhat by excluding the air. Calcium carbonate, old mortar, calicum silicate, and a mixture of calcium carbonate and sand are not much affected in their corrosive power whether air be excluded or not. With potassium nitrate, however, the exclusion of air is important, since it becomes about as protective as calcium silicate when air is kept out, and as corrosive as water when exposed to air. Slaked lime is a powerful corroder, whether air be excluded or not. Peaty soil exerts a slight protective action on lead pipes. Sand, calcium carbonate, old mortar, calcium silicate, and a mixture of sand and calcium silicate exert a protective influence. The amount of silica in soft water reduces its corrosive power; and silica can be readily supplied to the water by passing it over a mixture of flints and limestone. A *mixture* of calcium carbonate and sand is better than either alone, perhaps by the formation of calcium silicate.

Digitized by Google

Hence also, perhaps, why *old* mortar is better than new in point of protective properties. The protective action of magnesium oxide is also very remarkable, being nearly equal to that of calcium silicate.

Electric Sugar.—The New York correspondent of the *Financial News*, writing under date of Sept. 7, says:—A trial of the new electric sugar process took place to-day. I am told this evening, at the office of the Electric Sugar Refining Company, that 13 barrels, of an average of 325lb. each, were refined in one hour and ten minutes. This is practically the first test of the new process. Three sizes of refined sugar were produced, and as a result the company claim that the process is established, and the machinery to operate it. Mr. Willett (a prominent sugar merchant in this city) witnessed the experiment, and says:—"At the trial about 13 barrels of refined sugar of various grades were produced, by every appearance to experts being freshly made sugars. Visitors were not allowed to inspect the machinery, or take any precautions against deception; but their confidence in the success of the manufacture was increased by what they saw. The sugar produced was beautiful in colour, entirely dissimilar from any refined sugars produced by refiners in America. Three different grades ran from one granulator. Four more grades were exhibited as having been produced at the same time in a private room from the same operation, all having the appearance of freshly made sugar. As far as the experiment went it was satisfactory, but not conclusive. The strain on the new machinery prevented a larger product. The time taken for the conversion from raw to refined sugar was 25 minutes. One barrel of refined sugar was filled every two minutes." I am told, further, that the experiment was hastened to-day in order to accommodate certain parties before leaving this country. A much larger experiment will be made in about a month. A fuller account of this invention was given in *The Electrician* of July 27th, 1888.

Electric Motors in Flour Mills.—The *Progressive Age* says that the first flour mill to use electric motors for power was built in Laramie, Wyoming, during last winter, by the Laramie Electric Light and Power Company, which company also operates the plant and furnishes that city with electric light. The plant is supplied with fuel-economising engine outfits and Edison dynamos far in advance of capacity to their present requirements, so their natural action was to use this surplus capacity in the driving of a flour mill rather than purchase an additional engine and boiler plant for the same duty. The mill has 125 to 130 barrels capacity per day, and besides supplying the local demand for flour, ships also flour to Yellowstone Park, the cattle ranches, Government posts, and mining camps within a radius of 200 miles. It has been in operation for about six months. The building is of stone, three stories in height, with basement. Seven double sets of 7 × 18 rolls accomplish the reductions of wheat and middlings. Centrifugals are used for bolting. The mill is complete in every detail, having all necessary cleaning machinery, packers, bran dusters, and dust collectors to enable the owner to do close milling. On the first floor of the mill are located two motors, one of which is connected by belt to the main shaft in the basement which drives all the rolls, scalpers, bolts, and elevators. The other motor is connected by belt to the fast shaft upstairs driving purifiers, cleaners, and the other machinery about the mill. Electricity comes from the lighting station to these motors by means of two copper wires, each of which is about 150ft. in length. These motors are under the eye of the miller, and can be stopped and started at will. Their convenient location avoids the necessity of long shafting and heavy belting, saving by this means power and machinery. Electric lights light the mill by night and steam heats it in cold weather. The absence of any fires about the mill insures a low rate of insurance, and makes this property a desirable risk. The two motors run at constant speed at 226 volts, and when running at full capacity require a current of about 150 amperes, or 48 horse-power; hence it is a very light running mill, for most milling engineers allow about 60 horse-power for a mill of this size. In cases where a mill owner has a good water-power a distance of five or ten miles from some good town, the electrical method of power transmission is practical, and has advantages over any other. The installation of the outfit would be the principal expense, but after that there would be practically no expense, for the machinery requires very little repair with proper handling.

The Electric Cable Railway on the Burgenstock.—In our issue of August 31st we gave some account of this interesting line from the pen of a non-technical writer. The following technical details appeared last week in *Industries*:—"The Bürgenstock, although a lower mountain than either the Righi or Pilatus, offers a most charming view over the Lake of Lucerne, and has thus become a favourite resort of tourists. A cable line was opened for passenger traffic two months ago, and is remarkable as being the first instance where the cable system and electric traction have been combined. On the Bürgenstock there was neither fuel nor water available, and it became necessary to carry the motive power to the railway, over a distance of about two and a-half miles, from a generating station on the River Aa, where a 60 horse-power turbine has been established. The transmission of energy takes place by means of a 20-ampere current under a pressure of 1,600 volts. At the generating station there are two Thury dynamos, each capable of an output of 25 amperes at 800 volts, when driven at 800 revolutions per minute. The two machines are coupled in series, and the circuit is arranged on the three-wire system, the wires being of naked copper 180mils. diameter, and supported on poles. The total length of the railway is 3,100ft., and the grade varies from 32ft. to 57ft. in 100ft. It is a single line, with a passing place about midway between the two termini. There are two cars, each accommodating thirty passengers, one car ascending whilst the other is descending. The cars are suspended from the ends of a steel wire cable, the bight of which passes over a series of cable pulleys at the top station, where the motors are installed. The wheels on one side of the car have inner and outer flanges; on the other side they are without flanges, by which means the passage of the crossing place is made possible without the employment of any switch. Midway between the rails is laid one of Herr Abt's steel racks into which gear spur wheels attached to the under side of the car, and which are controlled by brakes, one hand-worked and one automatic. In regular work the spur wheels run idle; but should the cable break, the car is instantly gripped and held in place by the spur gear, a hanger with cross head passing under the foot of the rack rails preventing the spur wheels from jumping out of gear. Power is supplied to the winding pulley in the engine house at the upper terminus of the line by two Thury motors, which are coupled in series and joined in the usual manner with the three-wire circuit. There is some power to spare, and this is utilised for driving a lighting dynamo supplying current to the glow lamps in the hotels. During the daytime one generator and one motor suffice to work the railway, and some of the primary current is sent to a small motor placed at the pumping station lower down the side of the mountain, from where the hotels are supplied with potable water. The speed of the cable is 200ft. per minute."

NOTE ON MAGNETIC HYSTERESIS.

BY J. A. FLEMING, M.A., D.SC.

When an ascending magnetisation curve is drawn connecting the values of magnetising force and corresponding magnetisation, we find on examination that the curves for soft iron rings or longish iron bars present a certain general similarity. For very small values of the force the curve begins by rising at a small angle. By the time the force has reached about 1 C.-G.-S. unit or so a pretty sharp upward bend begins to take place, and then the curve continues upwards, passing through a point of contrary flexure in its upward path. For a value somewhere between 5 and 10 C.-G.-S. units of the magnetising force another bend or "knee" occurs in the curve, bringing it down to a lesser slope, at which diminished slope it then proceeds upwards for further forces, but as far as experiment has yet indicated it never becomes quite horizontal. When the bar or ring has reached the state popularly called saturation, let the magnetising force be gradually diminished. It is found that the magnetisation now has, during the descent, for the same force a higher value than during the ascent. If at any point in the descent we pause and begin again to increase the magnetising force, and then after a certain rise decrease it again to the point at

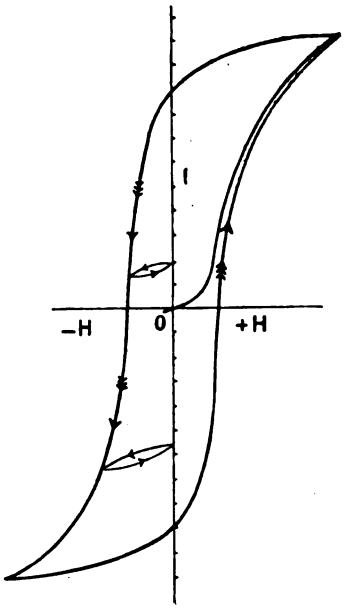

FIG. 1.

Magnetisation curve for very soft iron ring, showing loops due to hysteresis on the descending branch, and enclosed area due to a complete cycle (Ewing).

which we first arrested the descent, these values of the magnetisations exhibit *a loop* on the magnetisation curve (Fig. 1). If we operate on a ring, and draw the complete magnetisation curve described in carrying the ring from strong magnetisation in one direction to strong magnetisation in the other, we find the curve has two branches (Fig. 2) enclosing a large area. If the horizontal distances or abscissæ represent magnetising force **H**, and corresponding vertical ones the magnetisation I, then any area on the plane of **H**, I, is analytically represented by the integral $\int \mathrm{I}\, d\,\mathrm{H}$.

The physical meaning of these loops or enclosed areas in the magnetisation curves seems first to have been pointed out by Prof. E. Warburg.* This "lagging behind" of the magnetisation has been called by Prof. Ewing *magnetic hysteresis*.

The quantity $-\int \mathrm{I}\, d\,\mathrm{H}$, or the area of any loop of a magnetising curve formed by taking the metal through a complete magnetic cycle, represents in absolute measure the energy spent per unit of volume in performing this cycle. Thus, in Fig 2 the whole area included between the upward and downward curve represents the work spent per unit of volume of the ring in taking the ring from strong positive to strong negative magnetisation and back again.

The curve in Fig. 2, taken from a paper by Prof. Ewing, represents the course of the magnetisation in conducting the ring from strong positive magnetisation O C to equally strong negative O F. The "residual magnetism" or "retentiveness" is represented by O E, and may amount to as much as 93 per cent. of the maximum magnetisation. The work spent in carrying the iron round the magnetic cycle or along the course C D E F A G C is represented by the integral $-\int \mathrm{I}\, d\,\mathrm{H}$, and is represented numerically per unit of volume by the area

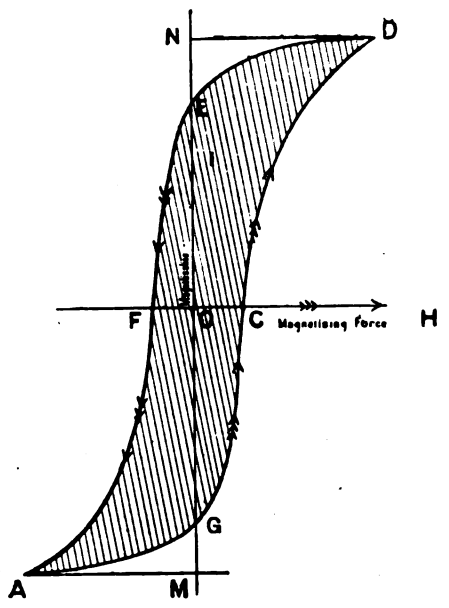

FIG. 2.

Complete Magnetisation Curve for soft iron ring (Ewing) carried from strong positive to strong negative magnetisation. The arrows show the direction of the magnetising operation, the shaded area the work done due to hysteresis.

(shaded) enclosed by the two curves. It has been shown by Maxwell* that the energy represented by a certain magnetic induction, **B**, produced by a certain magnetising force, **H**, is numerically equal per unit of volume of the material to $-\frac{1}{8\pi}$ times the product of the magnetic induction and the magnetic force resolved in the same direction. In the case before us **B** and **H** have the same direction; hence, differentiat-

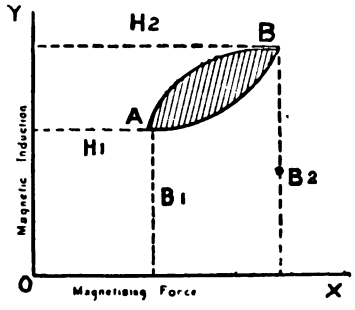

FIG. 3.

ing this expression for the energy per unit of volume, we have the expression

$$d\,\mathrm{E} = -\frac{1}{8\pi}(\mathrm{H}\, d\,\mathrm{B} + \mathrm{B}\, d\,\mathrm{H})$$

which denotes the value of the increment of energy per unit of volume expended in increasing **B** by $d\,\mathrm{B}$ and **H** by $d\,\mathrm{H}$.

When the change is cyclic

$$\int \mathrm{H}\, d\,\mathrm{B} = \int \mathrm{B}\, d\,\mathrm{H},$$

* Wiedemann's *Annalen*, XIII., p. 141, 1881

* "Electricity and Magnetism," Vol. II., § 636.

Digitized by Google

for if we are integrating the area of a closed loop (Fig. 3), A B, we arrive at the same result, viz., the area of the loop, whether we proceed by integration along O X, which is obtaining the value

of $$\int_{H_1}^{H_2} \mathbf{B}\, d\,\mathbf{H},$$

or proceed by integrating along O Y and obtain

$$\int_{B_1}^{B_2} \mathbf{H}\, d\,\mathbf{B}.$$

Hence, integrating the equation

$$d\,E = -\frac{1}{8\pi}(\mathbf{H}\, d\,\mathbf{B} + \mathbf{B}\, d\,\mathbf{H}),$$

for a complete cycle of magnetisation gives us

$$E = -\frac{1}{4\pi}\int \mathbf{B}\, d\,\mathbf{H};$$

but by the fundamental equation

$$\mathbf{B} = \mathbf{H} + 4\pi\,\mathbf{I},$$

and hence $$\mathbf{B}\, d\,\mathbf{H} = \mathbf{H}\, d\,\mathbf{H} + 4\pi\,\mathbf{I}\, d\,\mathbf{H};$$

but $\int \mathbf{H}\, d\,\mathbf{H}$ is zero for a complete cycle, because for each value of $\mathbf{H}$ or $d\,\mathbf{H}$ there is one of equal value and of opposite sign; hence $$\int \mathbf{B}\, d\,\mathbf{H} = 4\pi \int \mathbf{I}\, d\,\mathbf{H}$$

and $$E = -\int \mathbf{I}\, d\,\mathbf{H}.$$

In his paper entitled "Researches in Magnetism" (*Phil. Trans.*, Part II., 1885), Prof. Ewing has given the values of the energy dissipated in ergs per cubic centimetre experimentally determined for complete magnetic cycles performed on various samples of iron :—

Sample of iron operated upon.	Energy dissipated in ergs per cubic centimetre during a complete cycle of doubly-reversed strong magnetisation.
Very soft annealed iron	9,300 ergs.
Less soft annealed iron	16,300 ,,
Hard drawn steel wire.....	60,000 ,,
Annealed steel wire	70,500 ,,
Same steel, glass hard	76,000 ,,
Pianoforte steel wire, normal temper..	116,000 ,,
Same, annealed.....	94,000 ,,
Same, glass hard	117,000 ,,

From the above we can deduce that, roughly speaking, it requires 28 foot-pounds of energy to make a double-reversal of strong magnetisation in a cubic foot of soft iron. The energy so expended can take no other form than that of heat diffused throughout the mass.

A similar table of experimental results has been given by Dr. J. Hopkinson (*Trans.* Roy. Soc., Part II., 1885, p. 463), in which Paper the chemical analysis of the samples operated upon is given. The highest value of specific hysteresial dissipation was found for Tungsten steel, oil hardened, in which the value of the energy in ergs per cubic centimetre dissipated in a complete magnetic reversal was 216,864.

This *static hysteresis* is a quality of iron in virtue of which reversal of magnetisation is accompanied by dissipation of energy. If we fall back upon current hypotheses of magnetism (Ampere-Weber-Maxwell) to afford us some explanation of it, we can find it to some extent by supposing that the magnetic molecules or molecular magnets, the arrangement of which constitutes magnetisation, move stiffly, and the dissipation of energy we are considering is the work done in making the necessary magnetic displacement against a sort of internal magnetic friction.

This dissipation of energy into heat during magnetisation is something quite apart from any production of heat by eddy (or so-called Foucault) electric currents induced in the mass, and would take place in iron so perfectly divided that no eddy currents could exist.

One result of Prof. Ewing's researches has been to show that if the iron is kept in a state of mechanical vibration hysteresis is greatly diminished, and the value of the energy dissipated in a complete cycle is much reduced. The removal of strong residual magnetism from soft iron by slight tapping or twisting has also been noticed and commented on by Prof. Hughes.*

If we place the above facts side by side we see that in magnetising the field magnets of an ordinary continuous-current dynamo, work has to be done to a small amount at first to bestow upon the iron its initial magnetisation. If iron possessed the property of retaining strongly some 90 per cent. of its maximum magnetisation when the magnetising force is withdrawn there would be no further need for a field-exciting current; but as the least shock or vibration removes the slightly held magnetisation of iron, we see that one function of the field-exciting current, and of the energy expenditure necessary to maintain it, is to keep on reproducing the magnetism which the continual vibration knocks out of the iron. Hence, in an ordinary dynamo, we may consider that one part of the duty of the field-exciting current is to keep on re-generating magnetisation because mechanical vibration is continuously tending to remove it.

Hysteresis will also operate to cause a dissipation of energy in the armature of dynamos. For in this case we have a mass of soft iron, viz., the armature core, which has its direction of magnetisation reversed every revolution. Suppose the core has a volume of 9,000 cubic centimetres, and that it makes 15 revolutions per second. Taking the specific hysteresis for this sample of iron at 13,356 ergs, we find that the dissipation of energy in ergs per second is equal to $9{,}000 \times 15 \times 13{,}356 = 180 \times 10^7 = 180$ joules, or a loss of about a quarter of a horse-power.

Experiments have been made by Joule and others to determine by direct observation the heating effect of magnetisation upon iron, but in these direct experiments it is probable that the results were mostly impure, and qualified largely by the production of heat by local currents.†

Since about 10,000 ergs per cubic centimetre are dissipated by a double reversal of strong magnetisation of soft iron, it is not difficult to show that the consequent rise of temperature, if all the heat is retained in the iron, is ·000284° C., or that some 4,000 reversals would be required to raise the temperature 1° C., even provided all the heat generated is retained in the metal. Hence it follows that any very marked rise in temperature cannot be due to hysteresis.

In connection with this subject it is interesting to touch upon the question whether magnetised iron *per se* represents a store of energy; in other words, is magnetised iron analogous to a bent spring?

It is not disputed that available energy accompanies the magnetisation of a short iron bar, but this is a virtue of free polarity. In consequence of the attraction of opposite poles, if a magnetic bar were flexible the two poles would bend round to meet each other, and when this operation was finished there would be no longer any work to be got out of the bar.

In the case, however, of a ring, the magnetisation, though strong, represents no available energy. It requires energy to be applied to demagnetise the iron, and for all practical purposes magnetised iron *per se* cannot be regarded as a source of energy.‡ It requires work to be done to displace the magnetic particles from their positions, and work also to be done to push them back.

The operation of magnetising iron is not analogous to the stretching of a spring, but rather to the bending of an inelastic wire, such as a lead wire, in which work has to be done in twisting the wire to make the several sections shear over each other, though the operation when finished represents no available work.

Digitized by Google

In addition to the *static hysteresis*, experiments by Prof. Ewing and others also indicate the existence of *viscous hysteresis*. There is evidence of a true *time lag* in magnetisation, especially in the earlier stages of magnetisation. The iron requires time for a given magnetising force to produce its effect, and this sluggishness does not appear explicable as an effect either of induction in the iron or to self-induction in the magnetising circuit. The result of this magnetic viscosity is to augment the value of $-\int I\,dH$ in any rapidly performed cycle, and, consequently, to increase the dissipation of energy into heat. When we come to consider the question of induction transformers it will be seen that this viscous hysteresis has to be taken into account in establishing the full theory.

With respect to this *time lag* of magnetisation Prof. Ewing says:* "I repeatedly observed that when the magnetising current was applied to long wires of soft iron there was a distinct *creeping up* of the magnetometer deflection after the current had attained a steady value."†

If this is so it would seem that a sufficiently rapid reversal of magnetising force would render such force inoperative in magnetising the iron. Just as the self-induction of a circuit operates to make a certain delay in the appearance of the current corresponding to the application of a given electromotive force, and hence renders a circuit apparently a worse conductor for rapidly reversed electromotive forces, so the magnetic lag would introduce a sort of *magnetic self-induction* or retardation in the appearance of the magnetisation corresponding to a given magnetising force.

This time lag appears to be most manifest in the softest iron, and to be especially noticeable near the beginning of the steep part of the magnetisation curve.

In an investigation on the magnetisation of iron under feeble magnetic forces, Lord Rayleigh has also drawn attention to the fact that the settling down of iron when very soft or annealed the into a new magnetic state is far from instantaneous.‡ If strength of the earth's horizontal magnetic field is called h, Lord Rayleigh has shown that for unannealed iron and steel magnetising forces ranging from $\frac{1}{5}h$ to $\frac{1}{10000}h$ call forth proportional magnetisation. In other words, the susceptibility is constant over this range, and the value of the corresponding permeability is from 90 to 100, and that this small proportional magnetisation takes place independently of what may be the actual magnetisation of the iron provided it is not very near the condition usually called saturation.

The moment, however, that the magnetising force is pushed beyond these limits the phenomena of hysteresis and retentiveness make their appearance. According to Prof. Ewing (*loc. cit.*) the following group or constellation of hypotheses has to be made in order to approximate to a mechanical explanation of the magnetisation of iron:—

1. An elastic tendency on the part of the magnetic molecules to recover their primitive position when displaced.
2. A static frictional resistance to their displacement and to their return removable largely by vibration.
3. A limit for each such that if the displacement of the molecule exceeds it a permanent displacement not removable by vibration results.
4. Probably a viscous resistance to the displacement and return of the molecules.
5. An unequal distribution amongst the molecules of the frictional resistance, such that in some of the molecules it is, perhaps, very small.

Aided by these suppositions we might proceed to build up, in imagination, a mechanical model, which should imitate, under the application of certain stresses, the behaviour of iron under magnetising force, but it is certain that the result would not be practically of much value; and it must still be left to future research to collect and analyse the necessary facts before the mystery of the magnetisation of iron is fully unraveled.

HERTZ'S RESEARCHES ON ELECTRICAL OSCILLATIONS.

BY G. W. DE TUNZELMANN, B SC.

H. Hertz has been engaged for some time past in a series of researches on electrical oscillations, which have led to results of very exceptional interest, as was pointed out by Prof. Fitzgerald in his inaugural address to Section A of the British Association last week; and as these results throw considerable light on the nature of electrical action, it will be of interest to readers of *The Electrician* to have a connected account of the investigations, to which I therefore propose to devote a short series of papers.

In Hertz's first Paper on the subject, viz., "On Very Rapid Electrical Oscillations" (Wied. *Ann.*, Vol. XXXI., page 421, 1887), he refers to a Paper by Colley, "On some New Methods for Observing Electrical Oscillations, with Applications" (*ibid.*, Vol. XXVI., page 432), who calls attention to the fact that Sir William Thomson in 1853 first showed the possibility of producing electrical oscillations by the discharge of a charged conductor, and gives references to all the investigations in the same direction which were known to him.

For the benefit of readers who may wish to pursue the subject further the list is reproduced below:—

According to these investigations, the electrical oscillations produced in an open circuit by means of an induction coil are measured by ten thousandths of a second, while in the case of the oscillatory discharge of a Leyden jar they are about a hundred times as rapid, as was shown by Feddersen.

According to theory, still more rapid oscillations should possible in an open circuit of wire of good conducting material, provided its ends are not connected with conductors of any considerable capacity; but it is not possible to determine from theory whether measurable oscillations are actually produced. Some observations of Hertz's led him to believe that under certain circumstances oscillations of this kind were produced, and his researches show that this is so, and that the oscillations are about a hundred times as rapid as those observed by Feddersen; so that their periods are measured by hundred millionths of a second, and, therefore, they occupy a position intermediate between acoustic and luminous vibrations.

Preliminary Experiments.—It is known that if in the secondary circuit of an induction coil there be inserted, in addition to the ordinary air space, across which sparks pass, a Riess spark micrometer, with its poles joined by a long wire,

Digitized by Google

the discharge will pass across the air space of the micrometer in preference to following the path of least resistance through the wire, provided this air space does not exceed a certain limit, and it is upon this principle that lightning protectors for telegraph lines are constructed. It might be expected that the sparks could be made to disappear by diminishing the length and resistance of the connecting wire; but Hertz finds that though the length of the sparks can be diminished in this way, it is almost impossible to get rid of them entirely, and they can still be observed when the balls of the micrometer are connected by a thick copper wire only a few centimetres in length.

This shows that there must be variations in the potential measureable in hundredths of a volt in a portion of the circuit only a few centimetres in length, and it also gives an indirect proof of the enormous rapidity of the discharge, for the difference of potential between the micrometer knobs can only be due to self-induction in the connecting wire. Now the time occupied by variations in the potential of one of the knobs must be of the same order as that in which these variations can be transmitted through a short length of a good conductor to the second knob. The resistance of the wire connecting the knobs is found to be without sensible effect on the results.

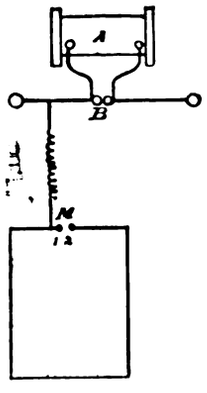

FIG. 1.

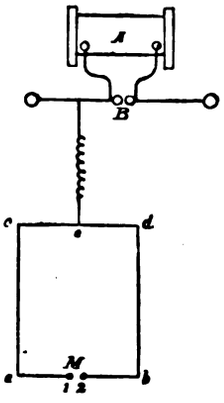

FIG. 2.

In Fig. 1, A is an induction coil and B a discharger. The wire connecting the knobs 1 and 2 of the spark micrometer M, consists of a rectangle, half a metre in length, of copper wire 2 millimetres in diameter. This rectangle is connected with the secondary circuit of the coil in the manner shown in the diagram, and when the coil is in action sparks, sometimes several millimetres in length, are seen to pass between the knobs 1 and 2, showing that there are violent electrical oscillations, not only in the secondary circuit itself, but in any conductor in contact with it. This experiment shows even more clearly than the previous one that the rapidity of the oscillations is comparable with the velocity of transmission of electrical disturbances through the copper wire, which according to all the evidence at our disposal is nearly equal to the velocity of light.

In order to obtain micrometer sparks some millimetres in length, a powerful induction coil is required, and the one used by Hertz was 52 centimetres in length and 20 centimetres in diameter, provided with a mercury contact breaker, and excited by six large Bunsen cells. The discharger terminals consisted of brass knobs 3 centimetres in diameter. The experiments showed that the phenomenon depends to a very great extent on the nature of the sparks at the discharger, the micrometer sparks being found to be much weaker when the discharge in the secondary circuit took place between two points, or between a point and a plate, than when knobs were used. The micrometer sparks were also found to be greatly enfeebled when the secondary discharge took place in a rarefied gas, and also when the sparks in the secondary were less than half a centimetre in length, while, on the other hand, if they exceeded 1½ centimetres the sparks could no longer be observed between the micrometer knobs. The length of secondary spark which was found to give the best results, and which was, therefore, employed in the further observations, was about three-quarters of a centimetre.

Very slight differences in the nature of the secondary sparks were found to have great effect on those at the micrometer, and Hertz states that after some practice he was able to determine at once from the sound and appearance of the secondary spark whether it was of a kind to give the most powerful effects at the micrometer. The sparks which gave the best results were of a brilliant white colour, only slightly jagged, and accompanied by a sharp crack.

The influence of the spark is readily shown by increasing the distance between the discharger knobs beyond the striking distance, when the micrometer sparks disappear entirely, although the variations of potential are now greater than before. The length of the micrometer circuit has naturally an important influence on the length of the spark, as the greater its length the greater will be the retardation of the electrical wave in its passage through it from one knob of the micrometer to the other.

The material, the resistance, and the diameter of the wire of which the micrometer circuit is formed have very little influence on the spark. The potential variations cannot, therefore, be due to the resistance, and this was to be expected, for the rate of propagation of an electrical disturbance along a conductor depends mainly on its capacity and coefficient of self-induction, and only to a very small extent on its resistance. The length of the wire connecting the micrometer circuit with the secondary circuit of the coil is also found to have very little influence, provided it does not exceed a few metres in length. The electrical disturbances must therefore traverse it without undergoing any appreciable change. The position of the point of the micrometer circuit which is joined to the secondary circuit is, on the other hand, of the greatest importance, as would be expected, for if the point is placed symmetrically with respect to the two micrometer knobs the variations of potential will reach the latter in the same phase, and there will be no effect, as is verified by observation. If the two branches of the micrometer circuit on each side of the point of contact of the connection with the secondary are not symmetrical, the spark cannot be made to disappear entirely; but a minimum effect is obtained when the point of contact is about half-way between the micrometer knobs. This point may be called the null point.

Fig. 2 shows the arrangement employed, *e* being the null point of the rectangular circuit, which is 125 centimetres long by 80 centimetres broad. When the point of contact is at *a* or *b*, sparks of from 3 to 4 milimetres in length are observed, when it is at *e* no sparks are seen; but they can be made to reappear by shifting the point of contact a few centimetres to the right or left of the null point. It should be noted that sparks only a few hundredths of a milimetre in length can be observed. If when the point of contact is at *e* another conductor is placed in contact with one of the micrometer knobs the sparks reappear.

Now, the addition of this conductor cannot produce any alteration in the time taken by the disturbances proceeding from *e* to reach the knobs, and, therefore, the phenomenon cannot be due simply to single waves in the directions *c a* and *d b* respectively, but must be due to repeated reflection of the waves until a condition of stationary vibration is attained, and the addition of the conductor to one of the knobs must diminish or prevent the reflection of the waves from that terminal. It must be assumed, then, that definite oscillations are set up in the micrometer circuit just as an elastic bar is thrown into definite vibrations by blows from a hammer. If this assumption is correct, the condition for the disappearance of the sparks at M will be that the vibration periods of the two branches *e* 1 and *e* 2 shall be equal. These periods are determined by the products of the coefficients of self-induction of these conductors into the capacities of their terminals, and are practically independent of their resistances.

In confirmation of this, it is found that if when the point of contact is at *e* and the sparks have been made to reappear by connecting a conductor with one of the knobs, this conductor is replaced by one of greater capacity, the sparking is greatly increased. If a conductor of equal capacity, is connected with

Digitized by Google

the other micrometer knob the sparks disappear again; the effect of the first conductor can also be counteracted by shifting the point of contact towards it, thereby diminishing the self-induction in that branch. The conclusions were further confirmed by the results obtained when coils of copper wire were inserted into one or other, and then into both of the branches of the micrometer circuit.

Hertz supposed that as the self-induction of iron wires is, for slow alternations, from eight to ten times that of copper wires, therefore a short iron wire would balance a long copper one; but this was not found to be the case, and he concludes that, owing to the great rapidity of the alternations, the magnetism of the iron is unable to follow them, and therefore has no effect on the self-induction.

(To be continued.)

MANUFACTURE OF LIGHT.*

BY DR. OLIVER LODGE, F.R.S.

The conclusions at which we have arrived, that light is an electrical disturbance, and that light-waves are excited by electric oscillations, must ultimately, and very shortly, have a practical import.

Our present systems of making light artificially are wasteful and ineffective. We want a certain range of oscillation, between 7,000 and 4,000 billion vibrations per second; no other is useful to us, because no other has any effect on our retina; but we do not know how to produce vibrations of this rate. We can produce a definite vibration of one or two hundred or thousand per second; in other words, we can excite a pure tone of definite pitch, and we can command any desired range of such tones continuously by means of bellows and a key-board. We can also (though the fact is less well known) excite momentarily definite ethereal vibrations of some millions per second, as I have at length explained; but we do not at present seem to know how to maintain this rate quite continuously. To get much faster rates of vibration than this we have to fall back upon atoms. We know how to make atoms vibrate; it is done by what we call "heating" the substance, and if we could deal with individual atoms unhampered by others, it is possible that we might get a pure and simple mode of vibration from them. It is possible, but unlikely; for atoms, even when isolated, have a multitude of modes of vibration special to themselves, of which only a few are of practical use to us, and we do not know how to excite some without also the others. However, we do not at present even deal with individual atoms; we treat them crowded together in a compact mass, so that their modes of vibration are really infinite.

We take a lump of matter, say a carbon filament or a piece of quicklime, and by raising its temperature we impress upon its atoms higher and higher modes of vibration, not transmuting the lower into the higher, but superposing the higher upon the lower, until at length we get such rates of vibration as our retina is constructed for, and we are satisfied. But how wasteful and indirect and empirical is the process. We want a small range of rapid vibrations, and we know no better than to make the whole series leading up to them. It is as though, in order to sound some little shrill octave of pipes in an organ, we were obliged to depress every key and every pedal, and to blow a young hurricane.

I have purposely selected as examples the more perfect methods of obtaining artificial light, wherein the waste radiation is only useless, and not noxious. But the old-fashioned plan was cruder even than this; it consisted simply in setting something burning, whereby not only the fuel but the air was consumed, whereby also a most powerful radiation was produced in the waste waves of which we were content to sit stewing, for the sake of the minute, almost infinitesimal, fraction of it which enabled us to see.

Everyone knows now, however, that combustion is not a pleasant or healthy mode of obtaining light; but everybody does not realise that neither is incandescence a satisfactory and unwasteful method which is likely to be practised for more than a few decades, or perhaps a century.

Look at the furnaces and boilers of a great steam engine driving a group of dynamos, and estimate the energy expended; and then look at the incandescent filaments of the lamps excited by them, and estimate how much of their radiated energy is of real service to the eye. It will be as the energy of a pitch pipe to an entire orchestra.

It is not too much to say that a boy turning a handle could, if his energy were properly directed, produce quite as much real light as is produced by all this mass of mechanism and consumption of material.

There might, perhaps, be something contrary to the laws of Nature in thus hoping to get and utilise some specific kind of radiation without the rest; but Lord Rayleigh has shown in a short communication to the British Association at York* that it is not so, and that therefore we have a right to try to do it.

We do not yet know how it is true, but it is one of the things we have got to learn.

Anyone looking at a common glow worm must be struck with the fact that not by ordinary combustion, nor yet on the steam engine and dynamo principle, is that easy light produced. Very little waste radiation is there from phosphorescent things in general. Light of the kind able to affect the retina is directly emitted, and for this, for even a large supply of this, a modicum of energy suffices.

Solar radiation consists of waves of all sizes, it is true; but then solar radiation has innumerable things to do besides making things visible. The whole of its energy is useful. In artificial lighting nothing but light is desired; when heat is wanted it is best obtained separately, by combustion. And so soon as we clearly recognise that light is an electrical vibration, so soon shall we begin to beat about for some mode of exciting and maintaining an electrical vibration of any required degree of rapidity. When this has been accomplished, the problem of artificial lighting will have been solved.

* Extract from "Modern Views of Electricity," *Nature*, August 30] by kind permission of the author.

ON RECENT DEVELOPMENTS OF THE COWLES' ALUMINIUM PROCESS.†

BY R. E. CROMPTON.

It is unnecessary to again describe the earlier stages of the Brothers Cowles' invention of the electric furnace. I confine myself to a description of such parts of the new plant which has been recently put down at Milton, near Stoke-upon-Trent, that I think will be of general scientific interest.

The experience in America at the works at Lockport, Ohio, showed conclusively that great economies were to be expected from increasing the size of the furnaces and the strength of the electric currents employed to work them; but no current larger than 3,000 amperes had been used up to the time that the Milton Works were planned.

Mr. Eugene Cowles came over to England to ascertain whether English makers of dynamo machines were prepared to supply one 60 per cent. larger than Mr. Brush's "Colossus," which had been made specially for them in America, and which was then the largest direct-current machine in the world. He prepared his specification for a dynamo to give a current of 5,000 amperes at 60 volts, and eventually Messrs. Crompton's designs and tender were accepted.

The works were built near the Milton Station on the North Staffordshire Railway; the boilers for generating the steam required are of the Babcock-Wilcox type, and are provided with mechanical stokers; the steam engine is of 600 horse-power, and is a compound condensing horizontal tandem, made by Messrs. Pollit and Wigzel, of Sowerby Bridge; it is furnished with an exceedingly perfect centrifugal governor, which maintains the speed accurately at seventy-six revolutions in spite of very great fluctuations in the load. The electrical

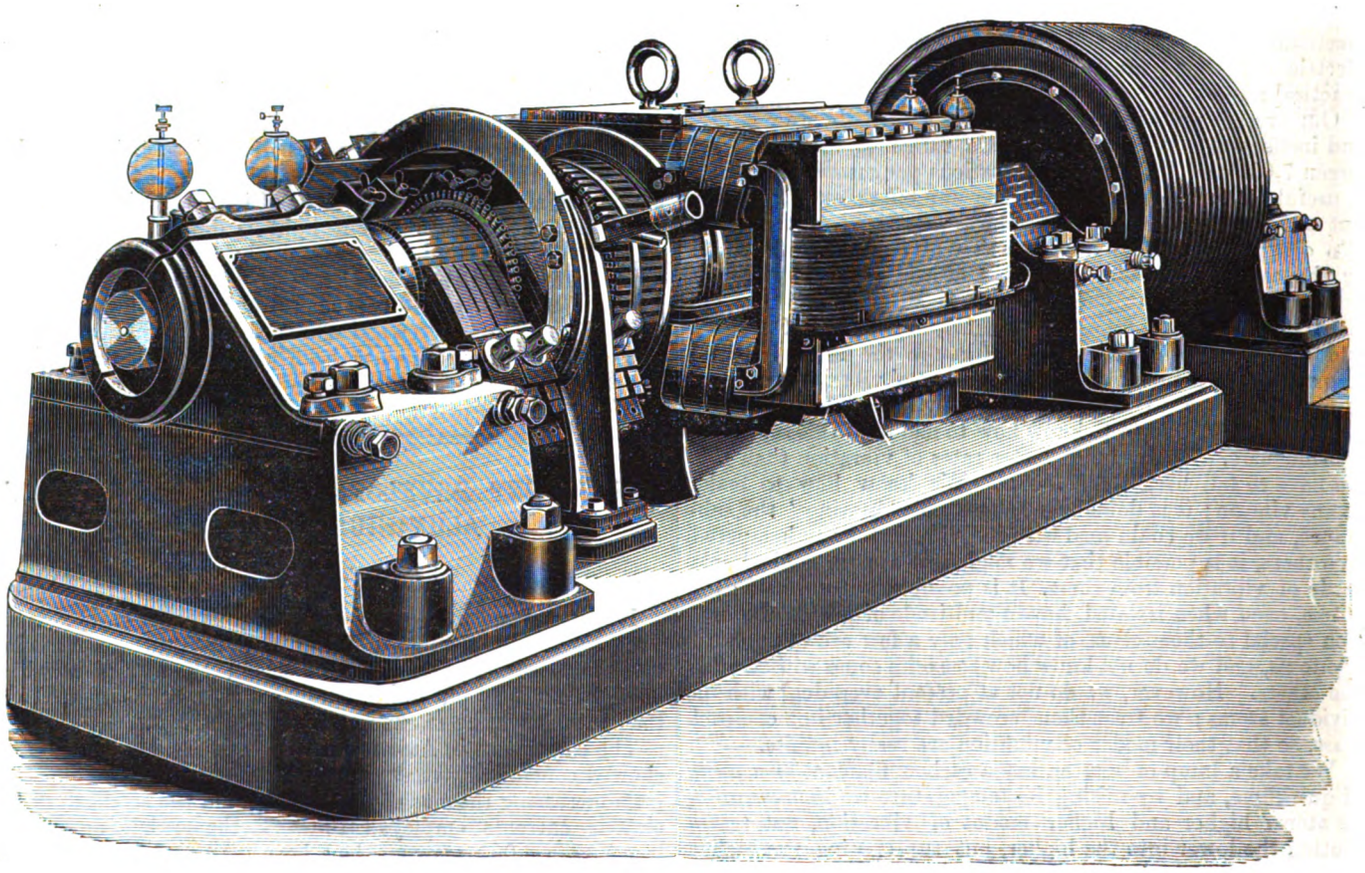
* B. A. Report, 1881, p. 526

† Paper read before the British Association meeting (Section G), at Bath, September, 1888.

Digitized by Google

means of stopping the engine have been provided in the shape of Tate's electrical stop valve, which may be described as an electro-magnet arrangement, with the ordinary pushes for completing its circuit, which actuates a steam relay piston set to close the main stop valve. The fly-wheel of this engine is 20ft. in diameter, and weighs 30 tons, and is geared to the pulley of the dynamo, so that the latter makes five revolutions for each revolution of the engine by rope driving gear consisting of eighteen ropes.

This engine is an extremely fine specimen of a modern steam engine; it works so silently that a visitor standing in the engine room with his back to the engine railings at the time the engine is being started cannot tell whether it is in motion or not. The dynamo at first sight seems very small when compared with the steam engine driving it, the fact being that it is dwarfed by the enormous fly-wheel of the engine; it is only when one stands close to the plummer block bearings that one realises the great size of the spindle, and of all the parts required to transmit the power to the armature coils.



GENERAL VIEW OF 400 H.-P. CROMPTON DYNAMO.

The author was still aware when designing this machine that the mechanical strains on the spindle, core attachments, and winding were likely to be of an extraordinary nature. The following precautions were therefore adopted, and as events have turned out they have been more than justified. The spindle is of steel, 18ft. long, with three bearings, one being placed on either side of the driving pulley. The diameter is 7in. in the bearings and 10in. in the part within the core. This part in the original forging was 14in. diameter, and was planed longitudinally so as to leave four projecting ribs or radial bars on to which the core discs are driven, each disc having four key-ways corresponding to these ribs. There are about 900 of these discs, the external diameter being 20in., and the total length of the core 36in. Originally this core was provided with 32 driving teeth made of steel, each both riveted to sockets attached to eight of the core discs. It may here be mentioned that as the working has shown the strain on these driving teeth was perilously near their factor of safety, their number has been doubled, so that now the tangential strains are borne by a very considerable percentage of the core discs.

The armature winding consists of 128 copper bars, each seven-eighths of an inch deep measured radially by three-eighths wide. These 128 bars are coupled up so as to form thirty-two conductors only. This arrangement has been adopted to avoid the heating from Foucault currents which, with one and a-half inch conductors, would have been very considerable. The bars are coupled at the ends of the core across a certain chord according to an arrangement patented by the author and Mr. Swinburne, which consists of crescent shaped bars so formed that the whole surface is thoroughly exposed to the current of air passing through the armature; they are also somewhat shorter than those usually employed on drum-wound armatures. The bars are insulated by a covering of "fiburite," a material which has been recently introduced by Messrs. Crompton, and which will stand a temperature of 160° C. for long periods without the least discoloration, softening or alteration of its mechanical and insulating properties.

The commutator is 20in. long, has 64 parts, and in addition to the usual tightening nuts at the two ends, is provided with a third tightening ring at the centre to prevent the tendency of such long commutator strips to spring when worn down thin. The current is collected by eight brushes mounted on a separate ring placed concentric to the commutator, and the current is led away from these brushes by a large number of thin bands of sheet copper, strapped together into convenient groups.

The field-magnets are of the horizontal double type, and were adopted by the author and Mr. Swinburne, after a careful series of experiments, which convinced them that the fashionable single magnet form was very unsuitable for this kind of machine.

Digitized by Google

As this machine is virtually a series-wound machine, the magnet coils each consist of a few turns only of forged copper bars, one and a-half inch wide by one inch thick, forged to fit the magnet cores; there is no insulation, other than mica wedges, to keep the bars from touching the core.

The armature is ventilated by a current of air from a Schiele fan, driven by a belt from the armature spindle. At 380 revolutions the armature can give 5,000 amperes at 60 volts, and temperature of the hottest part, which is at the end plates next the commutator, never rises beyond 70° C. Although this machine was designed to give only 5,000 amperes, yet, electrically speaking, it is capable of doing very much more, and in actual practice it has frequently to stand a current of 8,000 amperes for short periods; but, as will be shown later, when the furnaces are employed to produce ferro-aluminium, there are frequently violent oscillations in the current, which would make it unsafe to employ an average current much in excess of 5,000. In fact, as has been stated above, it has been found necessary already to increase the number of driving-teeth, in order to provide against the driving strains at the times of maximum current. When the machine was first tried the main circuit was unprovided with a cut-out, and there is no doubt that at this time the armature stood the test more than once of temporary currents exceeding 16,000 amperes. Since that time a safety cut-out has been provided calculated to fuse at 8,000 amperes; this, probably the largest one that has ever been designed, consists of a framework carrying 12 lead plates, and these fuse at the calculated point in a most satisfactory manner, without any undue detonation or scattering of the molten lead.

Next to the cut-out comes the current indicator, which is simply a solenoid of nine turns, through which the whole current passes; the core is attached by chain gear to the pointers, of which there are two mounted on one spindle, one pointer and dial is placed in the engine room, and the other in the furnace room; the gearing of this spindle is calculated so that the range of the instrument up to 8,000 amperes extends over the entire circle of 360°. The construction of the solenoid for this indicator is somewhat novel. It is cut out of a cylinder of cast copper by means of a parting tool in a screw-cutting lathe.

There are two furnace rooms, each containing six furnaces, and the conductors after leaving the current indicator pass right across the two rooms at a height somewhat above the attendant's heads. The current is supplied to the furnaces as follows:—

Each furnace pit consists of a long trough built of fire brick, the ends being closed by cast-iron pipes through which carbon electrodes are arranged so that they can be moved lengthways to and fro by the attendant in charge. It will be remembered that one of the main features of the Cowles invention is the use of limed charcoal as a lining for their furnace; they thus obtain a highly refractory nonoxidising lining, which is also a non-conductor of electricity, as the lime prevents the particles of carbon fusing together, and thus forming a continuous conductor, which would otherwise short-circuit the furnace and be consumed under the action of the current, instead of the latter performing its proper duty of maintaining the furnace contents at the required high temperature. The electrodes, each of which consists of nine carbon rods attached to a cast-iron head mounted on a copper rod passing through the above-mentioned cast-iron pipes, are each provided with flexible copper wire cable connections, having an attachment sliding along the conductors passing overhead and somewhat behind them. When it is desired to supply the current to any one furnace the attachments are slid into position opposite it and clamped fast to the conductors; to start the furnace the electrodes are brought together so as to touch and then separate, until the whole of the contents of the furnace between them is an incandescent mass at the required high temperature.

The working of a charge in the furnace is carried out as follows:—The bottom of the empty furnace is covered with limed charcoal, the electrodes are brought into position, and a former, or iron box without top or bottom, and of a size determined by the space to be occupied by the charge, is placed in the furnace; the ends of this sheet-iron box are arched out, so that it can be dropped over the electrodes, the furnace lining of limed charcoal is then rammed up in the space between the iron former and the furnace walls, the space inside the box is filled with the furnace charge, which, when ferro-aluminium is to be produced, consists of a mixture of charcoal, bauxite, and iron turnings, but when the cupro-aluminium is required granulated copper is substituted for the iron turnings. When the furnace lining and contents are brought up to the proper level, the iron former is carefully lifted, much as a moulder draws a pattern from the sand, the cover is then lifted on to the furnace, and it is then ready for the electric current.

This at first is kept down to 3,000 amperes, but as soon as the charge is thoroughly warmed through, and the furnace contents become incandescent throughout, the current is increased to 5,000 amperes, and in about one hour's time the reduction is complete.

The reduced aluminium trickles through the furnace contents, and collects at the bottom below the electrodes, from which in the furnaces last constructed it can be tapped out continuously. Mr. Cowles believes that the temperature of the centre of the furnace is so high that both the reduced aluminium and the metal with which it is to be alloyed are vapourised, and combine as a chemical compound, when in this condition being condensed in the upper and cooler part of the furnace, and from thence passing down the sides to the bottom.

The working of the furnace when cupro-aluminium is to be produced leaves nothing to be desired; the current can be steadily increased towards the commencement, and towards the end of the reduction the current is extremely constant, so that the load on the boilers, engine, and dynamo is fairly steady throughout; but when making ferro-aluminium, the conductivity of the furnace contents varies through very wide limits, and this brings heavy strains on both the steam engine and dynamo, which must be met by correspondingly increased strength of parts. The chief feature of the process which strikes a visitor to Milton Works is the small number of men necessary to work the process. Two men in the engine and dynamo room, one man at the boilers, and one boy to manipulate the electrodes of the furnaces are all that are required for the active part of the operation. Two labourers can easily charge and reline the furnaces, and the remaining staff required for melting down, standardising, and casting into ingots the various classes of furnace products is correspondingly small.

From the experience already gained the author sees no difficulty in designing and constructing engines and dynamos to supply currents of 15,000 or even 20,000 amperes, if such be required, for Cowles furnaces of enlarged size. The electrical difficulties met with in the construction of this large machine have been comparatively small, whereas the mechanical strains have been unexpectedly great, and must be provided for by extreme solidity and massive construction.

Recent investigations made in America by Mr. W. J. Keep have shown that the use of ferro-aluminium is likely to be enormously extended when its properties in relation to cast iron are thoroughly understood and appreciated by the engineering world. Mr. Keep is a gentleman who is well known in America, and his statements are entitled to be received with the utmost respect. We already knew in this country that the addition of ferro-aluminium to cast steel or to ingot iron in such proportion that the finished castings will contain not more than one-thousandth part of aluminium produced extraordinary effects, in some cases reducing the melting point 300° C., and in all cases imparting great fluidity to the metal, thus giving us sharp castings free from blow-holes; but it has remained for Mr. Keep to show us that the addition of an infinitesimally small percentage of aluminium to cast iron insures perfect castings, freedom from blow-holes, and almost all the ills to which the ironfounder is subject. Mr. Keep's report is so very full that it is impossible to give any *résumé* of it here. I only call attention to it to show the extreme importance that ferro-aluminium is likely to assume in future engineering, and that as far as we know at present the perfected Cowles furnace is capable of producing the desired material in any quantity, and at a moderate cost.

THE COMPARATIVE DANGER OF ALTERNATING VERSUS DIRECT CURRENTS.*

BY DR. P. H. VANDER WEYDE.

It is only a few days ago that I received the flattering invitation to appear before this meeting of the most eminent electricians of the United States, and present a Paper containing my conclusions about the comparative danger to life lurking in the alternate and direct dynamo currents. I do so readily, as I have lately had the opportunity to become acquainted with the arguments made on both sides of the question. I was not prepared to do so when, a few weeks ago, I attended a meeting of the New York Board of Electrical Control, where several Papers were read, most of them in opposition to Mr. Harold P. Brown, who had expressed himself in opposition to the use of the alternate-current system, the introduction of which has lately been commenced. When the president of that meeting asked me to express my opinion I was compelled to decline, stating that my appearance there was solely as a listener to arguments upon the subject, about which I desired full information.

As some of the Papers read there were written in such a spirit as to compel Mr. Brown to defend himself, I made up my mind to attend his expected defence, especially as it might give me an opportunity to hear what powerful arguments and facts would be brought out by the person who has put himself forward as the champion of the enemies of the alternate-current system. . . .

A great portion of the Paper read by Mr. Brown consisted in complaints about the personal attacks made upon his capability as soon as he asserted in print that the alternate electric currents were more dangerous to life than the direct currents, namely, that a current of the electromotive force of, say, 300 volts alternate current would be more likely to destroy life than double or treble that strength of a direct current. One feature was prominent in the reading of the Paper as well as in the lecture and experiments. It was evident that the purpose was not so much to exhibit what was the truth in the matter as to show that he was right in what he had asserted. He attempted to prove this by experimenting upon a large dog, which, when subjected to a direct current, stated to be 300 volts, set up a short howl; 600 volts produced a longer howl and frantic efforts to escape from the cage, while a current of some 900 volts paralysed the dog, who kept up a laboured breathing. Then a representative of the New York Society for the Prevention of Cruelty to Animals interfered and forbade further trials of this kind, so that Mr. Brown was compelled to give the dog the *coup de grace* by applying the alternate current, which he said was of the strength of only 300 volts.

Unfortunately for Mr. Brown this proved nothing, as the dog was already half dead by the previous successive and increasing direct-current doses of 300, 600, and 900 volts respectively. Another dose of 300 or 600 volts direct current might in all probability have ended his life just as well. But what is more, his statement that the alternating current was nearly 300 volts was not proved, as he himself had stated previously that reliable instruments for measuring alternate currents were difficult to obtain, and confessed that he had only a voltmeter for this purpose, but no ammeter. After the lecture I examined the voltmeter, and found that, according to the statements of Mr. Brown himself, its operation was based upon indications of rise in temperature.

Now, it is well known that voltmeters based on this principle are based on false premises. Rise of temperature is not produced by electromotive force, but by amount of current; one Wollaston plunge battery cell, of one square metre acting surface, having, of course, the electromotive force of only one single volt, will produce far more heat than a series of 24 freshly prepared cups of a Leclanché battery of 40 volts electromotive force. This pretended voltmeter was, in fact, a kind of ammeter. . . . .

Mr. Brown stated that the quantity of the direct current he used was only a fraction of one ampere. This induced me to examine also the ammeter after the lecture, when I found that the ammeter and voltmeter were coupled together in series in the same single circuit. Now every experienced electrician knows that in order to measure the capacity of a dynamo current in amperes we must not place any other resistance in the circuit, much less the high resistance of a voltmeter, which may be 500 ohms, as then the indication of the ammeter may drop down 90 per cent. of the original indication; in fact, the ammeter indicated actually two-thirds of an ampere, as had been stated by Mr. Brown when he was asked during the lecture.

The manner in which the ammeter and voltmeter were used was considered by me in connection with the fact that, if really a current of only two-thirds of an ampere had been obtained, it would render the dynamical value of the three currents used only equal to 200, 400, and 600 watts respectively, which was incompatible with their effect on the dog. This caused me to go to the dynamo plant of Columbia College to inquire. I found that the direct-current machine used was an Edison municipal dynamo of 15 amperes and 1,200 volts. This dynamo did not belong to the Columbia College plant, but it was furnished by Mr. Edison for the occasion, as well as an alternate-current dynamo. Both were removed after Mr. Brown finished his experiments, which, it appears, he continued privately for a few days after the lecture.

One of the dynamos used belonged to the college plant; it was an incandescent light dynamo, of which the capacity was stated by the engineer to be 125 amperes and 110 volts. This dynamo was employed to obtain the alternate currents, by using it to feed the field-magnets of a Siemens-Halske alternate-current machine, after the usual manner.

The kind of apparatus which was used and the nature of their arrangement for the production of the alternate current makes it very unlikely that it would produce a current of only 300 volts, especially when we take into consideration that the current developed must represent some kind of equivalent for the horse-power required: firstly, to drive the 125-ampere incandescent light dynamo; next, that required to drive the alternate-current dynamo. The latter must have considerable power, as the 125-ampere current was more than sufficient to saturate the great number of its stationary electro-magnets. According to the statement of the engineer, the engine driving the 125-ampere dynamo requires 36 horse-power, that of the alternate dynamo 36 horse-power—together 72 horse-power, which, at 746 watts per horse-power, gives 54,712 watts. If the amperes of such a current had been measured after the method employed by Mr. Brown for the direct current, it would have resulted in 54,712, divided by two-thirds of an ampere, or 82,063 volts.

Of course, this is an exaggerated estimate, but sufficient to show the worthlessness of all the figures as given by Mr. Brown. In order to come to correct conclusions it would be necessary to measure, by means of indicator diagrams, the engine-power utilised, and measure the currents obtained by proper instruments, properly used and conscientiously observed. One thing is certain, namely, that the dynamos used were not of such a defective quality as to warrant the supposition of such an enormous loss of the power applied, as would be the case if only an electromotive force of 300 volts had been obtained.

There was added on the lecture room table another important additional (however small) contrivance, for the right understanding and use of which I will have to make a short introductory explanation. I do this, also, because I have been especially requested to do so by several parties who have become interested in the operation of this, to them, very novel device.

Notwithstanding electricity is not a fluid like water, it behaves, however, also in this case, in a similar manner. At the moment a uniform electric current is suddenly interrupted a current of greater electromotive force (more pressure) is developed in the conductor, and will show itself as a spark at the break of contact, and as a shock through the body when the hands have hold of the wires when the contact is broken.

As it may be desirable for special purposes to eliminate these currents, an apparatus has been invented, which operates like a very sensitive relay, and then leads these extra currents off, or shunts them into another channel after the manner of lightning protectors. Such an apparatus was on the table during the experiments with the dog, and appeared to be intended to protect the animal against the effect of these extra currents. I must confess not to see why this was done except for the purpose to annul the most powerful and most dangerous item connected with the direct current. Therefore, I consider the addition of this contrivance improper if we wish to arrive at the truth in regard to the comparative danger of the alternate and direct currents, because in case of accidental exposure of person there is rarely such a safeguard enclosed in the circuit, and the person struck by the current must submit to the extra current as well.

In order to arrive at the truth of the matter we must also, above all, be able to make definite statements about the voltage and the volume of current, based on precise measurements, which, in regard to the alternate currents, could not be furnished, but was only guessed at.

Finally, as far as I can judge about the matter, guided by the present state of knowledge (especially in regard to some, in many respects, still unexplained peculiarities in the behaviour of alternate currents), I should say that their true voltage must be quite high. They do not behave like currents of low voltage (say 300 or 400), as they can be, and practically are, conducted over much longer lines and thinner wires than is the case with the direct current of, say, 1,000 volts. This fact is acknowledged as well by the enemies as by the friends of the alternating-current system. Experiments made by converters, especially with a new and very peculiar one of my own construction, appear also to show that there must be considerable voltage in the alternate currents so as to account for the generation of the enor-

Digitized by Google

mous volume of current into which the electromotive force is converted; in other words, for the thousands of amperes obtained by the conversion of the volts of the primary current, and for which amperes there is no ammeter yet to measure them, but their volume shows itself in the capacity to perform operations requiring the highest temperatures, such as welding iron, fusing the most refractory substances, &c.

Surely no dynamo could be constructed directly generating a current of such volume, as it would destroy itself by the heat of its own current; it is only by alternating-current machines of high voltage, assisted by proper converters, that currents of such great volume and high caloric capacity can be obtained.

After all, we must not lose sight of the main object of this controversy, which is the comparative danger lurking in the two systems. When it is found by experience that actually the danger of being killed is greater by the use of alternate currents, it does not make any difference if the voltage which does the killing is 300 or 1,300.

When, however, we consider that statistics show that the loss of life by the direct-current system is continually increasing in proportion that the system is extending, the probabilities appear to be that both systems will furnish their equal quota of victims, and the labour of comparing the relative danger of both systems, and especially the discussion about their comparative voltage, appears to become an idle occupation.

A NEW ELECTRIC DOG CART.

MESSRS. IMMISCH AND CO.'S NEW ELECTRIC DOG CART FOR THE SULTAN OF TURKEY.

We illustrate this week a new electric dog cart, which has been constructed by Messrs. Immisch for the Sultan of Turkey at a cost of £200. We had the opportunity of inspecting the vehicle on Wednesday at the Camden Town Skating Rink. In appearance it is similar to an ordinary four-wheeled dog cart, but, of course, has no shafts, the fore carriage being modified to carry a toothed rack, which engages with a pinion attached to a shaft passing upward through the footboard and terminating in a handle, by means of which the carriage can be guided with the greatest facility. The carriage is provided with an ordinary foot brake. It is constructed of walnut and light wood, bright varnished; the cushions of brown cloth are embroidered with the Turkish Imperial crest. The power is stored in 24 small accumulators of special type, which contain a charge sufficient to propel the vehicle for about 5 hours at a speed of 10 miles.

The motor is Messrs. Immisch and Co.'s one horse-power type, using in this case a current of 20 amperes, with an electromotive force of 48 volts. When the vehicle is running at a speed of ten miles an hour the motor makes 1,440 revolutions per minute, and develops ¾ horse-power. The weight of the accumulators is about 7cwt., and the weight of the carriage complete 11cwt.

The Electrician.

Published every Friday. Price Fourpence; Post Free, Fourpence Halfpenny.
Editorial and Publishing Offices
No. 1, SALISBURY COURT, FLEET STREET, LONDON, E.C.
Telephone No. 2714.

All Communications to be addressed to "The Electrician," 1, Salisbury-court, Fleet-street, London, E.C. Cheques and Money Orders should be made payable to "The Electrician."

All letters intended for insertion in "The Electrician," or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.

"The Electrician" is published every Friday morning, in time for the morning mails. Subscribers should receive their copies by the first post on Friday morning.

"The Electrician" is on sale at the railway bookstalls throughout the United Kingdom on Friday morning, and can be obtained at all Booksellers and Newsvendors; or direct from the office as above.

SPECIAL NOTICE.

Owing to the increase in the number of pages of "The Electrician," in order to partly cover the increased postage, we have been compelled to revise the rates for Foreign Subscriptions, which are now as follows:—

	3 months.	6 months.	12 months.
For Foreign Parts and Colonies:—	s. d.	s. d.	s. d.

„ Aden, Borneo, Ceylon, China, India, Japan, Java, Labuan, Mozambique, New Caledonia, Persia, Philippine Islands, Siam, Transvaal, and Zanzibar	7 6	... 14 6	... 28 0
The rates for the United Kingdom remain as follows:—	5 0	... 10 0	... 19 6

TO ADVERTISERS.

"The Electrician" offers exceptional advantages to Advertisers. **It has the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application to this office.

Advertisements intended for the current issue must be handed in not later than 4 p.m. on Thursday.

TECHNICAL PRINTING.

"The Electrician" Printing and Publishing Company (Limited) *beg to inform Electricians and Electric Light Engineers that they make a specialty of Technical Printing, and have a Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electrical Catalogues and Electro-Technical Literature generally.*

The Electricians' Directory.

Royal 8vo. Cloth Boards, 3s. 6d. Boards, 3s.

At the end of December in each year is issued The Electricians' Directory and Handbook. *The Directory was established in 1883, and has now attained considerable proportions. Every care is taken to make the names and addresses of all persons engaged in the Electrical Industries absolutely accurate. Useful Tables and Electrical Formulæ are given, together with popularly-written Biographical Notices of the leading Electricians, accompanied in many cases by Portraits.*

THE DIRECTORY FOR 1889 IS IN PREPARATION.

"THE ELECTRICAL WORLD" IN THE UNITED KINGDOM.

Arrangements have been made by which "The Electrical World" of New York can be obtained from "The Electrician" Office, 1, Salisbury-court, Fleet-street, London, E.C.

The Rate of Subscription (payable in advance), including postage, is **£1. 1s. 0d.** *per annum to this Country and Abroad.*

Single Copies of "The Electrical World" can also be obtained, **price 6d. each.**

The Rates for Advertisements in "The Electrical World" of New York can be obtained on application to "The Electrician" Printing and Publishing Company, Limited, as above.

"THE ELECTRICIAN" IN THE UNITED STATES.

Similarly, "The Electrician" can be obtained in America at the Offices of "The Electrical World," 168 to 177, Potter-building, New York.

"The Electrician" can also be obtained from D. Van Nostrand, *23, Murray-street, and 27, Warren-street, New York.*

The Rate of Subscription for American Subscribers (payable in advance) is $6 per annum.

THE POSTMASTER-GENERAL'S REPORT.

Although the annual Reports of the present Postmaster-General are devoid of those features of popular interest which used to adorn the Blue Books issued by some of his predecessors, he has no reason to be ashamed of the work performed by the Department of which he is now the Parliamentary head. His Report for the financial year 1887-8, frigidly formal and business-like as it is, discloses a remarkable growth in those two branches of the public service most closely identified with the commercial and social well-being of the country. Of the postal branch we need say no more than that the results would astound us if we had not been gradually trained to regard them as a matter of course and the profits arising from them as a source of unfailing revenue. The early struggles of the Post Office were by no means so uniformly cheering; and in

Digitized by Google

its efforts to meet the popular demands for cheapness it had to encounter many obstacles and to undergo many vicissitudes from which it is now wholly exempt. In the Telegraph service, however, which was added as a subsidiary branch of its business in 1870, the Post Office has repeated its earlier experiences, and from causes over which it has had no control, or for which it is not directly responsible, the business of the Telegraphs has been an uphill one from the first, and has still some ground to recover before it will rank, like the Post Office proper, as a revenue earning department of the State.

One of the causes of its financial shortcomings is the fact that the Telegraph system was purchased from private companies, who were carrying on a flourishing business, and had to be liberally compensated for its extinction. When, however, we remember that a business of £550,000 per annum has increased in the hands of the Post Office to £1,959,406, and the number of messages dealt with from 6,000,000 to 53,403,425, the twenty years' purchase money which was paid for it cannot be considered excessive. The business acquired on these conditions was then being rapidly developed, and unlike some businesses which have recently changed from private to public hands it continued to increase, and has had an uninterruptedly prosperous career. This at least may be said of it, measured by the standard of ordinary commercial undertakings. But, as a matter of fact, since its transfer to the State, the Telegraph service has been conducted not on commercial but on popular, and in some respects, it may be said, on political lines. In the first instance the tariff was extravagantly liberal; it reduced the price by more than half in compliance with public demands, but missed a golden opportunity of correcting the abuse of free addresses which the companies themselves had found unbearable. The result was, as many competent judges predicted it would be, that the shilling tariff did not pay its way. Not until the year 1881 did the net revenue yield sufficient to pay the interest on the original purchase money. This interest amounts to £326,417 per annum, and we believe that 1881 was the last as well as first year in which that charge was covered by profits.

Here we come to another of those hindrances to financial success which the Telegraphs of this country have encountered. No sooner did there appear signs of prosperity than demands arose for a still cheaper tariff; and the expenses incurred in anticipation of acceding to these demands, coupled with continued depression of trade and the necessarily increased charges of a service which had by this time attained dimensions far beyond expectations, soon converted a small surplus into a considerable deficit, which has lately been getting bigger every year, until the present, when it stands at £325,399. That is to say, the interest on capital swallows up what would otherwise be a small margin (£1,018) of profit, and leaves over £325,000 unpaid. The accumulated total of this annual arrears of interest now reaches several millions; and if the accounts were rendered on commercial principles this sum ought to be added to the capital account. A more reasonable ground for complaint, however, is that the outlay upon fresh works has always been charged against the revenue for the year in which they have been executed, instead of being, as they ought to be, placed to capital account bearing the usual interest. Mr. FAWCETT in his report for 1880-1 pointed out that by this system of account "the net profit in any particular year does not accurately measure the results of Telegraph business for that year, regarded from a commercial point of view;" and by way of illustrating his meaning he showed that the revenue for that year would have paid a dividend of 4·17 per cent. on the aggregate amount of capital invested down to date.

If Mr. RAIKES were to furnish a balance-sheet down to the present date framed on the same principles we rather fancy the figures would be not less satisfactory; and in that case the complaints of those who demur to the "deficit" column remaining a standing reproach to the Telegraph service would be amply justified. Retaining the present system of accounts, however, the revenue, advancing as it does by tremendous bounds, will speedily overtake the annual charge for interest, and we may confidently look forward, if the present sixpenny tariff remain undisturbed, to the Telegraphs soon paying their way and earning a handsome profit. In the years ending 31st March, 1883 and 1884, the revenue was increasing at the rate of twenty thousand per annum; in 1885 it fell five thousand below the year preceding; and in 1885-6, during six months of which the sixpenny tariff had been in operation, there was an increase of only three thousand pounds. But for the two years following, the increase has averaged one hundred thousand pounds, whilst, the working expenses seem to have reached a maximum, which at all events has not been exceeded in the year just expired. The process of extension is, however, not yet completed. During the past year 257 new offices were opened; and of course the expenditure on the staff of operators and officers must increase with their augmented responsibilities. One item of charge the metropolitan public will certainly not begrudge, namely that for placing the wires underground. Of the 1,745 lines of wire now entering the Central Office in London not one is overhead. In many cases the wires are conducted underground for distances of 12 to 22 miles from the office. If this example is not very welcome to the Telephone Companies, they have no ground for complaining of Post Office competition in their own line of business. The total number of subscribers to Postal Telephone Exchanges all told is only 1,370.

OBITUARY.

PROFESSOR EDLUND.

We learn with much regret that Prof. E. Edlund, who has for many years occupied the Chair of Physics at the Swedish Royal Academy of Sciences, died at Waxholm, near Stockholm, on the 10th of August, at the age of 69.

Prof. Edlund has done a considerable amount of valuable work in physics, and we have noted some fifty Papers which he has published in the scientific journals.

By far the greater number of these appeared in the *Transactions* of the Swedish Academy, and being written in the Swedish language could be studied in the original by only a very limited number of physicists.

Most of his more important Papers, however, were translated either into English or German, and appeared in the *Philosophical Magazine*, and in the *Annalen der Physik und Chemie* and other German journals. Some of his earlier Papers were devoted to the consideration of "Fluid Motion," the "Polarisation of Light During a Total Eclipse," the "Thermal Phenomena Accompanying Changes in Volume of Solid Bodies, and the Corresponding Mechanical Work," and other questions respecting heat and light. He, however, very soon turned his attention to electricity, and carried out a number of researches of some practical as well as of considerable theoretical value. In 1855 he described a method of simultaneously transmitting messages in opposite directions along the same telegraph wire, and a translation of the Paper was published in Dingler's *Polytechnisches Journal* for the following year.

Among other electrical Papers, we may mention the fol-

Digitized by Google

lowing: "Heat Disengaged by Induction Currents, and the Relation between the Disengagement of Heat and the Mechanical Force Employed to Produce Them;" "Experimental Demonstration of the Elongation of a Wire, Independently of Heat Effects, by the Passage of an Electric Current through It." An abstract of this Paper was published in the *Philosophical Magazine*. Some very interesting Papers, translated in the *Philosophical Magazine*, contained accounts of a series of researches on the electric arc, viz.:—"Investigation of the Electric Light;" "Least E.M.F. by which a Galvanic Luminous Arc can be Produced;" "The New E.M.F. in the Voltaic Arc;" and "The Resistance of the Voltaic Arc." Another interesting Paper contains an account of researches into the cause of the Peltier effect.

He also published some investigations on the "E.M.F. of Contact of Different Metals," on the "Discharge of Electricity through Gases," and on the "Thermal Phenomena of the Galvanic Pile." His theories respecting the nature of electrical actions, especially as applied to unipolar induction, have excited a good deal of interest among physicists. He attempted to obtain an explanation of atmospheric electricity from his theory of unipolar induction, which he defended with vigour, but not, in our opinion, with success, against the attacks of numerous physicists. This subject has lately been treated at some length in our columns, and Prof. Edlund's theories have led to a considerable number of interesting investigations.

IMPROVEMENTS IN THE TELEPHONE SYSTEM OF GLASGOW AND THE WEST OF SCOTLAND.

By D. Sinclair, Engineer, National Telephone Company.

(Continued from page 564.)

I have said that the multiple switch-board is the best within our experience, and the fact that they are being adopted all over the world shows how much they are appreciated; but that they are perfect, or that they fulfil all that a perfect switch-board should do, is not the case. The chief point in which they are deficient is, that when two subscribers are joined together they have only what at best can be called a partial ring-off system. There have been several attempts to fulfil the requirements of the ring-off. One of these is what is known as the "Law" system, which is a loop wire circuit, starting from the exchange, entering into, say, 50 subscribers' offices, and returning to the exchange, and this circuit is used for speaking to the exchange only, each subscriber having an additional wire to the exchange in the ordinary way.

A modification of this system is at work in the National Telephone Company's Centre in Dundee, being a single wire, not a loop, and a connection from it is taken into, say, fifty offices in passing, and is used entirely for calling the exchange. This plan works with very marked success. It gives what is undoubtedly a great advantage to subscribers, but at the same time it causes a very considerable expense to the company. A little consideration will show that while a subscriber is using his call wire his other wire is idle, so that what is wanted is such switching facilities as will enable the subscriber to use his ordinary wire either as a call wire or as an ordinary wire at pleasure, and thus to do away with the trouble and cost of the circuit wire.

After working at the subject for some considerable time, I had an arrangement set up to do this work, the details of which are shown on Fig. 7, and is called "Sinclair's Automatic Ring-Off System." Its main points may be briefly stated as follows:—

In the subscriber's office is placed a commutated magneto, with a small two-way switch on it—one way exchange and the other subscriber—so that either a continuous or intermittent current can be sent from it. Now, as a continuous current will not ring a magneto bell, and will attract the armature of an indicator with that degree of tension upon it which prevents it being affected by an intermittent current, it is only necessary to use the switch to have the power to ring the subscriber without causing any effect in the exchange. When the exchange is wanted, a continuous current is sent which does not ring the subscriber's bell, and does cause the tongue of the indicator to be affected so as to automatically put it in connection with the operator's telephone. Instantaneous attention is the result, and in the same way, as with the "Law" system, the subscriber can say what is wanted. If then connected with any other subscriber, the operator puts the indicator into normal position, clearing her telephone, and leaving the subscribers free to talk privately until either of them wishes to get the exchange, when, as has been said, a continuous current will put his line automatically in connection with the operator's telephone in a moment.

When we can have this system at work with the "multiple" boards there will be no need for description of getting a telephone exchange connection such as *Punch* made so much of; nor will there be any necessity for the use on the part of telephone subscribers of so many adjectives not generally included in the Queen's English.

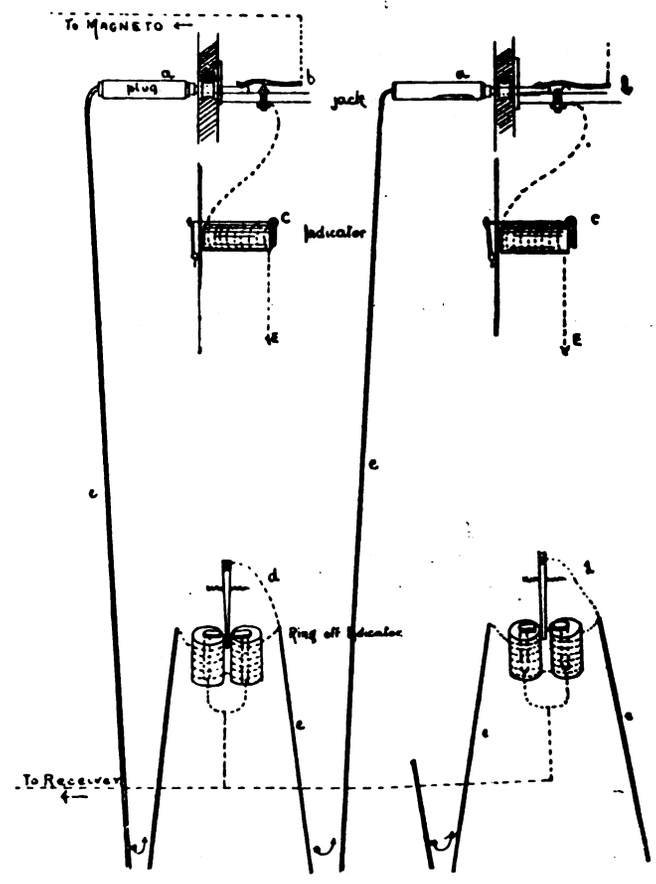

Fig. 7.

In Glasgow, as in other places, we have opened several branch exchanges in the town; they are six in number. At one time the perfect working of these seemed to be a great difficulty, but as they have now been arranged this has entirely disappeared. The wires connecting these branch exchanges we call "junction" wires, to distinguish them from "trunk" wires. At the Central Exchange we have a special operator and table set apart for working these wires. This we call our "junction wire exchange table," and from this table to each of the branch exchanges we have a wire used entirely for speaking between the operators. A plan of the connections is given on Figs. 8A and 8B.

The operating is extremely simple and quick, as it is but the work of a moment for the branch operator to close the circuit wire and tell the junction operator what is wanted, whether it be to connect with a subscriber in the "Central" or to connect with some other branch exchange.

As there is no ringing or calling attention the number of connections one operator can put through in this way is

Digitized by Google

wonderful; any two branch exchange wires can be connected together by the movement of one plug. To meet the requirements of the Central Exchange in getting the branch exchanges, the wires are led through the multiple boards, so that each operator has power to connect her subscribers with these junction wires in the same way as if they had been subscribers' lines. Everything works very quietly and smoothly; there are no indicators, and no ringing on these junction wires. In the figure I have shown all the connections, as I am not aware of this being at work elsewhere.

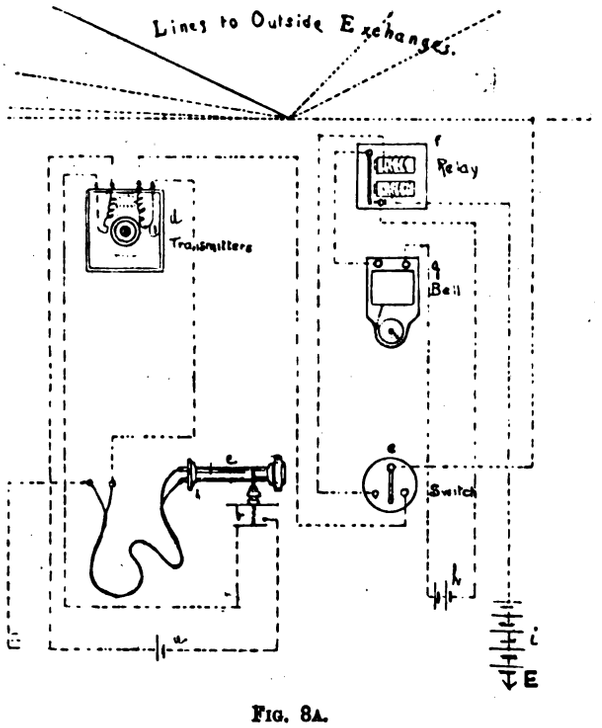

FIG. 8A.

Connections of junction board in Central Exchange. This diagram shows how junction wires are joined up on board; *m*, plug; *k*, jack; *l*, connecting cord.

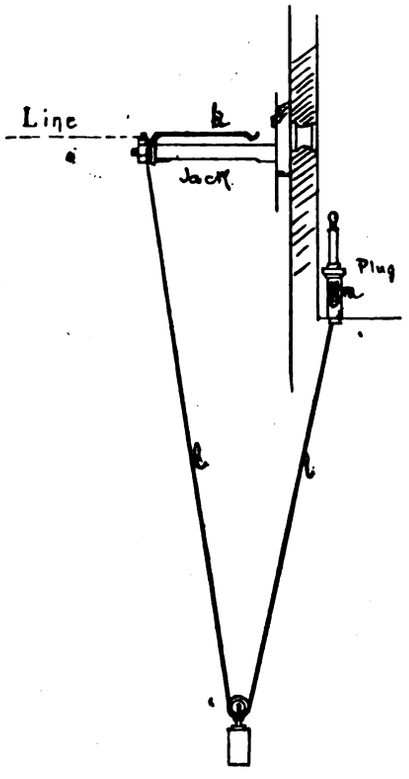

FIG. 8B.

Operator's circuit with lines from outside exchanges meeting on a common line on which connections are asked; *a*, local battery; *b*, receiver rest and battery cut-out; *c*, receiver; *d*, transmitter; *e*, two-way switch to put line direct on to instrument or to introduce relay *f*, bell *g*, and battery *h*; *i*, battery, introduced when switch is to relay and line is put to earth at distant exchange.

As a rule the junction operator keeps the telephone to her ear constantly. If she sets it down the switch puts a bell in circuit, so that any of the branches putting the wire to earth closes the circuit of the relay and bell, and commands immediate attention.

In doing the ordinary work of our Central Exchange it is necessary to ring about 10,000 times each day. This is accomplished by one of the magneto-electric generators of the same kind as used in the ordinary instruments, the apparatus being driven continuously by a small water motor. The amount of water used in this way for driving a generator for each of four exchanges so supplied costs about £5 per annum. The arrangement is fitted up in the basement of the building, and a wire led from the generator there to the central and three of the branch exchanges.

This works well, and gives complete satisfaction to all, unless, indeed, to the lineman who in wet weather catches a wire while the ringing current is on it. The high tension is much more than is agreeable to bear, and I have not been successful in clearing their minds of an idea that this arrangement was devised merely to smarten them up.

I shall next refer to "Sinclair's Automatic Branch Exchange Commutator." It will be readily understood that if six houses placed near each other at a point ten miles distant from London wish to have telephone communication, a wire run to each of them would be very costly, and, at most, would only be required thirty or forty minutes each day.

This instrument provides facilities so that only one wire requires to be run out to the place, and attached to the instrument there, then six branches are taken from it into the different houses. The instrument in this way constitutes a small automatic exchange without an office or operator. The working of the apparatus is as follows:—

When one of the six houses wishes communication the magneto is rung in the ordinary way, which has the effect, at the automatic instrument, of disconnecting the other five lines and connecting the caller's own wire with the main line going into the central exchange. If one of the other five lines on the intrument is wanted, the exchange operator would send a certain number of successive currents, which by an ordinary step-by-step movement puts the pointer to the number wished for, and connects up the wire of that particular subscriber. The two local instruments are now in communication. The exchange disconnects her wire while they are speaking. When finished the instrument is made to perform a complete revolution, thereby putting everything back into normal position, so that any other subscriber may again ring up. When the exchange wishes, say, No. 3, the peg of the "sender" is put in that number, and allows three currents to go out to line, which causes the pointer on the automatic instrument to go round to No. 3. The others, being disconnected, cannot interfere. A magneto current is then used to ring up No. 3, who replies in the ordinary way. As before, when finished the "sender" is allowed to go to zero, which puts the automatic instrument into proper position again. Some of these have been at work in Glasgow with as many as twelve wires, and have given every satisfaction.

I think it is evident that when the time arrives for the telephone enterprise to be freed from patent restrictions and Government royalties then the outside wires which this instrument has been designed to save will have a much higher relative value in the system as a whole; consequently the use of such an instrument will be of greater importance.

(To be continued.)

The Berlin-Breslau Telephone Line.—Telephonic communication was opened on Tuesday between Berlin and Breslau. The line is the longest in Germany, being 360 kilometres. Every word was heard most distinctly.

THE ELECTRIC TRANSMISSION OF POWER.*

BY PROF. AYRTON, F.R.S.

What is power, and why should we wish to transmit it? Power has one very definite meaning in science, and several rather vague meanings in practice. We speak of a powerful athlete, the power of the law, we sing of the power of love, we say knowledge is power, and so on, using the word in several different senses. Now, in spite of the fact that a general audience feels a little anxious as to what troubles may be in store for it when a lecturer begins by being painfully exact, my telling you that by power an engineer understands the rate of doing work will not, I hope, make you fear that my remarks will bristle with technicalities.

When you walk upstairs you exert power, only, perhaps, the one-twentieth of a horse when you go up slowly talking to other people; but when you run upstairs, because you have forgotten something that you intended to bring down, then your exertions represent, perhaps, the one-tenth of a horse-power. You only get to the top of the stairs in either case, but the breathless sensation of running fast upstairs tells you that the more quickly you go the harder you are working. A person exercises power in the engineer's sense when he exerts himself physically, and the greater the exertion the greater the power. The exercise of power by the ruling classes, however, is unfortunately not necessarily accompanied by any exertion, physical or mental.

Probably, the most familiar example of exerting power at a distance, that is of transmitting power, is pulling a handle and ringing a bell in another room. I pull the handle, exerting myself slightly, and as the result the bell at the other end of the platform rings. Were not this such a very familiar operation I would call it experiment No. 1. You have, doubtless, all of you performed this experiment several times to-day, and what is all important with an experiment, performed it successfully.

And yet it was not until just one hundred years ago that it dawned on people that if one person, A, wanted to attract the attention of another person, B, the place where the bell ought to sound was where B was, and not where A was. Indeed, in many English villages down to the present day the knocker principle of attracting attention is alone resorted to, with the result which you may remember happened when Mr. Pickwick was staying in Bath at lodgings in the Royal Crescent, and Mr. Dowler undertook to sit up for Mrs. Dowler, but "made up his mind that he would throw himself on the bed in the back room and *think*—not sleep, of course. . . Just as the clock struck three there was blown into the Crescent a sedan chair, with Mrs. Dowler inside, borne by one short, fat chairman, and one long thin one. . . They gave a good round double knock at the street door. . . 'Knock again, if you please,' said Mrs. Dowler, from the chair. 'Knock two or three times, if you please.' The short man stood on the step, and gave four or five most startling double knocks of eight or ten knocks apiece while the long man went into the road and looked up at the windows for a light. Nobody came; it was as silent and as dark as ever." But the tall thin man you may remember "kept on perpetually knocking double knocks of two loud knocks each like an insane postman," till Mr. Winkle, waking up from a dream "that he was at a club where the chairman was obliged to hammer the table a good deal to preserve order," met with the catastrophe which the readers of Pickwick will remember.

This episode shows what it is to have plenty of power and no means of utilising it. But if some houses can still dispense with mechanical or other methods of transmitting power, even to ring bells, factories cannot. The looms, the lathes, or whatever the machinery used in the factory may be, must either be worked by hand or foot, in the old style, or it must be connected with the steam, gas, or water engine in the new. On entering a large factory you see lines of rapidly rotating shafting, and a network of rapidly revolving belting, all employed in transmitting power. As a contrast to this, I now throw on the screen a photograph of Sir David Salomons' workshop at Tunbridge Wells, in which every machine is worked by a separate electric motor, thus saving to a great extent the loss of power that usually accompanies the mechanical transmission.

In America there are 6,000 electro-motors working machinery; in Great Britain hardly 100.

But it is not only in transmitting the power from the steam, gas, or water engine of a factory to the various machines working in it that electricity can be utilised. An incredible amount of power is daily running to waste in this and other countries because many of the rapid streams of water are too far away from towns for their power to have been hitherto utilised.

The holiday tourist when admiring the splashing water dashing over the stones hardly realises that the money loss is as if the foam were composed of flakes of silver.

If we take as a low estimate that a large well-made steam engine burns only 2lb. of coal per horse-power per hour, the coal consumption which would be equivalent to the waste of power at Niagara would exceed 150 millions of tons per annum, which, at only 5s. or 6s. per tons, means some 40 millions pounds sterling wasted. And descending from big things to small, the River Avon flowing through Bath, which, so far from being a roaring cataract, especially in dry weather, pursues its course with only a respectable orderly swish, still represents a certain amount of loss power. It has been estimated that from 25 to 130 horse-power runs to waste at the Bathwick Weir behind the Guildhall, depending on the season. If we take as an all-round average that the fall of this weir represents 50 horse-power, and that a steam engine producing this power burns 150lb. of coal per hour, it follows that with steam coal at 16s. per ton, the price at Bath, the waste at Bathwick Weir represents an income of £450 per annum—not a princely fortune, it is true, but too large to be utterly thrown away, as at present.

This state of things will, I hope, however, be shortly remedied, for, as you will see from the large map on the wall, it is proposed to put up 81 electric arc lamps throughout the streets of Bath, and to supply the 50 horse-power required for these lamps by the fall of the Bathwick Weir, supplementing the fall with a steam engine at dry seasons.

The next large diagram shows the use that Lord Salisbury has made of the River Lea to electrically light Hatfield House and to supply electric motive power to the various machines working on his estate; and the following diagram shows the course of the Portrush Electric Railway (see *Electrician*, April 21, 1883, p. 545; October 27, 1883, p. 566), 6½ miles long, which is worked by the Bushmill Falls, situated at about one mile from the nearest point of the railway; and, lastly, this working model on the table, kindly lent me by Dr. E. Hopkinson, as well as the diagram on the wall, represent the Bessbrook and Newry Electric Tramway, a little over three miles in length, which is also worked entirely by water-power, the turbine and dynamo which convert the water-power into electric power being at about three-quarters of a mile from the Bessbrook terminus. [Model of electric tramway shown in action.]

The newspapers of last week contained a long account of the spiral electric mountain railway that has just been opened to carry people up the Burgenstock, near Lucerne, and worked by the River Aar, three miles away, so that we see electric traction worked by distant water-power is extending. But splendid as are these most successful uses of water-power to actuate distant electro-motors, it is but a stray stream here and there that has yet been utilised, and countless wealth is still being squandered in all the torrents all over the world.

The familiarity of the fact makes it none the less striking that, while we obtain in a laborious way from the depths of the earth the power we employ, we let run to waste every hour of our lives many, many times as much as we use.

It is also a well-established, time-honoured fact that large steam engines can be worked much more economically than small ones, and that, therefore, if it were possible to *economically* transmit the power from a few very large steam engines to a great number of small workshops, there would be a great saving of power, as well as a great saving of time, from the workmen in these many small workshops having only to employ this power for various industrial purposes, instead of having to stoke, clean, repair, and generally attend to a great number of small, uneconomical steam engines.

When delivering the lecture which I had the honour to give at the meeting of the British Association at Sheffield nine years ago, I entered fully into Prof. Perry's and my own views on this subject, and, therefore, I will not enlarge on them now. You can all realise the difference between the luxury of merely getting into a train instead of having to engage post horses, of being able to send a telegram instead of employing a special messenger, or being able to turn on a gas tap and apply a match when you want a light, instead of having to purchase oil and a wick and trim a lamp. Well, a general supply of power to workshops is to the manufacturer what a general supply of light or a general supply of post office facilities is to the householder; it is all part of the steady advance of civilisation that leads the man of to-day to go to the tailor, the shoemaker, the baker, the butcher, instead of manufacturing his own mocassins and lassoing a buffalo for dinner. And in case any of you may be inclined to think that we have gone far enough in these new-fangled notions—and we are all, perhaps, prone to fall into this mistake as we grow older—let me remind you that while each age regards with justifiable pride the superiority of its ways to those of its ancestors, that very age will appear but semi-civilised to its great grandchildren. Let us accept as an undoubted fact that a general distribution of power would enable the wants of civilised life to be better satisfied, and therefore would greatly benefit industry.

There are four methods of transmitting power to a distance:—

1. By a moving rope.
2. By air compressed or rarefied at one end of a pipe operating an air motor at the other end.
3. By water forced through a pipe working a water motor.
4. By electricity.

* Delivered at the Drill Hall, Bath, Friday, Sept. 7, 1888.

Digitized by Google

We have an example of the transmission of power through a short distance by an endless belt or rope in the machines geared together by belts on this platform, and in the rotatory hairbrushes at Mr. Hall's establishment in the Corridor, Bath. At Schaffhausen, and elsewhere in Switzerland, the principle is employed on a large scale. Spain and other countries use it in connection with the mining operations, and lastly, wire ropes replace horses on many hilly tramways. Do not look, however, for the wire rope of the Bath Cable Tramways, for cable is only to be found painted on the sides of the cars.

For short distances of a mile or so there is no system of transmitting power in a *straight line* along the open country so cheap to erect, and so economical of power as a *rapidly* moving endless rope; but the other systems give much greater facilities for distributing the power along the line of route, are much less noisy, and far surpass wire rope transmission in economy, when the rope must move somewhat slowly, as in tramway traction, or when the distance is considerable over which the power is transmitted, or when the line of route has many bends.

In the same sense that an ordinary house bell man be considered as a crude example of the transmission of power by a moving rope, the pneumatic bell at the other end of the hall, which I now ring by sending a puff of air through the tube, is a crude example of the transmission of power by compressed air. [Pnuematic bell rung.] Compressed air is employed to work from a distance the boring machines used in tunnelling; the continuous vacuum brakes used on many of the railways are also probably familiar to you, and the pneumatic system of transmitting power to workshops is shortly to be tried on a fairly large scale at Birmingham.

But distribution of power by water pressure is the plan that has hitherto found most favour in this country. That little water motor at the other end of the platform rapidly revolves when I work this garden syringe, and serves as a puny illustration of the transmission of water pressure. [Experiment shown.] Pressure water has been employed for years on a large scale at Hull for distributing power; also by Mr. Tweddle as a means of communicating a very large amount of power through a flexible tube to tools that have to be moved about, but the grandest illustration of this principle is the vast system of high-pressure mains that has been laid throughout London, as you will see from the photograph that I now project on the screen of the map kindly lent me by Mr. Ellington.

The economy of this system is so marked, and the success that has attended its use so great, that, did I not feel sure that electricity offers a grander system still, it would be with fear and trembling that I should approach the subject of this evening, the "Electric Transmission of Power." *Punch* drew six years ago the giant steam and the giant coal looking aghast at the suckling babe, electricity, in its cradle. That babe is a strong boy now. Let the giant water look to its laurels ere that boy becomes a man, for the electric transmission of power even now bids fair to surpass all other methods in

1. Economy in consumption of fuel.

2. More perfect control over each individual machine, for see how easily I can start this electric-motor and how easily I can vary its speed. [Experiment shown.]

3. Ability to bring the tool to the work instead of the work to the tool. This rapidly rotating polishing brush, with its thin flexible wires conveying the power, I can handle as easily as if it were a simple nail brush.

4. In greater cleanliness, no small benefit in this dirty, smoky age.

5. And, lastly, there is still one more advantage possessed by this electric method of transmitting power that no other method can lay claim to—the power which during the daytime may be mainly used for driving machinery can, in the easiest possible way, be used during the night for driving light. I turn this handle one way and the electric current, coming by one of these wires and returning by the other, works this electro-motor; now I turn the handle the other way and the current, which comes and returns by the same wires as before, keeps this electric lamp glowing. [Experiment shown.]

It might be said that the transmission of power by coal-gas, which I have omitted from my list, fulfils the condition; but so also does the transmission of power by a loaded coal waggon. In both these cases, however, it is fuel itself that is transported, and not the power obtained by burning the fuel at a distant place.

Let us study this electric transmission a little in detail. I pull this handle, and the bell at the other end of the room rings, but in this case there is no visible motion of anything between the handle and the bell. [Electric bell rung by an electric current produced by pulling the handle of a very small magneto electric machine.] Whether I ring the bell by pulling a wire, or by sending an air puff, or by generating an electric current by the exertion of my hand, the work necessary for ringing the bell is done by my hand exactly as if I took up a hand bell and rung it. In each of the three cases I put in the power at one end of the arrangement and it produces its effect at the other. In the electric transmission how does this power travel? Well, we do not know; it may go through the wires, or through the space outside them. But although we are really quite in the dark as to the mechanism by means of which the electric power is transmitted, one thing we do know from experience, and that is this—given any arrangement of familiar electrical combinations, then we can foretell the result.

Our knowledge of electrical action in this respect resembles our knowledge of gravitation action. The only thing quite certain about the reason why a body falls to the ground is that we do not know it; and yet astronomical phenomena can be predicted with marvellous accuracy. I mention the analogy since some people fancy because the answer to that oft-repeated question "What is electricity?" not only cannot be given exactly, but can only be guessed at in the haziest way, even by the most able, that therefore all electric action is haphazard. As well might the determinations of a ship's latitude at sea be regarded as a mere game of chance because we have not even a mental picture of the ropes that pull the earth and sun together.

This power of producing an action at a distance of many yards, or it may be many miles, by the aid of electricity without the visible motion of any substance in the intervening space is by no means new. It is the essence of the electric telegraph, and electric transmission of power was employed by Gauss and Weber when they sent the first electric message. I am transmitting power electrically whether I now work this small model needle telegraph instrument, or whether I turn this handle and set in motion that little electric fan. [Experiment shown.]

But until about ten years ago the facility that electricity gave for producing signals almost instantaneously at a great distance was the main thing thought of. The electric power consumed for sending the telegraphic messages was so small, the amount of power lost *en route* comparatively so valueless, that the telegraph engineer had no need to trouble himself with those considerations that govern us to-day, when we are transmitting power large enough to work a factory or an electric tramway. Although there are as many as 22,560 galvanic cells at the Central Telegraph Office, London, which cost some thousands annually to keep in order, what is that compared with the salaries of all the 3,089 superintendents, assistants, telegraph clerks, messengers, and the maintenance of the 1,150 telegraph lines that start from the central office?

In all last three of the systems on my list, some form of power, such as flowing water or the potential energy stored up in coal, wood, zinc, or other fuel, has initially to be utilised; this power is given to some form of air, water, or electric pump, which transfers the air power to the air, water, or electricity, by which it is conveyed to the other end of the system. There it is re-converted into useful mechanical power by means of an air, water, or electro motor.

You will observe that I class together air, water, and electricity; by that I do not mean to imply that electricity is a fluid, although in many respects it acts like a fluid—like a fluid of very little mass, however, or, odd as it may seem, like a fluid moving extremely slowly, for electricity goes round sharp corners with perfect ease, and without any of the phenomena of momentum possessed by rushing water. But what I particularly wish to impress on you by classing air, water, and electricity together is that electricity is not, as some people seem to think, a something that can be burnt or in some way used up and so work got out of it. Electricity is no more a source of power than a bell wire is; electricity is a marvellously convenient agent for conveying a push or a pull to a great distance; but it is not by the using up of the electricity that electric lights burn or that electro-motors revolve. It is by the electricity losing pressure, exactly as water loses head when turning the miller's wheel as it flows down hill that work is done electrically.

This model shows, in a rough, symbolical way, what takes place in the transmission of power, whether by air, water, or electricity. [Model shown.] The working stuff, whichever of the three it may be, is first raised in pressure and endowed with energy, symbolised by this ball being raised up in the model; it then gradually loses pressure as it proceeds along the tube or wire which conveys it to the other end of the system, the loss of pressure being accompanied by its giving up power to the tube or wire and heating it.

This is shown in the model by the ball gradually falling in its course. At the other end there is a great drop of pressure corresponding with a great transference of power from the working stuff to the motor, and finally it comes back along the return pipe or wire, losing, as it returns, all that remains of the pressure given to it initially by the pump. The ball has, in fact, come back to its original level.

The problem of economically transmitting power by air, water, or electricity is the problem of causing one or other of these working stuffs—air, water, or electricity—to economically perform the cycle I have described.

Digitized by Google

In each of the four stages of the process :—

1. Transference of power to the working substance at the pump,
2. Conveyance of power to the distant place,
3. Transference of power from the working substance to the motor at the distant place,
4. Bringing back the working substance,

there is a loss of power, and the efficiency of the arrangement depends on the amount of these four losses. The losses may be shortly called—

1. Loss at the pump.
2 and 4. Loss on the road.
3. Loss at the motor.

Until 1870 the pump most generally employed for pumping up electricity and giving it pressure was the galvanic battery, a scientifically and extremely efficient converter of the energy in fuel into electric energy, only unfortunately the only fuel a battery will burn is so expensive. A very perfect fireplace, in which there was very complete combustion, and very little loss of heat, but which had the misfortune that it would only burn the very best wax candles, would be analogous with a battery. The impossibility of using zinc as fuel to commercially work electro-motors has been known for the last half century, and the matter was very clearly put in an extremely interesting Paper, "On Electro-Magnetism as a Motive Power," read in 1857 by Mr. Hunt before the Institution of Civil Engineers, a copy of which has been kindly lent me by Dr. Silvanus Thompson. Prof. William Thomson (Glasgow)—I quote from the discussion on the Paper—put the matter very pithily by showing that even if it were possible to construct a theoretically perfect electro-motor, the best that could be hoped for, if it worked with a Daniell's battery, would be the production of a 1 horse-power by the combustion of 2lb. of zinc per hour, whereas with a good actual steam engine of even thirty years ago 1 horse-power could be produced by the combustion of exactly the same weight of the much cheaper fuel, coal. This argument against the commercial employment of zinc to produce electric currents is irresistible unless—and this is a very important consideration which is only beginning to receive the attention it deserves—unless, I say, the compound of zinc formed by the action of the battery can he reduced again to metallic zinc by a comparatively inexpensive process, and the zinc used over and over again in the battery. If the compound of zinc obtained from the battery be regarded as a waste product, then it would be much too expensive to work even theoretically perfect electro-motors if they were existent by consuming zinc. Suppose, however, a process be devised by means of which burnt zinc can be unburnt with an expenditure comparable with the burning of the same weight of coal, then it might be that although coal would still form the basis of our supply of energy, the consumption of zinc batteries might be an important intermediary in transforming the energy of coal economically into mechanical energy.

While, then, some experimenters are aiming at possibly increasing the working power of a ton of coal to eight times its present value by earnestly seeking for a method of converting the energy it contains directly into electric energy without the intervention of a wasteful heat engine, it should not be forgotten that in the cheap unburning of oxidised metal may lie another solution.

The solution of this latter problem is quite consistent with the principles of the conservation and dissipation of energy, since the heat required to theoretically unburn 1lb. of zinc is only one-seventh of that given out by the burning of 1lb. of coal. Further, it involves no commercial absurdity like that found in the calculations given in the prospectuses of many primary battery companies which are based on zinc oxide, a material used in the manufacture of paint, maintaining its present price even if thousands of tons were produced. Unless all those who use primary batteries on this expectation intend to have the painters doing up their houses all the year round, they will find themselves possessed of the stock-in-trade of an oil and colourman on a scale only justified by a roaring business in paint.

Now about waste No. 3, the waste of power at the motor. That also is gone into fully in the discussion in Mr. Hunt's Paper, and Mr. Robert Stephenson concluded that discussion by remarking :—"That there could be no doubt from what had been said that the application of voltaic electricity in whatever shape it might be developed was entirely out of the question, commercially speaking. . . . The power exhibited by electro-magnets extended through so small a space as to be practically useless. A powerful electro-magnet might be compared for the sake of illustration to a steam engine with an enormous piston, but with an exceedingly short stroke. Such an arrangement was well known to be very undesirable."

And this objection, made with perfect justice against the electro-motors of thirty years ago, might also have been made to all the machines then existing for the mechanical production of electric currents. I have two coils of wire at the two sides of the platform joined together with two wires. I move this magnet backwards and forwards in front of this coil, and you observe the magnet suspended near the coil begins to swing in time with my hand. [Experiment shown.] Here you have in its most rudimentary form the conversion of mechanical power into electric-power and the re-conversion of electric power into mechanical power ; but the apparatus at both ends has the defects pointed out by Mr. Hunt and all the speakers in the discussion on his Paper—the effect diminishes very rapidly as the distance separating the coil from the moving magne increases.

As long as electro-motors as well as machines for the production of electric currents had this defect the electric transmission of power was like carrying coals to Newcastle in a leaky waggon. You would pay at least 16 shillings for your coals in Bath, lose most of them on the way, and sell any small portion that had not tumbled out of the waggon for, say, two shillings a ton at Newcastle, a commercial speculation not to be recommended.

A very great improvement in electro-motors was made by Pacinotti in 1860, but although his new form of electro-motor was described in 1864, it attracted but little attention, probably because any form of electro-motor, no matter how perfect, was commercially almost useless until some much more economical method of producing electric currents had been devised than the consumption of zinc and acids. Pacinotti's invention removed from motors that great defect that had been so fully emphasised by the various speakers at the reading of Mr. Hunt's Paper in 1857. When describing his motor in the *Nuovo Cimento*, in 1884, he pointed out that his principle was reversible, and that it might be used in a mechanical current generator. This idea was utilised by Gramme in 1870, who constructed the well-known Gramme dynamo for converting mechanical into electric power, a machine far more efficient than even Pacinotti had contemplated, and gave the whole subject of electrical engineering a vigorous forward impulse. Every subsequent maker of direct-current dynamos, or motors, has followed Gramme's example in utilising the principle devised by Pacinotti, which was as follows :—In all the early forms of dynamos or motors there were a number of magnets and a number of coils of wire, the magnets moving relatively to the coils, or the coils relatively to the magnets, as you see in this rather old specimen of alternate-current dynamo. To produce magnetism by a large number of little magnets is not economical, and Pacinotti's device consisted in arranging a number of coils round a ring in the way shown in the large wooden model [model shown] so that they could all be acted on by one large magnet. Instead of frittering away his magnetism, Pacinotti showed how it could be concentrated, and thus he led the way to dynamos and motors becoming commercial machines. Pacinotti's science, engineered by Gramme, not only made electric lighting commercially possible, but led to electricity being used as a valuable motive power. It was in their work that the electric transmission of power in its modern sense sprang into existence.

Quite recently an improvement in the same direction has been introduced into alternate-current dynamos by Mr. W. N. Mordey, for he has replaced the many magnets of the ordinary alternate-current dynamos with one large magnet, and so with his alternator weighing 41cwt., which you see in this hall, he has succeeded in obtaining at a speed of 650 revolutions per minute an output of 53·6 horse-power with a high efficiency.

It may be convenient to mention at this stage the valuable work that has been done by the Drs. Hopkinson, Mr. Crompton, Mr. Kapp, and others in the improving dynamos and motors by applying scientific principles in the construction of these machines. Were I lecturing on dynamos and motors instead of on the electric transmission of power, I would explain to you how, by putting more iron into the rotating armature, as it is called, and less wire on it, by shortening the stationary magnet, and generally by concentrating the magnetic action, these constructors have raised the commercial efficiency of these machines to actually as high as between 93 and 94 per cent. ; further, how by recognising the force of the general principles laid down by Prof. Perry and myself as to the difference that should exist in the construction of a motor and a dynamo, Messrs. Immisch have succeeded in constructing strong, durable electro-motors, weighing not more than 62lb. per effective horse-power developed.

The subject is so entrancing to me, the results commercially so important, that I am strongly tempted to branch off, but the inexorable clock warns me that I must concentrate my remarks as they have concentrated the magnetic action.

Eighty-seven and a-half per cent. of the power put into an Edison-Hopkinson dynamo has actually been given out by the motor spindle when 50 horse-power was being transmitted. How does this compare with the *combined* efficiencies of an air pump and an air motor, or of a water pump and a water motor ? I understand that in either of these cases 60 per cent. is considered a very satisfactory result. As far, then, as the terminal losses are concerned, electric transmission of power is certainly superior to air or water transmission.

The next point to consider is the loss of power on the road

Digitized by Google

between the dynamo at the one end and the motor at the other. This problem was perhaps seriously attacked for the first time in the discussion of a Paper read by Messrs. Higgs and Brittle, at the Institution of Civil Engineers, in 1878, and that problem was considered in some detail theoretically and experimentally at the lecture I gave during the meeting of the British Association in Sheffield in the following year. It was then shown that, since the power developed by the generator and motor depended on the product of the current into the electric pressure, while the loss when power was transmitted through a given wire depended on the square of the current and was independent of the electric pressure, the economical transmission of power by electricity on a large scale depended on the use of a very large electric pressure and the small current, just as the economic transmission of much power by water depended on the use of a very large water pressure and a small flow of water. At that time it was not thought possible to construct a small dynamo to develop a very large electric pressure, or potential difference as it is technically called, and therefore it was proposed to join up many dynamos in series at the one end, and many lamps or electro-motors in series at the other, and to transmit the power by a very small current which passed through all the dynamos and all the lamps in succession one after the other.

You have an example to-night of the realisation of this principle in the 15 arc lamps that are all in series outside this Drill Hall, and are worked with a small current of only 6·8 amperes, and a further example in the 30 arc lamps at the Bath Flower Show, which are also all worked in series with the small current passing through them; but it is known now how to produce a large potential difference with a single dynamo, so that a single Thomson-Houston dynamo belonging to Messrs. Laing, Wharton and Down supplies the current for each of the two circuits.

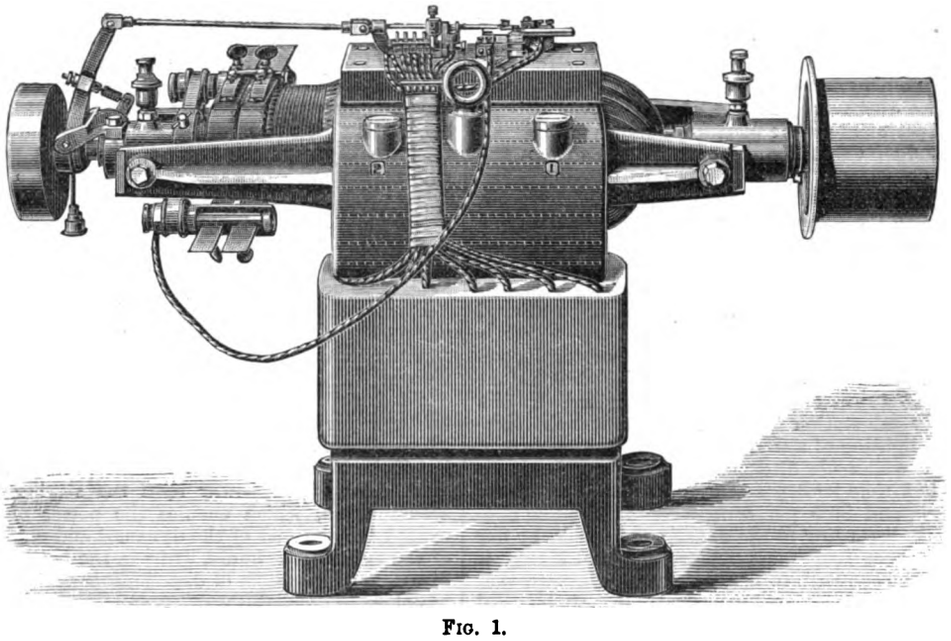

Fig. 1.

The electric pressure, or potential difference, between the terminals of any arc lamp is not high, but it is between the main wires near the dynamo as well as between these wires and the ground. How far does this lead to the risk of sparks or unpleasnt shocks? That is a point that can be looked at in a variety of ways. First, there is the American view of the matter, which consists in pointing out to people exactly what the danger is, if there be any, and training them to look out for themselves. Let ordinary railway trains, say the Americans, run through the streets, and let horses learn to respect the warning bell. Next, there is the semi-paternal English system, which cripples all attempts at street mechanical locomotion, because we are conservative in our use of horses, and horses are conservative in the way of looking at horseless tramcars. Lastly, there is their foreign paternal system, which, carried to its limit, would prohibit the eating of dinners because some people have at some time choked themselves, and would render going to bed a penal offence because it is in bed that most people have died.

We laugh a good deal at the rough and ready manner adopted on the other side of the Atlantic. The Americans, no doubt, are very ignorant of the difficulties that properly-minded people would meet with, but it is a blissful ignorance where it is folly to be wise. Every English electrician who has travelled in America comes back fully impressed with their enterprise and their happy-go-lucky success. They have twenty two electric tramways, carrying some four million passengers annually, to our four electric tramways at Portrush, Blackpool, Brighton, and Bessbrook. Why, New York city alone, Mr. Reckenzaun tells me, possesses 300 miles of ordinary tramway track, and Philadelphia city 430 miles, so there are more tramway lines in these two cities than in the whole of the United Kingdom put together. Now, there would be no difficulty in proving to anyone unfamiliar with railway travelling that to go at 50 miles an hour round a curve, with only a bit of iron rail between him and eternity, would be far too risky to be even contemplated. And yet we do go in express trains, and even 80 miles an hour is beginning to be considered not to put too great a demand on the funds of life insurance companies. The American plan of basing a conclusion on experience rather than on anticipations is not a bad one, and if we follow that plan, then taking into account that there are 75,000 arc lights alight every night on the Thomson-Houston high-potential circuits throughout the world, and the comparatively small number of people that have suffered in consequence (not a single person, I am assured, outside the companies' staffs), we are compelled to conclude that high potential now is what 30 miles an hour was half a century ago—uncanny rather than dangerous.

But it is possible to use a very large potential difference between the main wires by means of which the electric power is economically conveyed a considerable distance and transformed into a very small potential difference in the houses where it is utilised. An electric transformer is equivalent to a lever, or wheel and axle, or any other of the so-called mechanical powers. You know that a large weight moving through a small distance can raise a small weight through a large distance, there is no gain in the amount of work, but only a transformation of the way in which the work is done. A large weight moving through a small distance is analogous with a high potential difference and a small current, while a small weight moving through a large distance is analogous with a small potential difference and a large current; and an electric transformer is for the purpose of effecting the transformation with as little loss as possible, so that what is lost in potential difference may be all gained in current.

Electrical transformation may be effected by—

1. Alternate-current transformers.
2. Motor-dynamos.
3. Accumulators, or secondary batteries.
4. Direct-current transformers.

Of these apparatus, the eldest by far is the alternate-current transformer, as it is merely the development of the classical apparatus invented by Faraday in 1831, and familiar to many of you as the Ruhmkorff or induction coil. A combination of a motor and dynamo was suggested by Gramme in 1874. Accumulators are the outcome of Planté's work, while direct-current transformers are quite modern, and not yet out of the experimental stage.

After studying the literature on this subject, it appears, as far as I have been able to judge, that the first definite proposal to use a high-potential difference in the street mains and transform down to a low-potential difference in the houses was made in the lecture given by me at the meeting of the British Association in Sheffield in 1879, on which occasion I explained and showed in action the motor-dynamo principle suggested by Prof. Perry and myself. The apparatus on the platform is not unlike that shown on the former occasion. An Immisch motor (Fig. 1), working at 500

Digitized by Google

volts, and with a current of 6·8 amperes, is geared direct to a Victoria Brush dynamo giving five times that current, and we will now use this larger current to produce an electric fire. [Experiment shown.] Messrs. Paris and Scott have combined the motor and dynamo into one machine, which they have kindly lent me, and by means of which we are now transforming about 700 volts and 6·8 amperes into 100 volts, and about 40 amperes used to light that group of incandescent lamps and work these motors. [Experiment shown.]

Lastly, here is a working illustration of the double transformation proposed by MM. Deprez and Carpentier in 1881 by means of which, while the potential difference between the mains may be two or ten thousand volts if you like, not merely is the potential difference in the house so low that you could hardly feel anything if you touched the wires, but, in addition, there is the same security against shocks in the dynamo room. This alternate-current machine is producing about 50 volts, which is transformed up to 2,000 volts by means of this transformer. At the other end of the platform by means of a similar transformer the 2,000 volts is transformed down again to 50 volts employed to light that cluster of low voltage incandescent lamps. I have to thank the Anglo-American Brush Company for the loan of this apparatus. [Experiment shown.]

In this experiment there is, as a matter of fact, still more transformation than that I have yet mentioned, because whereas in actual practice the alternate-current dynamo, as well as the small dynamo used to produce the current for magnetising the electromagnets in the alternate-current dynamo, would be worked by a steam, gas, or water engine, I am working them both by electromotors, since a steam engine or a water wheel would be an unsuitable occupant of the Drill Hall. Practically, then, a steam engine on the land belonging to the Midland Railway Company on the other side of the Lower Bristol road is driving a Thomson-Houston dynamo; this is sending a small current working these high-voltage constant-current Immisch motors. The motors being geared with low-voltage dynamos the potential difference is transformed down, the first alternate-current transformer tranforms it up again, and the second alternate-current transformer transforms it down again, so that there are, in fact, three transformations taking place in this experiment on the platform before you (Fig. 2). A vast district in London, extending from Regent's Park on the north to the Thames on the south, from the Law Courts on the east to Hyde Park on the west, has over 20,000 incandescent lamps scattered over it, all worked from the Grosvenor Gallery in Bond-street, by means of alternate-current transformers, which convert the 2,000 volts maintained between the street mains into 100 volts in the houses; and this London electric supply company have arranged for a vast extension of this system to be worked from Deptford.

In America alternate-current transformers are, due to the remarkable enterprise of Mr. Westinghouse, used to light 120,000 incandescent lamps in 68 towns; in fact, the electric lighting of a whole town from a central station begins to excite less astonishment than the electric lighting of a single house did ten years ago.

The efficiency of a well-made alternate-current transformer is very high, being no less than 96·2 per cent. when the transformer is doing its full work, and 89·5 per cent. when it is doing one-quarter of its full work, according to the experiments made by our students. It certainly does seem most remarkable, and it reflects the highest praise on the constructors of electrical machinery, that motor power can be converted into electrical power, electrical power at low pressure into electrical power at high pressure, or electrical power at high pressure into electrical power at low pressure; or, lastly, electrical power into motor power—in each case with an efficiency of 94 per cent.

As a further illustration of the commercial importance of this electric transformation I will show you some experiments on electric welding, one of the latest developments in electrical engineering. To weld a bar of iron one square inch in section requires a gigantic current of some 13,000 amperes. To convey this current even a few yards would be attended with a great waste of power, consequently while an enormous current is passed through the iron to be welded, only a comparatively small current is transmitted along the circuit from the dynamo to the welding apparatus. Mr. Fish, the representative of Prof. Elihu Thomson, of America, to whom this apparatus is due, will be so kind as to first show us the welding together of two bars of square tool steel, the edge of each bar being three-quarters of an inch, and the operation is, as you see, entirely completed in some 15 seconds. For this experiment an alternate current of 20 amperes will be produced by the dynamo at the other side of the Lower Bristol-road, and this current will be converted by the transformer on the platform into one of 9,000 amperes, large enough for 12,000 of those incandescent lamps if these were placed in parallel and the current divided among them. He will next try welding some thicker bars; and, lastly, he proposes welding together two pieces of aluminium, which it is extremely difficult, if not impossible, to weld in any other way. The bars, as you see, are in each case pressed together end on, and, in consequence of the electric resistance of the very small gap between the bars being much higher than that of the bars themselves, the current makes the ends of the bars plastic long before it even warms the whole bar, so that I can, as you see, take hold of the iron or steel two or three inches away from the weld without its feeling hot. The temperature of the weld can be adjusted with the most perfect nicety so as not to burn the steel, and the ends of the bars to be joined are softened to the centre, consequently a very good weld indeed can be made electrically by simple end pressure.

We have to thank Mr. Fish, not only for showing us the welding, but also for the very valuable assistance he has given us in supplying the electric power for the experiments on transformers and for the electric lighting for the outside of the Drill Hall. That "go-a-head" which is so characteristic a feature of his countrymen has been ever present in my mind while we have been working together during the last few days.

To Mr. Albion Snell, the representative of Messrs. Immisch and Co., we must also give our best thanks for so generously devoting some days of hard work to the arrangement of his high-voltage constant-current motors, used in driving the alternate-current machine and the small dynamos employed to magnetise the magnets of the former.

This ingenious telpher model, to which I shall refer later on, is Mr. Bourne's handiwork, and, considering that it has been hastily taken to pieces and hastily erected again, it is most creditable to him that it automatically blocks as well as it does. A watch, for example, is a very trustworthy piece of mechanism, but if one hurriedly took it all to pieces and hurriedly put it together again, one would not be surprised if it lost a little; indeed, if you or I did it, we should not be surprised if it refused to go at all, and were only right twice in twenty-four hours.

For the arangement of the smaller illustrations, and the careful execution of several of the diagrams, I have to thank Mr. Raine.

Did time allow I should like to describe to you to what perfection the system of economical distribution with accumulators—originally proposed by Sir William Thomson in 1881, and shown in its very simplest form in the wall diagram—has been brought by Mr. King, the engineer to the Electrical Power Storage Company; how the cells, when they are fully charged, are automatically disconnected from the charging circuit, and electrically connected with the discharging circuit; how the electric pressure on the discharging, or house mains, is automatically kept constant, so that the brightness of the lamps is unaffected by the number turned on, and how cells that are too energetic have their ardour automatically handicapped, and not allowed to give more current than is being supplied by the less active ones.

During the last few months fierce has been the battle raging among the electricians, the war cry being alternate-current transformers *versus* accumulators, while the lookers on, with that better view of the contest that they are proverbially said to possess, have decided that the battle is a drawn one. Neither system is the better under all circumstances; if the district to be lighted be a very scattered one use alternate-current transformers by all means, but if the houses to be lighted are clustered together at a distance from the supply of power then the storing property possessed by accumulators, which enables the power of electric power to far exceed the capacity of the dynamos and engines in the busiest part of the twenty-four hours, will win the battle for accumulators. Any direct-current system of distribution such as is furnished by accumulators has also the very great advantage that it lends itself to the use of the very efficient electro-motors which I have been using this evening. Alternate-current motors do exist, but they are still in the experimental stage, and are not yet articles of commerce.

Secondary batteries have caused much heartburning for their uses from the apparent fickleness of their complex chemical action, yet but imperfectly understood. But we have at length been taught what is good and what is bad treatment for them, and after years of brave persevering application on the part of the Electrical Power Storage Company, that forlorn hope, the secondary battery, has become one of the most useful tools of the electrical engineers; and secondary cells, some of which, thanks to the kindness of that company, I am using here to-night to supply power for lamps and motors, may now be trusted to have a vigorous long life. That company, I learn, undertake henceforth to keep their cells in order, when used for central station work, for 12½ per cent. per annum, and I understand that they have such confidence in them that they anticipate making no little money by incurring this insurance office responsibility. It is not, then, surprising that the Chelsea Supply Company have decided to use secondary batteries on a large scale for the economical distribution of light and power in their district.

Oliver Goldsmith said, more than 100 years ago, in his "Life of Richard Nash, Esq.:—"People of fashion at Bath . . . . when so disposed attend lectures on the arts and sciences, which are frequently taught in a pretty superficial manner, so as not to tease the understanding, while they afford the imagination some amusement." I want not to be superficial, yet I must not tease

V E Victoria Exciter.
S. A. Siemens Alternator.
M. T. Mordey Transformers.
V. L. Victoria Lamps (forty-five of 10 candle-power.

your understanding, and so we will not lose ourselves in technical details. If, however, my remarks have led you to appreciate the vast economical importance of using very large electric pressures, and to grasp that by substituting 2,000 volts for 50 volts when transmitting a certain amount of electric power the current can be reduced to the one-fortieth part, and the waste of power when transmitted along a given length of a given wire to the one-fortieth of the one-fortieth—that is, to the 1-1,600th part—your imagination will have been kindled as well as amused.

With a loss on the road of only 11 per cent. M. Deprez has, by using 6,000 volts, transmitted 52 horse-power over a distance of about 37 miles through a copper wire only one-fifth of an inch in dia-

Digitized by Google

meter (see *Electrician*, 27th August, 1886, p. 318). A piece of the actual conductor he employed I hold in my hand ; the copper wire is coated with an insulated material and then with a leaden tubing, so that the outside may be touched with perfect impunity, in spite of the high potential difference employed. M. Deprez's dynamo and motor were not nearly as efficient as he could make them now, so that his terminal losses were unnecessarily great, and the efficiency of the whole arrangement, wonderful as it was, not so startling as it would otherwise have been. I have told you that the loss in dynamo and motor has actually been reduced to only 12½ per cent., so that if a dynamo and motor of this efficiency had been used by M. Deprez the total loss in the whole transmission over thirty-seven miles would have been under 25 per cent. Indeed, by using only 1,250 volts, Mr. Brown has sueceeded in transmitting 50 horse-power supplied by falling water at Kriegstetten to Solothun in Switzerland, five miles away, with an entire loss in the dynamo, motor, and the five miles of going and returning wire of only 25 per cent., so that three-quarters of the total power supplied by the water at Kriegstetten were actually delivered to machinery at Solothun, five miles away.

In less than twenty years, then, from Gramme's practical realisation of Pacinotti's invention, we have power transmitted over considerable distances by electricity, with only a total loss of 25 per cent., whereas the combined loss in an air pump and air motor or in a water pump and water motor is 40 per cent., irrespective of the additional loss by friction or leakage that occurs *en route*. We cannot help feeling that we are rapidly arriving at a new era, and that it will not merely be for the inauguration of the quick transmission of our bodies by steam, or the quick transmission of our thoughts by telegraph, but for the economical transmission of power by electricity that the Victorian age will be remembered.

I showed you a little while ago an electric fire. Was that a mere toy, or had it any commercial importance ? To burn coal, to work dynamos, and to use the electric current to light your houses and your streets is clean and commercial ; to use the current to warm your rooms is clean but wasteful, on account of the inefficiency of the steam engine. But when the dynamos are turned by water power which would otherwise be wasted the electric current may be economically used, not merely to give light but also to give heat. And when the electric transmission of power becomes still more perfect than at present, even to burn coal at the pit's mouth where it is worth a shilling a ton may, in spite of the efficiency of the steam engine being only one.tenth, be the most economical way of warming distant towns where coal would cost 20s. a ton. Think what that would mean—no smoke, no dust, a reform effected commercially which the laws of the land on smoke prevention are powerless to bring about, a reform effected without the intervention of the State, and, therefore, dear to the hearts of Englishmen.

I am aware that this idea of burning coal at the pit's mouth and electrically transmitting its power has quite recently been stated to be commercially impracticable. But is that quite so certain, for in 1878 it was stated that, although telephones might do very well for America, they certainly would never be introduced into Great Britain, as we had plenty of boys who were willing to act as messengers for a few shillings a week ? The phonograph was also declared to be worked by a ventriloquist, and electric lighting on a large scale was proved to be too expensive a luxury to be ever carried out.

To-day the electric current is used for countless purposes ; not only is it used to weld, but by putting the electric arc inside a closed crucible smelting can be effected with a rapidity and ease quite unattainable with the ordinary method of putting the fire outside the crucible. If one had pointed out a few years ago that it was as depressing, scientifically, to put a fire outside a crucible when you wanted to warm the inside, as Joey Ladle, the cellarman, found it depressing, mentally, "to take in the wine through the pores of the skin, instead of by the convivial channel of the throttle," who would have believed that in 1888 a 500 horse-power dynamo would be actually employed to produce an electric arc inside a closed crucible in the manufacture of aluminium-bronze ? Putting a conservative drag on the wheels is a very good precaution to take when going down hill, but it is out of place in the up-hill work of progress.

But of all the many commercial uses to which the electric cuurent may be put, probably, after the electric light, electric traction has most public interest. The English are a commercial people, but they are also a humane people, and when, as in this case, their pockets and their feelings are alike touched, surely they will be radicals in welcoming electric traction whatever may be their political sentiments on other burning topics of the day. It is not a nice thing to feel that you are helping to reduce the life of a pair of poor tramway horses to three or four years ; it would be a very nice thing to be carried in a tramcar for even a less fare than at present. Now, while it costs 6d. or 7d. to run a car one mile with horses, it only costs 3d. or 4d. to propel it electrically. Indeed, from the very minute details that have recently been published of the four months' expenses of electrically propelling 30 cars at 7½ miles an hour along 12 miles tramway line in Richmond, Virginia, it would appear that the total cost, inclusive of coal, oil, water, engineers, firemen, electricians, mechanicians, dynamo and motor repairers, inspectors, linemen, cleaners, lighting, depreciation on engine, boiler, cars, dynamo, and line work, has been only 1½d. per car per mile. That is small enough at any rate, let us hope that it is true. This tramway is no doubt particularly favourable for propelling cars on the *parallel* system (that is, the system in which the current produced by the dynamo is the sum of the currents going through all the motors on the cars) without a great waste of power being produced by a very large current having to be sent a very long distance, because the tramway track is very curved, and the dynamo is placed at the centre of the curve with feeding wires to convey the current from the dynamo to all parts of the track. But even in the case of a straight tramway line with a dynamo only at one end, it is quite possible to obtain the same high econony in working by employing a *large* potential difference, and by sending a small current through all the trains in *series* instead of running the train in *parallel*, as is done on the Portrush, Blackpool, Brighton, and Bessbrook tramways.

This *series* system (see *The Electrician*, April 29, 1887, p. 549) of propelling electric trains was, oddly enough, entirely ignored in all the discussions that have taken place this year at the Institution of Civil Engineers and at the Institution of Mechanical Engineers regarding the relative cost of working tramways by horses, by a moving rope, and by electricity, and yet this series system is actually at work in America, as you will see from an instantaneous photograph, which I will now project on the screen, of a series electric tramway in Denver, Colorado ; and a series electric tramway 12 miles long, on which 40 cars are to be run, is in course of construction in Columbus, Ohio. The first track on which electric trams were run in *series* was the experimental "Telpher Line" erected in Glynde in 1883, under the superintendence of the late Prof. Fleeming Jenkin, Prof. Perry, and myself, for the automatic electric transport of goods. A photograph of this actual line

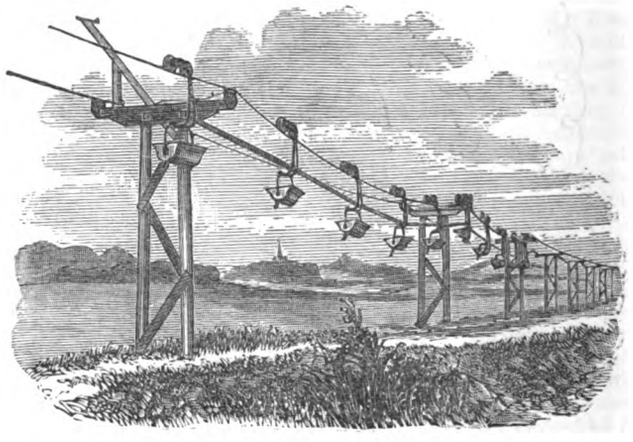

Fig. 3.

is now projected on the screen (Fig. 3). The large wall diagram shows symbolically, in the crudest form, our plan of series working. The current follows a zigzag path through the contact pieces, and when a train enters any section the contact-piece is automatically removed, and the current now passes through the motor on that train instead of through the contact-piece. The Series Electrical Traction Syndicate are now developing our idea, but it has received its greater development in the States, where the Americans are employing it instead of spending time proving, *à priori*, that the automatic contact arrangements could never work.

Mental inertia, like mechanical inertia, may be defined in two distinct ways. Inertia is the resistance to motion—that is the English definition ; but inertia is also the resistance to stopping—that is the American definition.

In addition to the small waste of power and consequent diminished cost of constructing the conductors that lead the current into and out of the passing trains, the series system has another very marked advantage. Some years ago we pointed out that when an electric train was running down hill, or when it was desirable to stop the train, there was no necessity to apply a brake and waste the energy of the moving train in friction, because the electric motor could, by turning a handle, be converted into a dynamo, and the train could be slowed or stopped by its energy being given up to all the other trains running on the same railway, so that the trains going down hill helped the trains going up hill, the stopping trains helped the moving trains. At that time we suggested detailed methods for carrying out this economical mutual aid arrangement, whether the trains were running on the parallel or on the

Digitized by Google

series system. But there is this difference, that whereas on the parallel system it is only when a train is running fairly fast that it can help other trains, the series system has the advantage that, when a motor is temporarily converted into a dynamo by the reversal of the connections of its stationary magnet, the slowing train can help all the other trains even to the very last rotation of its wheels. Brakes that save the power instead of wasting it are of purely English extraction, but their conception has recently come across the Atlantic with such a strong Yankee accent, that it might pass for having been born and bred in the States.

Economy is one feature which gives electric traction that right to claim your attention, safety is another. This model telpher line (see *Electrician*, February 19, 1886, p. 286), worked on "the post-head contact" system, is so arranged that no two trains ever run into one another, for in addition to each of the three trains being provided with an automatic governor which cuts off electric power from a train when that train is going too fast, the line is divided into five sections, connected together electrically in such a way that as long as a train is on any Section A no power is provided to the Section B behind, so that if a train comes into Section B it cannot move on as long as the train in front is on Section A (three trains shown running on a model telpher line with four automatic locks). Whenever a train—it may be even a runaway electric locomotive—enters a blocked section it finds all motive power withdrawn from it quite independently of the action of signalmen, guard, or engine driver, even if either of the latter two men accompanied the train, which they do not in the case of telpherage; no fog, nor colour blindness, nor different codes of signals on different lines, nor mistakes arising from the exhausted nervous condition of overworked signalmen can with our system produce a collision. Human fallibility, in fact, is eliminated. While the ordinary system of blocking means merely given an order to stop, and whether this is understood or intelligently carried out, is only settled by the happening or non-happening of a subsequent collision, our automatic block acts as if the steam were automatically cut off; nay, it does more than this, it acts as if the fires were put out in an ordinary locomotive, and all the coal taken away, since it is quite out of the power of the engine driver to restart the electric train until the one in front is at a safe distance ahead.

The photograph now seen on the screen shows the general appearance of the Glynde line, which has recently been much extended in length by its owners, the Sussex Portland Cement Company, and a telpher line, with automatic blocking on the broad principles I have described, is about to be constructed between the East Pool tin mine in Cornwall and the stamps. There will be four trains running, each consisting of 33 skeps containing 3cwt. each, so that the load carried by each train will be about five tons.

It may be interesting to mention that the last difficulty in telpherage, which consisted in getting a proper adhesion between the driving wheels of the locomotive and the wire rope has now been overcome. The history of telpher locomotives is the history of steam locomotives over again, except that we never tried to fit the electric locomotives with legs, as was proposed in the early days for steam locomotives. It is a tedious discouraging history, but it is so easy to be wise when criticising the past, so difficult to be wise when prospecting the future. Gripping wheels of all kinds, even the India-rubber tyres used for the last three years, have all been abandoned in favour of simple slightly loose cheap iron tyres, which wear for a very long time and give a very perfect grip when the bar supporting the electro-motor is so pivoted pendulum-wise to the framework of the locomotive that the weight of the motor no longer makes the locomotive jump in passing the posts, as it did until quite recently. . . .

After several years of experimenting we have in telpherage, I venture to think, at last a perfectly trustworthy and at the same time a most economical method of utilising distant steam or water-power to automatically transport our goods, and in time it may even be our people, over hills and valleys without roads or bridges, and without interfering with the crops or the cattle, or the uses to which the land may be put over which the telpher trains pursue heir snakelike way. We have, in fact, the luxury of ballooning ithout its dangers.

The Gadot Accumulator.—The Gadot accumulator has undergone several important modifications lately; the proportion of active material has been increased to 54 per cent. of the total weight of the plate, and an output of 21·75 ampere-hours per kilogramme of plate has been attained. Owing to the system of double plates adopted by M. Gadot, it is asserted that these improvements have not been obtained at the expense of durability. The plates are 45mm. in thickness, and the discharge takes place at the rate of 1·5 amperes per kilogramme of plate.

A SIMPLE HYPOTHESIS FOR ELECTRO-MAGNETIC INDUCTION OF INCOMPLETE CIRCUITS; WITH CONSEQUENT EQUATIONS OF ELECTRIC MOTION IN FIXED HOMOGENEOUS OR HETEROGENEOUS SOLID MATTER.*

BY SIR WILLIAM THOMSON.

1. To avoid mathematical formulas till needed for calculation consider three cases of liquid† motion, which for brevity I call Primary, Secondary, Tertiary, defined as follows:—Half the velocity in the Secondary agrees numerically and directionally with the magnitude and axis of the molecular spin at the corresponding point of the Primary; or (short, but complete, statement) *half the velocity in the Secondary is the spin in the Primary, and (similarly) half the velocity in the Tertiary is the spin in the Secondary.*

2. In the Secondary and Tertiary the motion is essentially without change of density, and in each of them we naturally, therefore, take an incompressible fluid as the substance. The motion in the Primary we arbitrarily restrict by taking its fluid also as incompressible.

3. Helmholtz first solved the problem—Given the spin in any case of liquid motion, to find the motion. His solution consists in finding the potentials of three ideal distributions of gravitational matter having densities respectively equal to $1/4\pi$ of the rectangular components of the given spin; and, regarding for a moment these potentials as rectangular components of velocity in a case of liquid motion, taking the spin in this motion as the velocity in the required motion. Applying this solution to find the velocity in our Secondary from the velocity in our Tertiary, we see that the three velocity-components in our Primary are the potentials of three ideal distributions of gravitational matter having their densities respectively equal to $1/4\pi$ of the three velocity-components of our Tertiary. This proposition is proved in a moment,‡ in § 5 below, by expressing the velocity-components of our Tertiary in terms of those of our Secondary, and those of our Secondary in terms of those of our Primary; and then eliminating the velocity-components of Secondary, so as to have those of Tertiary directly in terms of those of Primary.

4. Consider now, in a fixed solid or solids of no magnetic susceptibility, any case of electric motion in which there is no change of electrification, and therefore no incomplete electric circuit, or, which is the same, any case of electric motion in which the distribution of electric current agrees with the distribution of velocity in a case of liquid motion. Let this case, with velocity of liquid numerically equal to 4π times the electric current density be our Tertiary. The velocity in our corresponding Secondary is then the magnetic force of the electric current system;§ and the velocity in our Primary is what Maxwell‖ has well called the "electro-magnetic momentum at any point" of the electric current system; and the rate of decrease per unit of time of any component of this last velocity at any point is the corresponding component of electromotive force, due to electro-magnetic induction of the electric current system when it experiences any change. This electromotive force, combined with the electrostatic force, if there is any, constitutes the whole electromotive force at any point of the system. Hence by Ohm's law each component of electric current at any point is equal to the electric conductivity multiplied into the sum of the corresponding component of electrostatic force and the rate of decrease per unit of time of the corresponding component of velocity of liquid in our Primary.

5. To express all this in symbols, let (u_1, v_1, w_1), (u_2, v_2, w_2), and (u_3, v_3, w_3) denote rectangular components of the velocity at time t, and point (x, y, z) of our Primary, Secondary, and

* Paper read before the British Association at Bath, in Section A (Mathematical and Physical Science), September, 1888.

† I use "liquid" for brevity to signify incompressible fluid.

‡ From Poisson's well-known elementary theorem, $\Delta^2 V = -4\pi\rho$.

§ "Electrostatics and Magnetism," § 517 (Postscript) (*c*).

‖ "Electricity and Magnetism," §§ 604, 585.

Digitized by Google

Tertiary. We have (§ 1)—

$$u_2=\frac{dw_1}{dy}-\frac{dv_1}{dz},\quad v_2=\frac{du_1}{dz}-\frac{dw_1}{dx},\quad w_2=\frac{dv_1}{dx}-\frac{du_1}{dy}\ .\ (1)$$

$$u_3=\frac{dw_2}{dy}-\frac{dv_2}{dz},\quad v_3=\frac{du_3}{dz}-\frac{dw_2}{dx},\quad w_3=\frac{dv_2}{dx}-\frac{du_2}{dy}\ .\ (2)$$

Eliminating u_2, v_2, w_2 from (2) by (1), we find—

$$u_3=\frac{d}{dx}\left(\frac{du_1}{dx}+\frac{dv_1}{dy}+\frac{dw_1}{dz}\right)-\left(\frac{d^2u_1}{dx^2}+\frac{d^2u_1}{dy^2}+\frac{d^2u_1}{dz^2}\right);\ \&c.\ .\ .\ (3)$$

But, by our assumption (§2) of incompressibility in the Primary

$$\frac{du_1}{dx}+\frac{dv_1}{dy}+\frac{dw_1}{dz}=0\ .\ .\ .\ .\ .\ (4)$$

Hence (3) becomes—

$$u_3=-\nabla^2u_1,\ v_3=-\nabla^2v_1,\ w_3=-\nabla^2w_1\ .\ .\ (5)$$

where, as in Article XXVII. (November, 1846) of my "Collected Papers" (Vol. I.)—

$$\nabla^2=\frac{d^2}{dx^2}+\frac{dy^2}{d^2}+\frac{d^2}{dz^2}\ .\ .\ .\ .\ .\ (6)*$$

This (5) is the promised proof of § 3.

6. Let now u, v, w denote the components of electric current at (x, y, z) in the electric system of § 4; so that—

$$4\pi u=u_3=-\nabla^2u_1;\ 4\pi v=v_3=-\nabla^2v_1;$$
$$4\pi w=w_3=-\nabla^2w_1;\ .\ .\ .\ .\ .\ (7)$$

which, in virtue of (4), give—

$$\frac{du}{dx}+\frac{dv}{dy}+\frac{dw}{dz}=0\ .\ .\ .\ .\ .\ (8)$$

Hence the components of electromotive force due to change of current, being (§ 5)—

$$-\frac{du_3}{dt},\quad -\frac{dv_3}{dt},\quad -\frac{dw_3}{dt},$$

are equal to—

$$4\pi\nabla^{-2}\frac{du}{dt},\quad 4\pi\nabla^{-2}\frac{dv}{dt},\quad 4\pi\nabla^{-2}\frac{dw}{dt};\ .\ .\ (9)$$

and therefore if Ψ denote electrostatic potential, we have, for the equations of the electric motion (§ 5)—

$$u=\frac{1}{\kappa}\left(\nabla^{-2}\frac{du}{dt}-\frac{d\Psi}{dx}\right);\quad v=\frac{1}{\kappa}\left(\nabla^{-2}\frac{dv}{dt}-\frac{d\Psi}{dy}\right);$$
$$w=\frac{1}{\kappa}\left(\nabla^{-2}\frac{dw}{dt}-\frac{d\Psi}{dz}\right)\ .\ .\ .\ (10)$$

where κ denotes $1/4\pi$ of the specific resistance.

7. As Ψ is independent of t, according to § 4, we may conveniently for a moment put—

$$u+\frac{d\Psi}{\kappa\,dx}=\alpha;\ v+\frac{d\Psi}{\kappa\,dy}=\beta;\ w+\frac{d\Psi}{\kappa\,dz}=\gamma\ .\ (11)$$

and so find as equivalents to (10)—

$$\frac{d\alpha}{dt}=\nabla^2(\kappa\alpha);\ \frac{d\beta}{dt}=\nabla^2(\kappa\beta);\ \frac{d\gamma}{dt}=\nabla^2(\kappa\gamma);\ (12)$$

The interpretation of this elimination of Ψ may be illustrated by considering for example a finite portion of *homogeneous* solid conductor of any shape (a long thin wire with two ends, or a short thick wire, or a solid globe, or a lump of any shape, of copper or other metal homogeneous throughout), with a constant flow of electricity maintained through it by electrodes from a voltaic battery or other source of electric energy, and with proper appliances over its whole boundary, so regulated as to keep any given constant potential at every point of the boundary; while currents are caused to circulate through the interior by changing currents in circuits external to it. There being no *changing electrification* by our supposition of § 4, Ψ can have no contribution from electrification within our conductor; and therefore throughout our field—

$$\nabla^2\Psi=0\ .\ .\ .\ .\ .\ .\ .\ (13)$$

which, with (8) and (11), gives—

$$\frac{d\alpha}{dx}+\frac{d\beta}{dy}+\frac{d\gamma}{dz}=0\ .\ .\ .\ .\ .\ .\ (14)$$

Between (12) and (14) we have four equations for three unknown quantities. These, *in the case of homogeneousness* (κ constant), are equivalent to only three, because in this case (14) follows from (12), provided (14) is satisfied initially and proper surface condition is maintained to prevent any violation of it from supervening. But unless κ is constant throughout our field, the four equations (12) and (14) are mutually inconsistent; from which it follows that our supposition of unchangingness of electrification (§ 4) is not generally true. An interesting and important practical conclusion is that when currents are induced in any way in a solid composed of parts having different electric conductivities (pieces of copper and lead, for example, fixed together in metallic contact), there must in general be changing electrification over any interface between these parts. This conclusion was not at first obvious to me; but it ought to be so by anyone approaching the subject with mind undisturbed by mathematical formulas.

8. Being thus warned off heterogeneousness until we come to consider changing electrification and incomplete circuits, let us apply (10) to an infinite homogeneous solid. As (8) holds through all space according to our supposition in § 4, and as κ is constant, (13) must now hold through all space, and therefore $\Psi=0$, which reduces (10) to—

$$u=\frac{1}{\kappa}\nabla^{-2}\frac{du}{dt}\quad v=\frac{1}{\kappa}\nabla^{-2}\frac{dv}{dt}\quad w=\frac{1}{\kappa}\nabla^{-2}\frac{dw}{dt}.\ (15)$$

These equations express simply the known law of *electromagnetic* induction as we have it, and all we know about it from direct experiment. Maxwell's equations (7) of § 783 of his "Electricity and Magnetism" become in this case—

$$\mu\left(4\pi C+K\frac{d}{dt}\right)\frac{du}{dt}=\nabla^2u,\ \&c.\ .\ (15')$$

which cannot be right, I think (???), according to any conceivable hypothesis regarding electric conductivity, whether of metals, or stones, or gums, or resins, or wax, or shellac, or gutta percha, or India-rubber, or glasses, or solid or liquid electrolytes; being, as seems (?) to me, vitiated for complete circuits, by the curious and ingenious, but, as seems to me, not wholly tenable, hypothesis which he introduces, in § 610, for incomplete circuits.

9. The hypothesis which I suggest for incomplete circuits and consequently varying electrification, is simply that the components of the electromotive due to electro-magnetic induction are still $4\pi\nabla^{-2}du/dt$, &c. Thus for the equations of motion we have simply to keep equations (10) unchanged, while not imposing (8), but instead of it taking—

$$\text{"}v\text{"}^2\left(\frac{du}{dx}+\frac{dv}{dy}+\frac{dw}{dz}\right)=\frac{d}{dt}\nabla^2\Psi.\ .\ .\ .\ (16)$$

where "v" denotes the number of electrostatic units in the electro-magnetic unit of electric quantity. This equation expresses that the electrification of which Ψ is the potential increases and diminishes in any place according as electricity flows more out than in, or more in than out. We thus have four equations (10) and (16) for our four unknowns, u, v, w, Ψ; and I find simple and natural solutions with nothing vague, or difficult to understand, or to believe when understood, by their application to practical problems, or to conceivable ideal problems; such as the transmission of ordinary or telephonic signals along submarine telegraph conductors and land-lines, electric oscillations in a finite insulated conductor of any form, transference of electricity through an infinite solid, &c. This, however, does not prove my hypothesis. Experiment is required for informing us as to the real electro-magnetic effects of incomplete circuits, and as Helmholtz has remarked, it is not easy to imagine any kind of experiment which could decide between different hypotheses which may occur to anyone trying to evolve out of his inner consciousness a theory of the mutual force and induction between incomplete circuits.

* Maxwell, for quaternionic reasons, takes ∇^2 the negative of mine.

ON THE IMPEDANCE OF CONDUCTORS TO LEYDEN JAR DISCHARGES.*

BY DR. OLIVER LODGE.

Among other experiments which I made in connection with lightning conductors were some on what I call "the alternative path." These gave some surprising results, showing that iron and copper acted equally well as conductors, and that sometimes the iron was better than copper; also that thickness of conductor and ordinary conductivity mattered very little.

Since then I have more completely applied the theories of Clerk-Maxwell and Lord Rayleigh concerning the impedance of conductors to very high frequencies of alternation, and have been able to arrive at a complete understanding of all, or nearly all, the alternative path results. I bring forward these experiments, therefore, as a verification of Lord Rayleigh's modification of Maxwell for extremely high frequencies.

Impedance being defined as

$$\sqrt{R'^2+p^2L'^2} \quad \frac{I}{pL'} \quad R'$$

Rayleigh develops an expression of Maxwell's for E.M.F. into expressions for R′ and L′, which take the form, when p is infinitely great,

$$R' = \sqrt{\tfrac{1}{2} p l \mu_0 R}$$

$$L' = L + \frac{R'}{p},$$

these being the limits of a Bessel function series; where L refers only to the medium outside the substance of the wire, and μ_0 is the magnetic permeability of the material of the wire, l being its length.

Wherefore, $$I = \sqrt{(pL+R')^2+R'^2}.$$

$$= pL\sqrt{1+\frac{2m}{\sqrt{p}}+\frac{2m^2}{p}},$$

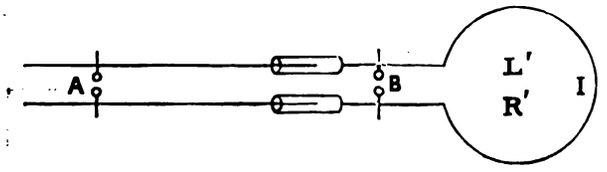
where $$m = \frac{\sqrt{\frac{1}{2} l \mu_0 R}}{L}.$$

L depends on the size and shape of the conductor but not at all on its material, and it only depends slightly on its thickness; m depends on the conducting substance, and increases with both μ and R. R is the ordinary resistance of the wire.

At very high frequencies the first term of those under the root in the expression for I alone matters, and therefore all substances which conduct at all behave in the same way. At less frequencies the terms involving R and μ begin to be of importance.

All this is borne out by the experiments, and the theoretical impedance is found to be very nearly proportional to the observed difference of potential needed to drive a given charge through any given conductor.

The experiment is conducted thus:—



Two jars are arranged to be charged and discharged at A. The circuit is completed either by an air gap at B, or by the conductor to be experimented on. The conductor is arranged in the form of a circle and connects the B knobs so as to afford an alternative path. The experiment consists in adjusting the B knobs until the spark jumps the air jet just about as often as it misses and chooses the conductor, the size of the jars, the length of the A spark, and the position of A on the two wires connected to the inner coatings being the things varied in successive series experiments. A whole lot of circular conductors, I, are tried one after the other with each adjustment.

* Paper read before the British Association Meeting (Section A) at Bath, September, 1888.

The length of spark B measures the E.M.F. needed to effect discharge through the conductor.

This is found proportional to the theoretical impedance for

No. 2 Iron,	No. 5 Copper,	No. 2 Brass,
No. 18 Iron,	No. 18 Copper,	No. 24 Brass,
No. 25 Iron,	No. 23 Copper,	
	No. 40 Copper,	

with frequencies varying in different experiments from 12 million vibrations per second to a quarter million vibrations per second.

The current amplitude during the discharge was 3,000 amperes, sometimes more, sometimes less.

The impedance of a conductor 2½ metres long bent into a circle was

180 ohms for thick wire, No. 2 } at 12 millions per
300 ohms „ thin „ „ 40 } second,

the ordinary resistance being ·004 ohms and 2·6 ohms respectively.

43 ohms for thick ..... } at 3 millions.
78 ohms „ thin..... }

At a quarter million vibrations the material just begins to matter, and iron has a trace more impedance than copper; but even now they are practically equal, being about 4 ohms for thick and 6 ohms for extremely thin wire.

These are the results of the latest experiments. In some of the older experiments iron came out distinctly better than copper—even thin iron better than thick copper.

Theory does not, so far as I see, throw any light upon this, and I am going to repeat those experiments in something like their original form, so as either to confirm or to modify these few anomalous results.

The main point established is that for frequencies comparable to a million per second, such frequencies as occur in jar discharges and probably in lightning, the impedance of all reasonably-conducting materials is the same, both by theory and by experiment, independently of their magnetic properties as well as of their conductivity; and that even the sectional area of a conductor only affects its impedance in a minor degree, so that a change to $\frac{1}{1000}$ the area scarcely doubles the impedance.

MEASUREMENT OF ELECTRO-MAGNETIC WAVE LENGTH.*

BY PROF. OLIVER J. LODGE, F.R.S.

When returning thanks for the reception of his address yesterday morning, our President thought fit to disclaim too much share in the suggestion of an oscillatory Leyden jar circuit as a practicable source of radiation of moderate wave length. But such a disclaimer he must not be allowed to make. He mentioned as coming before himself the names of Feddersen and other German experimenters on these alternations. But to them belongs not this credit, but another. What they accomplished was the experimental verification of the existence and the counting of the frequency of these already predicted oscillations. Prior credit must therefore be put further back. As is very well known, Helmholtz in 1847 suggested that a Leyden jar discharge must be oscillatory in a circuit of small dissipation, and Sir William Thomson in 1858 calculated out the whole details of the process and gave its equation; an equation which, though we now write it down glibly enough, was at that date unintelligible and difficult of comprehension to all but a very few—perhaps to all without exception—not the mere equation, of course, but the coefficient A which it contained, the electro-dynamic capacity of the discharger, or, as we now call it, the self-induction or inductance of the circuit. Every important detail of this prediction has now been verified by the labours of the German experimenters, Feddersen, Schiller and others. But any idea that radiation was propagated through the ether by such oscillations I am sure had never occurred to them. I remember the history of

* Paper read before the British Association meeting (Section A) at Bath, September, 1888.

Digitized by Google

the thing pretty well, because I had been thinking much myself on the direction of how directly to manufacture light, *i.e.*, how to construct an electrical oscillator of a given and sufficient frequency. In fact, a year or so before the Southport meeting I suggested to this section a plan whereby I fancied it might be done. That particular plan I saw soon afterwards to be incapable of working, and the suggestion has therefore no merit. But it made me able to clearly appreciate the suggestion, or rather the certainty, which was expressed by Prof. Fitzgerald at Southport, that the oscillations in a discharging Leyden jar circuit were just the things that would be practicable, and which would generate light of some measurable, though no doubt still considerable, wave length.

More recently Lord Rayleigh showed at a Friday evening discourse in the Royal Institution some remarkably beautiful interference experiments in sound, whereby inaudible sound waves could be detected, measured, converged, and, in fact, treated in just the same manner as one is accustomed to treat light waves.

Putting the two things together, I was hopeful of being able to attack the problem experimentally and to prove the existence of radiation with measurable wave lengths from a Leyden jar circuit by interference experiments conducted after the model of Lord Rayleigh's. Meanwhile I happened to be experimenting on lightning conductors, and somewhat to my surprise, as an outcome from those experiments, I hit on an arrangement which, without any thought or scheming at all, gave me evidence of the very waves I had been thinking so much about, and enabled me to measure their lengths, though not in a previously planned-out way. I described these experiments quite hastily and briefly in the midst of other matter, in a lecture to the Society of Arts last March on lightning conductors, as "the experiment of the recoil kick."

I continued the experiments after the lecture, and proved the existence of ether waves of various lengths, the shortest wave that I obtained distinct evidence of being three yards. I intended to describe those experiments at this meeting with a reference to the Southport suggestion of Prof. Fitzgerald, quite unknowing at the time that we should have the pleasure of seeing him in the chair. However, when going away from Liverpool on a holiday I read in the train the July number of Wiedemann's *Annalen*, and there found that Dr. Hertz had obtained much better and more striking evidence of these electro-magnetic waves, and had measured their length by an interference experiment exactly like one of those used by Lord Rayleigh for sound.

I hasten to acknowledge the superiority of Hertz's method of demonstration to my own; and so far as evidence of the waves is concerned a description of my experiments is now superfluous. Nevertheless, the mode of propagation of the pulses and their mode of reflection is different in my experiments from what they are in those of Hertz, and although mine is not so good a method, yet it may have some interest as confirming the view taught us by Poynting and others concerning the mode of propagation of energy through the ether, and the theory of Kirchhoff and Heaviside concerning the rate of transmission of signals by a telegraph wire.

The theory of the experiment is given in my Paper in the August number of the *Philosophical Magazine*.

The velocity of a pulse along a wire is $\frac{1}{\sqrt{l_1 s_1}}$,

where $l_1 = 4\mu \log \frac{b}{a} + \frac{r_1}{\mu}$, and where $r_1 = \sqrt{\frac{1}{2} p \mu_0 \mathrm{K}_1}$

$$s_1 = \frac{\mathrm{K}}{4 \log \frac{a}{b}}.$$

So velocity of pulse along a wire $= \frac{1}{\sqrt{\mu \mathrm{K}}}$, the same as in free space.

Now take an oscillatory Leyden jar circuit and apply Thomson's theory to it.

$$p = \frac{1}{\sqrt{\mathrm{L S}}}$$

Now, if this circuit emits waves of velocity V, their length in free space is $\lambda = \frac{2\pi \mathrm{V}}{p} = 2\pi \sqrt{\frac{\mathrm{L}}{\mu} \frac{\mathrm{S}}{\mathrm{K}}}$.

Along two parallel wires they go at the same pace, and therefore have the same length. Hence combine the two things, (Fig. 2), and we have waves of known length propagated along the wires.

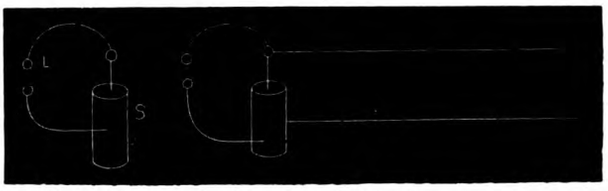


Fig. 1.

Fig. 2.

Now take the wires of infinite length. At the free ends we shall have reflexions, a sort of recoil or kick evidenced by a brush discharge or spitting off from the ends of the wire, and in the dark the far ends of the wires glow. Supply these with knobs, and we get surprisingly long sparks.*

When may we expect to get the longest sparks? When the period of oscillation of the circuit and of the appendages to it are the same. This will be when the length of each wire is half a wave length, or some multiple of half a wave length. The two will then vibrate together like a resonant column.

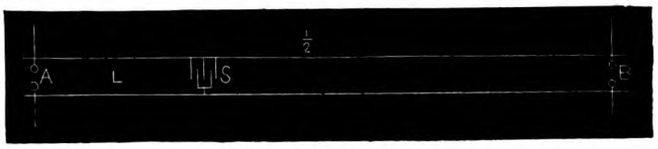

Fig. 3.

My experiment consisted, then, in so varying the current or the resonant wire that the recoil kick is a maximum.

The results of varying L are shown by some such curves as this, where horizontal distance represents distance of A knots from jars, and where vertical ordinates represent length of B spark (Fig. 4), and are such as entirely to confirm the theory so far as the accuracy of the experiments go.

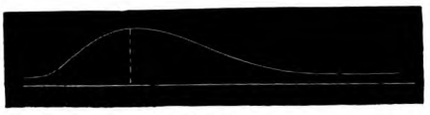

Fig. 4.

It is much easier to get good measurements with fairly big condensers, and therefore long waves, else the energy is not sufficient to give very marked results. With very long wires arranged out of doors on a dark night I hope to get evidence of modes by the periodic glow.

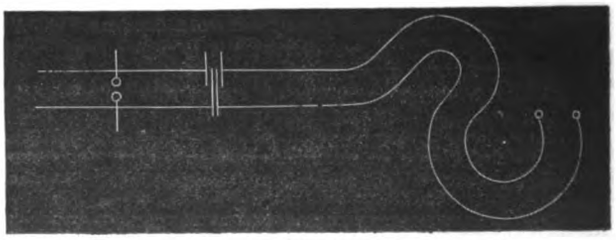

Fig. 5.

The experiments with shorter waves were made with an adjustable tube condenser, various lengths of which could be used (Fig. 5); and on the shortest waves with a mere coated disc condenser the size of a penny.

* For instance, A = 4·4; B = 15. (Fig. 3.)

Digitized by Google

To get frequencies of the rapidity of visible light the linear dimensions of the circuit must be something comparable to 10^{-6}, and so electric oscillations in atoms will give rise to ultra violet rays.

[ABSTRACT.]

The author has been endeavouring to manufacture light by direct electric action without the intervention of heat, utilising for the purpose Maxwell's theory that light is really an electric disturbance or vibration. The means adopted is the oscillatory discharge of a Leyden jar, whose rate of vibration has been made as high as 1,000 million complete vibrations per second. The waves so obtained are about three yards long, and are essentially light in every particular except that they are unable to affect the retina. To do this they must be shortened to the hundred-thousandth of an inch. All that has yet been accomplished, therefore, is the artificial production of direct electrical radiation, differing in no respect from the waves of light except in the one matter of length. The electrical waves travel through space with the same speed as light, and are refracted and absorbed by material substances according to the same laws. It only wants to be able to generate waves of any desired length in order to entirely revolutionise our present best systems of obtaining artificial light by help of steam engines and dynamos, which is a most wasteful and empirical process.

THE MEETING OF THE BRITISH ASSOCIATION.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *September 1st*, 1888.

The well-known superiority of wrought iron over cast iron for the cores of magnets of dynamos has led to their almost general adoption, but the yoke pieces connecting the limbs are still usually made of cast iron, its bulk being increased to make up for the lack of magnetic permeability as compared with wrought iron. There is evidently more or less of a magnetic resistance introduced into the circuit by the presence of a joint between the wrought and the cast iron ; and, indeed, unless they are carefully surfaced there is apt to be considerable of this resistance. In order to overcome this difficulty the Baxter motor, which has been recently modified, is now made with a perfect weld or joint between the wrought iron of the core and the cast iron of the pole-piece. We are not informed as to the exact manner in which this process is accomplished, but it points to the recognition of a difficulty which is sometimes the cause of poor performance in a machine.

By the reports from all quarters, the utmost activity prevails in electric railway circles, and new roads are reported as being contracted for in all parts of the country. I have already reported to you that Boston and Cleveland are to have electric roads, and it now seems likely that the fine city of Minneapolis will also have one. Omaha is to have a road two miles long, and new roads have just gone into operation at Framingham, Mass. ; Dayton, O. ; and Merriden, Ct. Active measures for the installation of roads are being taken at Kansas City, Brockton, Mass.; Seattle, Washington Territory ; Bangor, Maine ; Scranton, Pa. ; North Adams, Mass. ; Danvers, Mass. ; Desmoines, Iowa ; Davenport, Iowa ; Columbus, Ind. ; Springfield, Mo. ; and St. Joseph, Mo. ; and several other places. All the roads now in operation are reported to be doing a very large business, and are increasing at such a rate that they would keep the companies fairly busy, even if there were no new lines to construct. As it is, it looks as though there were more activity almost to-day in electric railway circles than in electric lighting, and yet in the latter department the growth is something tremendous.

With regard to stationary motors, the same progressive state of affairs may be reported, and the demand, if anything, exceeds the supply. It is reported, for example, that in this city alone there are over 300 "C. and C." motors running. This handy little motor has already been described in your columns, and I am not surprised to find it so popular. These

Digitized by Google

300 motors are distributed in nearly 120 different installations, and range in size from ⅛ horse-power up to 5 horse-power.

As might be expected, the recent experiments of killing dogs by continuous and alternating currents have revived the discussion on the desirability and feasibility of conducting executions by electricity. The law requiring such executions comes into effect on the 1st of January next; but up to the present no definite plan or arrangement seems to have been selected by the authorities for the purpose. The question which is now agitating the public and the press is whether electrical executions can be carried out without mutilating the objects of them. It is quite clear that although the public may be willing to approve of electrical executions, provided they are instantaneous and do not mutilate the criminal, there would be a great howl of indignation if it should be found that the body was burnt or injured.

A very interesting meeting has been held during the past week at Chicago of the United States Military Telegraph Corps and of the Old Timers' Association. These two bodies comprise in their membership a large number of the pioneer telegraphers in this country, including such men as Mr. James D. Reid, who was an intimate friend of Prof. Morse, and also has the distinction of being the first telegraph superintendent in the world. Mr. Reid is a well-preserved Scotchman, who, instead of making place for the young men, as he well might be excused for doing, is the soul and life of all gatherings in which he takes part, contributing speech or song as the occasion may need. It is an interesting fact that Andrew Carnegie, our great millionaire ironmaster, with his magnificent residences in this country and his castles in Scotland, was at one time Mr. Reid's messenger boy in Pittsburg. There are a great many other men with a history in these two associations, and when they get together you may depend upon it that the reminiscences of old times that are exchanged are of the most interesting character. Most of the Old Timers are members of the Military Corps, which is composed of men, many of them now of prominence and influence in this country, who served as operators during the Civil War. While our great national struggle was in progress, there were 15,000 miles of wire in use by the Union Army for military operations, and over 13,000,000 messages were sent. About 1,200 operators were employed, of which number nearly 300 were killed or wounded, or captured on the field of battle, or were lost, and now lie buried in nameless graves in the far South. The Military Telegraph Corps has received glowing tributes as to the value of its services from Generals Grant, Sherman, Sheridan, and others, and it now awaits from Congress a substantial recognition, which it fully deserves. The body has been striving to obtain for the old war operators some provision for pensions, and it is hoped that in an instance like this where the pensions have been so thoroughly earned, Congress will soon do justice. Of course, a number of the men are, as I have said, in good positions of life, many of them being at the front in telegraphic and electrical matters, but there are others to whom a little pecuniary help would be a great boon, and this it is that the corps seeks to obtain for them. The meeting at Chicago last week was of a very enjoyable nature, and the reception which was given to these veterans in the electrical field by the citizens of Chicago showed that their services had not been forgotten.

A noteworthy shipment of apparatus to South America has recently been made by the Ball Electric Light Company of this city. The plant is intended for the city of Quezaltenango, in the State of Guatemala, and the remarkable feature about it is that the place to which it is to be transported is 90 miles distant from either railroad or water communication. The weight of the plant is put at about 70,000 pounds, and the various pieces will have to be carried by a large number of natives by paths running across precipitous mountains at heights of 8,000ft. Fortunately, engines will not be required to run this plant, as the cost of transportation would in that event have been materially added to, and it is doubtful whether fuel could have been obtained cheaply. There is, however, an ample water supply, and this will be utilised to drive the dynamos. There are now a large number of electric light plants from this country scattered all over Central and South America, and from the fact that special efforts have been made in that line of export lately it seems likely that the number will be very largely increased. Another example of this is found in the plant of 100 arc lights which the Thomson-Houston Company has just sold for San José, the capital of Costa Rica, also, like Guatemala, a Central American station.

Note was made not long since by the papers of the use of artesian-well power at St. Augustine, Fla., to drive some of the dynamos there of the Edison plant, in the Ponce de Leon Hotel. This was looked upon as a unique installation, but attention is now called to another plant of similar character at Yankton, Dakota. There the United States dynamos of the Yankton Electric Company are driven by a well. It is one hundred feet deep. The water comes up through a 6in. casing, passes into an old boiler which catches the stones and *débris* sometimes shot up by the well, and then passes by a pipe to a 12in. turbine with a fall of 30ft. The turbine is controlled automatically by an electric governor. The pressure in the boiler is 71b. under full head, and 57lb. to the square inch when the well is closed. So successful has the plant proved that the present 30 horse-power is inadequate to meet the demand for lights, and a second well is to be sunk.

NOTES FROM PARIS.

(FROM OUR OWN CORRESPONDENT.)

September 11th, 1888.

The experiments on the electrical tramway I spoke of in my last letter have been successful, and the line will be open to the public by the 15th inst. The employment of accumulators is every day becoming more general in electric light installations, and the three firms who manufacture them in this country are unable to meet their orders. The Société pour le Travail Electrique des Métaux, which manufactures the Laurent-Cély accumulator, are about to open their works at St. Ouen, close to Paris, where the manufacture of these accumulators will be carried out on a very large scale. Accumulators are not only employed in the lighting of theatres, but it is proposed to erect an important public lighting station based on working accumulators in series. The Gadot accumulator also has undergone several important modifications lately; the proportion of active material has been increased to 54 per cent. of the total weight of the plate, and an output of 21·75 ampere-hours per kilogramme of plate has been attained. Owing to the system of double plates adopted by M. Gadot, it is asserted that these improvements have not been obtained at the expense of durability. The plates are 45mm. in thickness, and the discharge takes place at the rate of 1·5 ampere per kilogramme of plate. The recent improvements made in their manufacture have greatly increased their efficiency and durability, and the time is certainly not far off when accumulators will be sold with the same guarantees as other electrical machinery.

Tenders will in a very short time be received for the municipal electric lighting station at the Halles Centrales. There will be separate tenders for electricity and motive power, the total expenditure amounting to one million of francs:—Works and motive power, 565,000fr.; electric machinery, 192,000fr.; wiring, 221,300fr.; sundries, 21,700fr. The lighting of the Halles will only absorb 512 incandescent lamps and 168 arc lamps; the remainder of the plant, as I have mentioned before, will be devoted to private lighting. Part of the lighting will be done with 115-volt compound-wound dynamos, and part with transformers and 2,000-volt alternating dynamos.

Private installations in this city are rather numerous, the motive power being either steam or gas, and their number increases daily in view of the impossibility of foreseeing the time when central stations will be at work. The new printing works, Imprimerie de la Presse, Rue du Croissant, are lit with 500 incandescent lamps, and the works on the other side of the same street, in which about twenty papers are daily printed, will soon be lighted with 2,000 incandescent, and some twenty arc lamps.

NOTES FROM VIENNA.

(FROM OUR CORRESPONDENT.)

The reconstruction of the Central Electric Lighting Station of the Imperial Continental Gas Association, from which the Opera House is lighted, and which will also light the new Court Theatre, has just been completed. It will be remembered that one of your

Digitized by Google

contemporaries published some time ago a description, with illustrations, of this station. Anyone who had formed an idea of the place by this would not believe that the present station is the one there referred to, so entirely has it been reconstructed—it is not too much to say that really a new station has been built. How difficult the work must have been may be guessed by the fact that during the whole time this reconstruction was going on, involving as it did the taking up of the whole plant, removing and refixing it, the electric current has been supplied, and no interruption caused in the lighting of the Opera House. Numerous temporary makeshifts had to be resorted to, and to appreciate the difficulty of the task it is necessary to have seen the station as it was and as it now is. This new central station, as it may truly be called, was built entirely to the designs and under the superintendence of the company's able resident engineer, Mr. T. W. W. Melhuish, Assoc. M. Inst. C.E., who deserves great credit for the successful carrying out of a most difficult task. The new dynamo room, a splendid airy and well-lighted hall, is now full. It contains five 72-unit dynamos, three 100-unit dynamos, and four 7-unit dynamos by Crompton and Co. These are all coupled direct to Willans engines. The steam is supplied by eight Babcock and Wilcox boilers, each having 1,306 square feet heating surface. The boiler house is most conveniently arranged. The work has been done in a most thorough and substantial manner, showing that the engineer knew what he was about, and that he wanted to make this central station one of the best, if not the best in Europe.

NOTES FROM COPENHAGEN.

(FROM OUR CORRESPONDENT.)

The electric lighthouse at the Copenhagen Exhibition is now completed, and has been lighted for a couple of weeks. It is an exhibit of exceptional importance, and one which has probably never been exhibited before in its entirety. This is only another example of the trouble taken and the large expense incurred by the Danish Government and public institutions in connection with this Exhibition. It is intended for the Hanstholm, and is not only the first electric lighthouse in Denmark, but is one of the, or perhaps the, most powerful in Europe. Its power is no less than 20 million candles, or about 300 times more powerful than any other lighthouse on the west coast of Jutland. In clear weather only one-fourth of the light will be employed. The large and well known firm of Barbier, of Paris, has supplied the lenses; De Meritens, of the same city, has supplied the magneto-electric machines; the steam engines, &c., hail from the Elsinore Shipbuilding and Engineering Company Works at Elsinore; Messrs. Kemp and Lauritzen, electrical engineers, of Copenhagen, have supplied the air motor, dynamos and electro-magnets for the sirens; the latter are made by the firm of Tuxen and Hammersch, of Copenhagen. The electric lamp can be changed in the course of a few seconds, and should the electric light fail, a petroleum lamp can be instantaneously substituted without altering the character of the lighthouse, and a light twice as powerful as the Scaw lighthouse can be maintained. The lenses are of very large dimensions, allowing an admirable distribution of the light; they have been constructed in accordance with drawings from the chief engineer for the Danish lighthouses. The result is that a large portion of the light, which would otherwise fall within a few miles of the lighthouse, is sent to the horizon. There are two foghorns at the Hanstholm Lighthouse, which are both being worked by electricity, through the medium of a small motor, with dynamos at the lighthouse, and electro-magnets at the foghorns, by which these are actuated through a system of valves. The light of the Hanstholm Lighthouse is so powerful that people have been able to read by it at a distance of 24 miles from the exhibition.

The telephone line between Stockholm and Vesteros (Sweden) was opened on Wednesday, August 29th. The length is 10½ Swedish miles, and the wire is copper wire, of two millimetres in diameter. There are no intermediate stations between Stockholm and Vesteros. The business of the large Stockholm Telephone Company is increasing to such an extent that they have again been obliged to extend the premises occupied by them.

A very curious story comes to hand from Sillevorde, Jutland:—"On Monday, August 27th, a farmer and his wife were returning from a visit to some friends, it being close upon midnight, when, within a short distance of home, it suddenly appeared as if the horse had to use all its power to pull the carriage, although it was going down hill. At the same moment some fire was discovered at the front wheels. As to what happened next both the farmer and his wife are ignorant, as they became insensible. The man came to first, and found that the horse was gone and the trap was shattered. The seat was lying in one place, the cushions in another, and the cover was found in a cornfield. The farmer's wife was lying insensible some distance from the carriage. When the farmer and his wife finally arrived home the horse was standing with its nose against the stable door."

SWEDISH NOTES.

(FROM OUR CORRESPONDENT.)

STOCKHOLM, *Sept.* 7, 1888.

In Stockholm the question of a large central station for electric light appears to progress somewhat slowly, and more time is likely to elapse before any definite decision is arrived at than was at one time anticipated. In lieu of a plan which the gasworks submitted to the Corporation as early as December, 1886, and which comprised the erection of a central station for 4,000 incandescent lamps, entailing a cost of 585,000kr., the directors of the gasworks applied for and obtained leave to lay another proposal before the Corporation. The gasworks authorities then invited tenders from five foreign firms for the erection of a central station. The tender preferred was that of Messrs. Siemens and Halske, Berlin, it being the cheapest of the lot. Upon this basis a fresh plan was worked out by the gasworks, and brought before the Corporation; the cost had risen to 623,000kr., but the capacity of the station had been doubled, and was now calculated at 8,000 incandescent lamps. As this number of lamps was not excessive, the second plan was consequently far cheaper than the former. In order to ascertain the probable requirements of that part of the town for which the central station was in the first instance intended, people wanting electric light were requested to state the number of lamps they wanted, and in less than a fortnight 4,092 incandescent and nine arc lamps were asked for. The second plan of the gasworks has been before the Corporation for some ten months without any reply having been given. In the meantime, the Corporation appointed a committee, which was to look into the matter of the fixing of wires and cables, and to frame additional regulations in reference to this question. Although this committee was not appointed simply on account of the contemplated central station, but also on account of the rapid growth of telephony in Stockholm, the Corporation will probably await their report before giving the gasworks a reply.

In Sundsvall a comprehensive scheme for lighting the town by electricity has been mooted by the well-known firm of Thomson-Houston, of Boston. This firm has effected a number of important installations in Sweden, among them being those at Gothenberg, Hernösand, &c., and their system has gained many friends in Sweden. They now propose utilising the waterfall of Matfors for the above purpose, and the plan comprises not only the lighting of streets and houses, but it is under contemplation to extend it to electric tramways in the town and neighbourhood. An engineer is at present at Sundsvall, and the proposal meets with a favourable reception. The firm is supposed to be willing to complete the whole installation and submit it to a thorough trial before demanding payment. As the town of Sundsvall has been almost entirely destroyed by fire within the last two or three months, the conditions would appear to be exceptionally favourable.

The installation for the lighting of the town of Vesteros (Sweden) by electricity is nearly completed. The dynamos hail from the Stockholm Elektriska Aktiebalag, and the Motala Engineering Company has supplied the steam engines.

A new limited company for electric light has just been formed at Gothenburg, under the name of "Electran." At a meeting of persons interested in the undertaking, which was held at Statel, Christiania, Gothenburg, on Saturday, September 1st, it transpired that enough shares had already been applied for to leave sufficient funds for the building of a large central station. The directors *ad interim* were authorised to at once proceed with the works, as it was deemed desirable to be able to start as early as November. The money is exclusively Swedish, and a number of consumers of electric light are among the applicants for shares. The prospectus of the new company contains, among others, the following clauses:—"Electric light will be supplied both night and day; the light will be perfectly steady, and to attain this end the company will have a sufficiency (including reserves) of the best possible machines; the light will be supplied at such a price that both business people and private individuals may be able to use it."

CORRESPONDENCE.

UNIPOLAR INDUCTION.

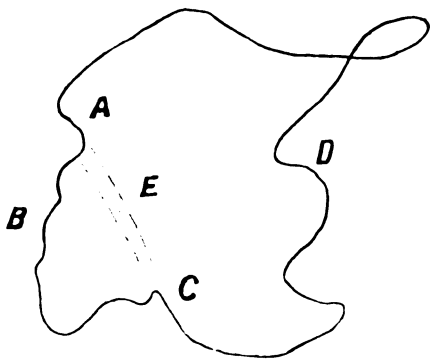
TO THE EDITOR OF THE ELECTRICIAN.

SIR: Referring to Mr. Tunzelmann's note in your last issue, suppose any curved figure, A B C D, to represent a conducting circuit, and to be situate in the field of a cylindrical magnet, and fixed in distance from the magnet's axis. The magnetic field being uniform about this axis the number of lines enclosed by the circuit A B C D does not change, whether the lines of force rotate about the axis, everything else being fixed; whether the circuit A B C D alone rotates about the magnetic axis,

Digitized by Google

maintaining a constant distance and position relative thereto; or whether both lines and circuit rotate simultaneously either in the same or in contrary directions about the magnet's axis. This is a very obvious fact.

Now, suppose that the part A B C of the circuit be replaced by a metallic cylinder (disc or what not), mounted concentrically with the magnet, and that sliding contacts be provided at the points of junction A and C. The *circuit* is now—whether the



cylinder rotates or whether the conductor A D C rotates—represented by the figure A E C D, A E C (representing the *path* of the diffused current within the cylinder) being fixed relatively to the points A D C. Hence it is perfectly obvious that, since the circuit A E C D is invariable in figure and in size, the number of lines bounded by it can no more vary than in the case of the former circuit A B C D. Surely this is simple enough, and entitles me to write Q.E.D. When the contacts A and C are sliding, owing to the relative rotation of the cylinder and A D C, then the conductor on the line A E C cuts a different number of lines of force to A D C., whatever way the lines be revolving, or if they are stationary. Hence the current, as in Forbes's dynamo.—Yours, &c.,

Staveley, Sept. 7, 1888. R. SNOWDON.

THE LINEFF ELECTRIC TRAMWAY SYSTEM.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Your contemporary, the *Electrical Review*, last week published a criticism of a report drawn up by Mr. Gisbert Kapp on my electric tramway system, which report you have published in your issue of 31st ult.

The *Electrical Review*, while criticising Mr. G. Kapp's report, has not printed it, and the readers of that paper cannot be in a position to appreciate the facts of the case, the more so as the Editor himself appears to labour under a misapprehension as regards the distinctive features of my system.

The point raised by the article quoted is, however, of some importance to engineers and electricians generally, and for this reason I trust you will allow me to make a few remarks on it.

The writer of the article seems to take exception to professional reports on the ground that they are based on tests and experiments made on a small scale and extending over a short time. Yet what other course would the author advise to the inventor who has to deal with tramways and railways, where an experiment on a *full-size scale* means an expenditure of many thousands of pounds, and would be the work of years? Is it not a most natural, proper, and, I may say, honourable course for an inventor, after having demonstrated on a small scale the capabilites of his system, to request to have the results thus obtained checked by an independent and thoroughly competent practical man? Surely my critic does not advise the adoption of what I would call the stock-jobbing system of "scientific" display, according to which a new invention is shown to a party of city gentlemen and half a dozen reporters from "friendly" papers, who witness a series of well-rehearsed showy experiments, in order to demonstrate the great "features" of the invention.

The contention of your contemporary that my system is identical with that of Mr. Holroyd Smith and that of Profs. Ayrton and Perry is so absurd that I need not waste your valuable space with details of the many vital points of difference. But let me respectfully ask my sapient critic the following question:—If "the leading feature of the Lineff system was demonstrated years ago by Profs. Ayrton and Perry and Mr. Holroyd Smith," then what is the difference between the two latter systems? Have they both the same leading features?—Yours, &c., ALEX. L. LINEFF.

88, High-road, Chiswick, W., 11th Sept., 1888.

LEA'S HAND-STARTER FOR GAS ENGINES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: It may be desirable to point out that an identical arrangement was in use here about six years ago, and the lever, with vertical arrangement, is still by me.

We found by experience that turning the wheel of the engine answered better, because at a particular moment a slightly quicker turn of the fly-wheel succeeded in producing the explosion, and this is not easily done with a lever device, as may easily be conceived. If Mr. Lea doubles his ratchet arrangement in a suitable manner so that the backward as well as the forward movement of the lever causes revolution in the same direction, by one of the well-known methods, success will follow. At the same time this arrangement can be made to allow the engine to run free. Rollers or balls are better than ratchets, if expense does not stand in the way.—Yours, &c.,

ELECTRIC STREET LIGHTING AT BARNET.

A correspondent writes from Barnet as follows :—On Saturday, Sept. 1, the streets of Barnet were for the first time lighted by electricity, and the general opinion appeared to be that the result was most satisfactory. The light was brilliant, steady, and well diffused. For many years great dissatisfaction has been felt at the quality and price of the gas supplied by the Barnet District Gas and Water Company, and the Local Board have frequently had under consideration the advisability of lighting the town with oil. The company gradually reduced the price per thousand cubic feet of gas from 6s. to 4s. 6d., but even this was considered far too high, and some few months back negotiations were entered into with Mr. H. F. Joel, C.E., of the firm of Messrs. Joel and Co., of Wilson-street, Finsbury, for the lighting of the town by electricity. This was the signal for a reduction of 3d. per thousand in the price of gas, and when the contract was at length provisionally accepted notice was given of a further reduction to 4s. per thousand. Mr. Joel's original proposal was to supply lamp for lamp with 16 candle-power burners (that being the supposed power of the gas) at a price about 3s. 6d. per lamp per annum less than that paid to the gas company. This proposal was eventually modified, and it was decided to give 32 candle-power lamps, the price still being based on the original offer ; but the Board have arranged to have more than half the number of lamps originally proposed, consequently the price will be slightly in advance of what has been paid for gas, and at the same time the amount of light will be proportionately greater. There are 71 lamps of 32 candle-power each placed in all the streets of the town and fixed on strong ornamental iron posts 12ft. high, each being provided with a powerful reflector by means of which the light is distributed over a large area. The posts have been specially designed for the work, and each is provided with a small door in order that, where necessary, switches may be used for cutting off independently any lamp or lamps. The electricity is conducted over the district by means of about five miles of hard drawn copper wire of 3 strands 17 gauge, supported on the top of the lamp-posts, which are provided with iron hoops for the purpose. The copper wires are attached to short lengths of well-insulated wire supported on cup insulators and then passed down through the globes to the incandescent lamps. Where the wires cross main thoroughfares they are laid underground in creosoted wooden troughs, and insulated with rubber and encased in leaden tubes to preserve them from mechanical injury. The electricity is generated by a dynamo machine fitted with Joel's patent armature, the pressure being 900 volts, with a current of 10 amperes, and the machine revolves at a speed of 800 per minute. The dynamo machine is fitted with Statter constant-current apparatus ;* this allows one lamp or any number of lamps up to 100 to be used, and the current is automatically adjusted in the required proportions. The machine is mounted on slide rails, so that the belt can be adjusted while it is running. The engine now used is an 8 horse-power (nominal), but this is only temporary, while the permanent engine is being erected. The latter will be inverted vertical engines, running at 240 revolutions per minute. The boilers are of the locomotive type, and the feed-water heaters, injectors, &c., are all of special design and in duplicate. The electric light station is at the Hadley end of High Barnet, and the company, who have taken over Mr. Joel's contract, propose at once laying down powerful engines, boilers and electrical machinery for from 1,000 to 5,000 lamps, for use in private houses, places of worship, &c., many orders having been received and promised. Already the enterprising proprietor of the Castle, one of the principal hotels of the town, has adopted the electric light, and the result is satisfactory in the extreme. The whole of the machinery and electrical apparatus has been designed and fitted by Mr. Joel, and the company have many inquiries from other towns anxious to keep pace with the times. The work in this instance has been carried out in an exceptionally short time, and under contract with the Barnet Local Board. We regret to learn that, owing to the excessive heating of a dynamo bearing, the town of Barnet was thrown into darkness for some time on Wednesday night. By 2 o'clock on Thursday morning everything was restored.

* *See The Electrician*, October 21, 1887, p. 497.

THE WOLVERHAMPTON CORPORATION AND THE LIGHTING OF THE BOROUGH.

At Monday's meeting of the Wolverhampton Town Council, the Special Gas Committee presented the following report :—

At a special meeting of the Council, held in December last, your committee were re-appointed to consider the question of the supply of artificial light for the use of the inhabitants of this borough, and to obtain such professional advice with reference thereto as they might think fit, and to report thereon to the Council. Your committee deemed it desirable to submit a series of questions to various corporations and gas companies in the country, with regard to their respective gas undertakings ; and a large number of replies have been received. It was also considered necessary to ascertain, as far as possible, to what extent electric light and oil were being used in those places for lighting the public streets. Your committee have to report upon the various points as follows :—

At Eastbourne, Hastings, and Blackpool electric light is used for lighting some of the principal places, streets, and thoroughfares ; but your committee have not sufficient information from those boroughs to enable them to judge as to the relative cost of gas and electric light for the areas supplied. The Corporations of Bristol, Carlisle, and Huddersfield have obtained Provisional Orders for the supply of electric light, but they have not been acted upon ; whilst at Norwich and Middlesbrough electric light has been tried and its use abandoned. The Town Council of Bath have recently decided to light about 50 streets with electric light.

Your committee have consulted Messrs. Elwell-Parker (Limited), of Wolverhampton, with regard to the cost of lighting the streets of the borough with electricity, who cannot at present recommend the Corporation to undertake the lighting of the streets alone, owing to the length of leads necessary to be used for the purpose, and the amount of labour of laying down mains necessary for this comparatively limited amount of lighting. Messrs. Elwell-Parker are of opinion that "if Wolverhampton is lighted by electricity it must be arranged to be done upon the same plan as gas—that is to say, by taking off the mains to light dwellings or shops, or wherever the current could be sold, so as to utilise the cables to the greatest extent." In case of carrying out such a plan of lighting, they have no hesitation "in recommending the Corporation to use electricity, as electrical engineering is sufficiently advanced to make the thing a thorough success, and to give a good return for capital invested at reasonable rates charged. Even in small installations, where not more than 4,000 lights are used, it will compare favourably with gas at 3s. 6d. per 1,000 feet. If a 40,000 lamp installation were entered into, the present price of gas in Wolverhampton could be successfully competed with by electricity."

Your committee find, on comparing the estimate of cost of plant, &c., which they have received from Messrs. Elwell-Parker (Limited) for light-

Digitized by Google

ing 60 miles of streets in the borough, and for providing for the probable requirements of the inhabitants, with that of Mr. J. N. Shoolbred, which was submitted to the Council in November, 1882, and which provided for the lighting of a small area in the centre of the town only, that an enormous reduction has been made in the cost of such plant, and there is no doubt that on the further development of electric light, still greater reductions will be made.

Your committee may also here call attention to the Electric Lighting Act, 1888 (51 and 52 Vict., c. 12) amending the Electric Lighting Act, 1882. Under this Act a Provisional Order for the supply of electric light in the district of any local authority is not to be granted, except with the consent of the local authority, unless where such consent is refused the Board of Trade are of opinion that such consent ought to be dispensed with, when they are to make a special report, stating the grounds upon which they have dispensed with such consent. The grant of authority to any undertakers to supply electricity within an area is not to restrict or hinder the granting of a license or Provisional Order to the local authority, or to any other company or person within the same area. The Act also gives local authorities power to purchase the undertakings for the supply of electric light from the undertakers within six months after the expiration of a period of 42 years from the date of the Act confirming the Provisional Order, or the passing of the Special Act, or within six months after the expiration of every subsequent period of ten years, or such shorter respective periods as may be specified in the Provisional Order or Special Act. These periods in the former Act were twenty-one and seven years respectively. The sale is to made without any additional price in respect of compulsory purchase or goodwill, or of any profits which may, or might have been, or be made from the undertaking, or of any similar considerations; but subject to any variation of the terms which may be made by the Board of Trade. It is generally thought that these modifications of the principal Act will have the effect of stimulating and extending the use of the electric light.

The report was of a most exhaustive character. In addition to the above extract, it dealt shortly with the question of oil lamps, and entered very fully into the price and quality of various gas supplies.

The report concluded as follows:—Your committee, in concluding their inquiry, desire to disclaim any suggestion of antagonism to the Gas Company in respect of the steps which they have taken. They have examined in an impartial manner the evidence brought before them, and in view of the facts of the case they are bound to remark that the position occupied by the Gas Company, by virtue of their legal monopoly, as regards the gas consumers, cannot be accepted as satisfactory to the public.

THE LOWRIE-HALL-KOLLE
(L-H-K) DIFFERENTIAL
ELECTRICITY METER
FOR RECORDING ALTERNATING CURRENTS,
IS MADE IN ALL SIZES
FROM 10 LIGHTS TO 1,000 LIGHTS.
FOR FURTHER PARTICULARS APPLY TO
HAMMOND & CO., 117, BISHOPSGATE STREET, E.C.,
SOLE CONCESSIONNAIRES.

BALDERSTON and COMPANY,
201, ST. VINCENT STREET, GLASGOW.
SOLE CONSIGNEES FOR EUROPE FOR
HOYT'S SHORT-LAP LEATHER BELTING.
MAIN DRIVING BELTS
Our Belts are made from pure oak tanned butts and from the heart or solid part of the hide. Each piece of leather is stretched by powerful machinery, jointed and secured in such a manner that both sides present an even surface to the pulley, and the Belt runs as if it were one piece. They work equally well for the largest driving belts or for the fastest running machinery and smallest pulleys, and are specially adapted for use on
ELECTRIC LIGHTING MACHINERY.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended September 7, 1888, amounted to £4,863.

CUBA SUBMARINE TELEGRAPH COMPANY.—The number of messages passing over the lines of this company during the month of August was 3 507, estimated to produce £2,800, against 2,983 messages, producing £2,280, in the corresponding month of last year. The traffic receipts for the month of May, estimated at £3,300, realised £3,337.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended September 7th, 1888, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company (Limited), were £4,011.

ELECTRICAL ENGINEERING AND LIGHTING.
IMPORTANT ANNOUNCEMENT TO GENTLEMEN'S SONS.
The LONDON COLLEGE of ELECTRICAL ENGINEERING is now LAYING DOWN an Important PUBLIC INSTALLATION of ELECTRIC LIGHTING (both Arc and Incandescent), in which the students will have the advantage of carrying out whole of the practical work, and afterwards of attending to the maintenance. The number of students will be strictly limited, and an early application should be addressed to the Principal, the London College of Electrical Engineering, Nos. 9, 10, and 7, Railway-approach, London Bridge, S.E. Established 1872.

"THE WORLD"
TYPE WRITER
Is the latest and by far the simplest Type Writer yet introduced.
It is absolutely simple and requires no learning.
After a little practice a speed of 40 words per minute can be obtained.
It prints very clearly, and different styles of type can be supplied.
Prints on Post-cards, Envelopes, or Tags.
Weighs 4lb., and is only 12in. long by 6in. wide, therefore is very portable. Can be used in a railway train. Re-inking of Type is extremely simple.
It is, in fact, a strong, perfect Type Writer, and only One-Third the Price of any other similar machines.
PRICE £2. 2s. COMPLETE.

Offices—**WINCHESTER HOUSE, OLD BROAD STREET. LONDON, E.C.**

The principal objects of the Corporation are:—

1. Performing the duties of Trustee, Executor and Administrator.
2. The Insurance of Bonds, Shares and all other Securities lodged with the Corporation against risks of all kinds.
3. The Issue of Warrants and Certificates against Securities deposited, and making and procuring advances on such Warrants.

The Office of Trustee or Executor is to private persons usually a thankless post, involving much anxiety, time and money, and frequently leads to serious actual loss; whilst death, illness and change of residence necessitate frequent fresh appointments, and consequent expense to the parties interested. The Corporation undertakes all the duties of Executor, Trustee or Administrator for reasonable remuneration proportioned to the work and responsibility in each case.

The Corporation insures existing Trustees and Executors against all risks attending those positions, where the business is conducted by the Solicitors to their Trusts under the supervision of the Corporation, it not being the desire of the Corporation to interfere in any way with the duties of the family solicitor.

The Corporation acts as Trustees for the Debenture Holders in Public Companies.

For terms, &c., application should be made to the General Manager at the Company's Office.

GEORGE PEARSON, *General Manager and Secretary.*

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL SCIENCE, INDUSTRY AND ENGINEERING.

No. 540.—Vol. XXI. FRIDAY, SEPTEMBER 21, 1888. Price 4d.

NOTES.

In another column there will be found a sketch by Prof. Lodge of the Electrical Papers read at the Bath Meeting of the British Association. The author has done well to call attention to the magnification of the engineer at the expense of the scientific investigator by the President of the Association and the President of Section G respectively. The scientific investigator is, from the point of view of practical applications, essentially a pioneer, and we fear that everywhere the pioneer receives very much less credit than he is entitled to. The remarks of the President and of the Sectional President were, however, couched in quite moderate terms compared with those of the extract quoted by the Professor from a technical contemporary.

We would specially call the attention of our non-mathematical readers to Prof. Lodge's excellent *résumé* of two Papers by Sir William Thomson, dealing mathematically with electrical theory, as in their original form they demand a not inconsiderable amount of mathematical knowledge on the part of the reader.

A Paper by Herr Marcher, of Mülheim, which we publish this week, directs attention to a class of dynamo with which very little has hitherto been done, nor do we altogether share our contributor's views as to the probability that the type will establish a permanent foothold. The commutator is undoubtedly the most delicate part of the organism of the dynamo. Other things being equal, a machine without commutator or brushes is undeniably to be preferred to one which possesses those adjuncts. But then at present other things are *not* equal: the increased cost and diminished efficiency of such a machine is too heavy a price to pay for dispensing with a device which after all works, at least in modern machines, with surprisingly little trouble or irregularity. At the same time we think the article will repay perusal, and has a certain historical interest.

An interesting letter from Prof. S. P. Thompson will be found in our "Correspondence" columns this week, referring to a Note in our issue of September 7th. The possibility of practically generating knotted lines of force is novel, and of considerable interest. As we are confined to space of only three dimensions, it would be impossible to produce knots by any inductive action, in lines of force proceeding from a conductor, and equally impossible to remove the "beknottedness." In space of four dimensions a knot, as known to us in our space, could be tied upon or untied from an endless cord, or one with both its ends fixed, without cutting it or detaching an end respectively; and therefore in space of four dimensions a true knot—that is to say, one which cannot be untied from a closed string—is impossible.

The eighth meeting of the National Electric Light Association of America was opened at the Hotel Brunswick at New York, on the 29th August, by an address from the President, Mr. S. A. Duncan, of Pittsburg (Pa). The address contained some interesting statistics relating to the present condition of electrical industry in America, an abstract of which will be found in another column. According to the Secretary's report, the Association now embraces 189 members, which shows a considerable increase upon last year.

The first Paper read at the meeting was by Mr. S. S. Leonard, giving a short account of his practical experience with petroleum fuel. The subject is one of considerable importance to American engineers, owing to the quantity and low price of the crude material, and his Paper therefore attracted a good deal of attention.

On the second morning three Papers were read—by Mr. S. S. Wheeler, on "Overhead and Underground Wires in New York;" by Mr. E. G. Acheson, on "Disruptive Discharges and their Relation to Underground Cables;" and by Mr. A. C. Chenoweth, "Description of an Underground Circuit." Mr. Acheson's Paper will be found in another part of the present issue, and we shall shortly give an abstract of Mr. Wheeler's. The three Papers were discussed together, and gave rise to a long and interesting debate. Dr. Van der Weyde's Paper, which we published last week, was read on the third day, and was followed by a valuable Paper on "Some Methods of Electrical Measurement," by Dr. G. A. Liebig, intended to draw the attention of American engineers to recent methods of exact measurement. We trust they will give it the attention it deserves. The other Papers read at the meeting were on "Electrical Education," by Mr. E. R. Weeks, and on "The Expense of Electro-Motor Service," by Mr. H. F. Lufkin.

Mr. Acheson's Paper on "Disruptive Discharges and their Relation to Underground Circuits" dealt with a subject which has scarcely as yet been forced upon the attention of electrical

Digitized by Google

engineers in this country, but which will in all probability assume considerable importance at no distant date. We should be glad to learn how far Mr. ACHESON's experimental results are confirmed by the experience of practical men, and how far the danger indicated is a real one.

IN the course of the discussion on Mr. ACHESON's and the two other Papers dealing with underground conductors, Mr. T. CARPENTER SMITH stated that when working an arc-light circuit containing a couple of Thomson-Houston lightning arresters at the ends, he had observed that when the circuit was opened or closed sparking took place across the lightning arresters, and when the machines were working badly there was a continuous stream of sparks. No explanation of the phenomenon had occurred to him until it had been given in Mr. ACHESON's Paper. Mr. SUNNY, while challenging some of Mr. ACHESON's results, also considered his investigations of great importance. The American technical journals generally express themselves to the same effect.

THE little pamphlet on the Technical Education of Engineers which has just been issued by the Manchester Association of Engineers contains some valuable suggestions as to the best course of study to be pursued by young men engaged in engineering workshops. We cordially endorse the remarks upon the importance of the study of practical geometry, which is usually very much neglected in this country. Its special importance to engineering students, whose knowledge of mathematics is but slender, is pointed out in the pamphlet, and we may add that it is of the greatest value as a preliminary even to the most thorough course of mathematical study, and especially so for engineering students, owing to the great assistance which it will afford them in applying their mathematical knowledge to practical problems. The essential importance to electrical engineers of acquiring a knowledge of applied mechanics, metallurgy, and machine and freehand drawing, is very properly insisted on, and also the value of a knowledge of the principles of steam and of chemistry. We are glad to see that the study of French and German is also strongly advised, as a knowledge of both of these languages is of the utmost value to the electrical engineer to enable him to keep himself abreast of the most recent advances in electrical engineering. The student should also bear in mind that a knowledge of these and other modern languages, such as Spanish and Italian, may often enable him to secure appointments from which he would otherwise be debarred.

THE breakdown at Barnet is all the more annoying because it appears to have been one of those "accidents" which an ordinary degree of prudence might have entirely obviated. To start a machine under a full load of responsibility directly it has been got into place may be "smart," but it certainly is not engineering. We take it that except in a case of the extremest urgency no engineer with a due sense of responsibility would dream of putting a dynamo on central station work without first making a preliminary run to see that the bearings are true. We feel bound to speak plainly and strongly when an incident of this character comes under our notice, for the fact is that the position of central station electric lighting in this country is not sufficiently well assured to withstand these rude buffets at the hands of its would-be exponents.

AS to the impression which Mr. JOEL's performance—apart from the interruption alluded to above—has made upon the public mind at Barnet, we may refer to our Note columns, in which we give an extract from a local journal. Our own views as to the propriety of lighting streets with glow lamps of low candle-power are well-known to our readers, and notwithstanding that our earlier remonstrances induced the Town Council to double the candle-power of the lamps, we are still not in the least surprised to learn that the mutterings of discontent are already heard. We trust the success of Mr. JOEL's scheme for the distribution of current to private consumers will be sufficient to atone as far as may be for the mistaken policy which he has adopted with regard to the public lighting.

WE are glad to notice that the Insurance Offices are beginning to realise the importance of exact electrical knowledge in connection with one branch of their business—the inspection of premises where electricity is employed for industrial or lighting purposes. The Insurance surveyors, according to the *Finance Chronicle and Insurance Circular*, will in future have to be men of "considerable scientific training, or at the least widely read in the sciences of chemistry and natural philosophy, in addition to their knowledge of assurance business." This is rather exacting; but it is better than protesting that there is nothing to learn, or pretending to teach electricians their own business. Electrical engineers as a body have much to gain by the Insurance surveyors becoming competent electricians; for otherwise and in the meanwhile the name and reputation of particular firms must necessarily carry undue weight, sometimes to the detriment of less prominent but equally trustworthy undertakers.

Frankfort.—It has been decided to construct a central station at Frankfort from which to light the streets of the town by electricity.

Paris.—The installation at the Variétés is about to be reorganised. Accumulators are to be employed, and the motive power will be compressed air.

The Telephone at Grimsby.—A telephone exchange, established by the National Telephone Company, was opened at Grimsby on Wednesday last.

University College, Dundee.—The winter session of this college will open on the 8th of October. Further details will be found in our advertisement columns.

Orleansville.—The municipal authorities of Orleansville, Algeria, have invited tenders for the erection and working of a central lighting station in that town.

Telegraphic Communication in Central Asia.—A new line of telegraph will very shortly be laid down in Central Asia, between Khiva and Chardjui, on the Amu Daria.

Dalkeith.—The Dalkeith Police Commission having been informed that the introduction of the electric light would mean an addition to the rates, has abandoned the idea of introducing it.

Digitized by Google

Chelmsford.—On the occasion of the festivities connected with the incorporation of Chelmsford, which took place on Wednesday last, the town was illuminated by Messrs. Crompton and Co. with the electric light.

Deutsche Naturforscher und Aerzte.—The sixty-first annual meeting of this society, which was recently announced in our columns, was opened at Cologne on Wednesday, and it is expected that about 1,500 members will attend.

The May Island Electric Light.—Captain Boldt, of the Danish mail steamer "Thyra," reports having sighted the May Island electric light at a distance of sixty-one nautical miles. This is the highest recorded distance at which the reflection of the light has been observed.

Electric Motors in Mines.—The Aspen Mining and Smelting Company (U.S.A.), which has a great number of electric motors for pumping, hoisting and haulage, is about to establish a large central power station to be run by water power, the energy to be transmitted to other mines in the district.

Toulon.—During the French Naval Manœuvres at this port several experiments were made with a view to test the utility of the electric light. According to the *Gaulois* the search lights on shore swept the water so thoroughly that not a single torpedo boat was able to get into the bay unseen.

Telephony in Portugal.—Messrs. Mourlon and Co., of Brussels, have received an order from the Portuguese Government for the erection of a telephone and telegraph line between Oporto and Lisbon, a distance of some 200 miles, similar to those at present existing between Paris and Brussels and Lyons and Marseilles.

Electric Light Installation at Smedley's.—Messrs. T. H. Holmes and Co., of Newcastle, have recently fitted this well-known hydropathic establishment with the electric light. The current is supplied by a 25-unit slow-speed compound "Castle" dynamo, and the fittings all over the building are of a very elaborate character.

The British Association.—The next meeting of the British Association will be held in Newcastle-on-Tyne, commencing on September 11, 1889, and the meeting in 1890 will be held in Leeds, Cardiff, probably, being favoured in 1891. Prof. W. H. Flower was unanimously elected President for the Newcastle meeting next year.

Verity and Sons' Catalogue.—We have just received the new catalogue of electric light fittings manufactured by this firm. The book contains a large number of illustrations of electroliers of various kinds and at various prices. Many of the designs are of exceptional beauty, and the catalogue is very handsomely got up, the designs being reproduced by the phototype process.

The Palais-Royal Central Station.—The plant for this central station will consist of 8,150 horse-power steam engines, each driving an Edison dynamo direct. The Théâtre Français will take 1,000 lamps, the Théâtre du Palais Royal 650 lamps, and various public buildings 1,500 lamps. The eight or ten thousand lamps still available are intended for private consumers.

Compiegne.—The central lighting station erected by MM. Buchin, Tricoche and Cie. commenced work on September 1st. It comprises two boilers, 130 horse-power Farcot steam engine, and two compound-wound 300-light Gramme dynamos. The wires are overhead, and the consumers are charged so much per lamp per annum, meters having been deemed unsatisfactory.

Lightning on a Telegraph Line.—The telegraph line between Wittower and Arkona, in the island of Rügen, was recently struck by lightning some 5 kilometres north of Wittower. Several posts were hurled to the ground and a large length of wire was melted into minute fragments. The lightning then ran along the conductor to Wittower, where it went to earth after shattering the ebonite insulator immediately outside the telegraph office. Some portion of the discharge entered the office, but, thanks to the lightning guard, no damage was done to the instruments.

The Hydrophone.—A submarine telephonic apparatus, called the hydrophone, has recently been submitted to some tests in Brest Bay by order of the Minister of Marine. The sound of a bell weighing 150 kilogrammes, which was struck under water, was heard at the greatest distance permitted by the configuration of the Bay—namely, 5,200 metres (3¼ miles). Excellent results were obtained on board a boat in motion, the bell being distinctly heard 1,400 metres off, as well as the noise of the screw of the tug on board which the sounding instruments were placed.

Use of Electricity in Diseases of the Throat.—Mr. J. Macintyre, M.B., in a Paper bearing this title read at the annual meeting of the British Medical Association last month at Glasgow, after alluding to the expense, and difficulties of arrangement for the various purposes required, when either primary or secondary batteries are employed, suggests that the transformer will probably in the future be generally adopted for this purpose, and expresses the opinion that a cheap and portable transformer suitable for all medical purposes would be of great value to the profession.

A Statue to Ampere.—At the meeting of the Academy of Sciences on Tuesday it was stated that in the beginning of next month a statue would be inaugurated at Lyons to Ampère. The authorities of that city have invited the Academy of Sciences to send a representative to the ceremony, and the President of the Republic has signified his intention to be present. The secretary recalled the various titles which Ampère has to take his place among the greatest men of science in this century. A member of the geometrical section is to be sent to represent the Academy at the inauguration of the monument.

Telephone Statistics.—The Russian Post Office authorities have recently published some statistics relating to the position of telephony in Russia. The total length of telephone lines amounts to 7,440 versts (4,960 miles), the total number of subscribers being 3,250. There are at the present moment 941 subscribers in St. Petersburg, 584 at Moscow, 472 at Odessa, and 365 at Riga. The Swiss Post Office authorities have also issued a similar report relating to Switzerland. The total number of subscribers at the end of 1887 was 5,988, being an increase of 990 since 1886; the total length of wire was 9,460 kilometres, an increase of 2,237 kilometres. The total length of trunk lines at the end of 1887 was 1,140 kilometres.

City and Guilds of London Institute.—The classes at the Technical College, Finsbury, for the Session 1889, will begin on Monday, the 1st October. They are divided into five departments, viz.:—(1) Mathematics and Mechanical Engineering; (2) Electrical Engineering and Applied Physics; (3) Industrial and Technical Chemistry; (4) Applied Art; (5) Special Trade Classes. The classes are conducted both in the day time and in the evening. The entrance examination, for day students, will take place on Wednesday, September 26th, at 10 o'clock a.m. Scholarships of £30 a year each, and the Holl Scholarships of £20 a year, all tenable for two years, will be awarded (in accordance with the several schemes) on the results of the entrance examination.

The Zanni Shippey Lamps.—With reference to a paragraph in our New York correspondent's letter, dated 7th instant, Mr. Arthur Shippey writes to us from Llandudno a letter, too long for insertion, suggesting that if our correspondent wishes for further and trustworthy information "respecting the new S.S. lamps" he should drop in at the offices of the undermentioned American firms :—The Edison Electric Light Company, the United States Electric Lighting Company, the Julien Electric Company, the Brush Electric Light Company, the Electric Light Accumulator Company, the Columbia Lamp and Lighting Company, the Fort Wayne Jenney Electric Light Company, all of whom, besides others, have been supplied with samples of the lamps. Mr. Shippey also gives the names of a number of learned and influential persons in the States who can testify to the scientific and financial merits of the invention.

An Electrical Time Call Register.—An automatic call-bell arrangement, whereby any number of rooms can be electrically connected with a clock, and called separately or together at any time which may be desired, has recently been designed by Mr. H. Boardman, of Bradford, and is in practical operation at Mr. George Armitage's dye works at Bradford. This arrangement is in use in several private establishments, varying from three circuits upwards. It will probably be of some value in hotels, as each bed room can be electrically connected with the clock, and the occupant called without the intervention of a servant. Mr. Boardman has also devised a method for recording, by electricity, the visits of watchmen to various stations in asylums, prisons, workplaces, and police districts, which will probably be largely adopted. The several stations are so arranged that the watchman must visit the whole of the place or district under his charge when he is on duty.

Electric Light and Power Statistics.—In his presidential address to the National Electric Light Association, Mr. S. A. Duncan gave the following remarkable statistics relating to the present position of electrical industry in America:—There are now 5,351 isolated plants and central stations in the United States, and there are burning every night no less than 192,500 arc lights and 1,925,000 incandescent lights. There are 459,495 horse-power of steam engines devoted to electric lighting, and there has been an increase in the capitalisation of the electric light companies of the United States in the last six months of no less than $42,210,100. There are thirty-four electric railways completed and in operation, having an aggregate of 138 miles of single track, and operating 223 motor cars, and utilising 4,180 horse-power for stationary engines. There are, also, now in progress of construction forty-nine other electric railways, aggregating 189 miles of single track, which will operate 244 motor cars.

A New Telephone.—In a short paper on "A Novel Form of Electro-Magnetic Telephone," Prof. R. B. Fulton, of the University of Mississippi, gave a description of a form of electro-magnetic telephone of his design, in which the ordinary spool electro-magnet and circular diaphragm are replaced by a magnetised tube of thin sheet iron, with the insulated wire wound round the tube. The tube has a rectangular cross section about 2in. square (it may be of any length), and open at one or both ends. It is magnetised by steel magnets, or a current, so as to have the lines of force running parallel to its length. The wire is coiled round those parts of the tube which form vibrating segments when vocal or other sounds are made near an open end of the tube. The lines of magnetic force, the direction of the vibratory motion of the walls of the tube, and the direction of the induced currents are thus each at right angles to the other two. The instrument may be used either as a receiver or transmitter, but seems to work best as a transmitter to a Bell receiver.

The "Rees" Electric Safety Lamp.—A few particulars concerning the "Rees" lamp, which has been very well spoken of by several colliery owners and managers, may be of interest. The body of the lamp is composed of a vulcanite case, measuring 5¼in. by 5in. by 3in. To the lid is attached a small brass cylinder, and on this cylinder is placed an elongated glass dome, ⅛in. thick. The handle is fixed to the vulcanite casing by means of a brass strap, and is so constructed that the lamp may evenly balance when suspended. In the vulcanite case are four cells, filled with a liquid prepared by the inventor. Within the lid is a flat piece of India-rubber covered with paraffin wax, which prevents the liquids from mixing or spilling whilst being carried. Inside the glass dome is the bulb with the incandescent lamp, and the space between the bulb and the dome is filled with compressed air, forced from a small hand-pump. This compressed air forces the bottom of the brass cylinder down, and completes the circuit. The compressed air may be left in for an indefinite time, and the circuit broken by opening the lid alone.

The Axo Battery.—The Axo battery, constructed by the Leclanché Battery Company of America, is an "improved" form of Leclanché, intended to overcome some of the defects of batteries of the porous cup class. The porous cup has a flange which rests on the rim of the jar and forms of itself a cover for the cell. The zinc passes through an independent aperture of its own in the shoulder of the jar. The carbon conductor has inclined sides, increasing in size from the top to the bottom. By gravitation, therefore, the particles of the surrounding mixture are always in perfect and continuous electrical contact with its surface. The carbon itself is provided with ventilating grooves extending along its sides, by which it is much more readily relieved of the bubbles of gas which form on its surface, and retard the electric action, than by the holes usually run through the seal and into the mixture. The well-known lead cap of the carbon is dispensed with, and in its place is used a thimble with thumbscrew, which can be slipped off and replaced in a moment. The battery wire passes through a small hole in the top of the thimble and into a recess in the carbon, against which it is clamped by the thumbscrew.

Mr. Preece's Definition of Electricity.—In *L'Electricien* of 14th September, M. Hospitalier, commenting on Mr. Preece's Presidential Address to Section G, remarks :—"We cannot agree with Mr. Preece's definition of electricity and energy. The disagreement between physicists and engineers is much less important than it looks, and may possibly disappear without inventing new terms, such as 'coulombism' and 'electron.' The confusion to which Mr. Preece calls attention arises simply from the attempts made to define a word which is in reality only a label denoting a series of phenomena called electrical. In former days the common cause of these phenomena was thought to be a mysterious fluid called 'electricity;' but it is now amply proved that this fluid does not exist. It is therefore perfectly idle in the present state of our knowledge to try and define something which does not allow of a definition. We can define electric energy, electromotive force, intensity of current, electric force, and quantity of electricity by applying the fundamental relations connecting the different physical quantities; but electricity, having no existence, cannot be defined. Such is the only answer which can be given to the question, What is electricity ?"

Galvanic Action in Ships.—A curious discovery has just been made in connection with the "Nymphe," one of the ships completing at Portsmouth. The "Nymphe" was laid down

Digitized by Google

ou July 5th, 1887, floated out of dock on May 1st last, and is to be completed some time during the present year. She is a composite vessel—that is to say, constructed of iron frames with a wood bottom, which is protected by copper sheathing. Before a ship is launched or floated out of dock it is customary to get the boss pieces on to the end of the steel shaft for the screw blades; but the boss pieces not being delivered in time from the makers of the machinery the "Nymphe" was floated out without them. There was in consequence no protection against galvanic action set up by the water between the steel shaft and the copper and other metal on the ship's bottom. Since leaving the dock in which she was built the "Nymphe" has been in one of the basins; but in order to complete the copper sheathing of her bottom, it was necessary a few days ago to take her into dock again, and then the discovery in question was made. It was found that galvanic action had been for some time proceeding, and that the steel was much eaten into and corroded. The damage is serious; but whether its extent is such as to necessitate the replacing of the shaft is not yet determined, the question being still under consideration.

The Telegraphists' School of Science.—The prize list and prospectus of this school, which was established at the London Central Telegraph Office in September, 1876, and which is, therefore, entering on its thirteenth annual session, has been issued, and a copy is before us. The success which was achieved in 1886-7 has been eclipsed by that of 1887-8, the 41 certificates gained last year being increased to 81 this year, 37 of them being first-class. The total number of registered students was 72. Thirteen out of the 16 candidates in mathematics were successful, and in the magnetism and electricity examination there were 42 candidates, of whom 39 were successful, including 19 first-class. In the telegraphy examination, under the City and Guilds Institute, 22 certificates were gained, the total for the kingdom being only 70, notwithstanding that there were candidates from upwards of 20 different schools. In the electrical instrument examination two candidates were presented in honours; both took first-class certificates, one of them, Mr. A. Brooker, being also awarded the prize of £5 and a medal. Only one other first-class Honours Certificate was awarded this year. During the past five years the school has gained six out of the thirty-three medals and £24 out of the £85 awarded in telegraphy. Chemistry is re-introduced into the time table for the coming session, and a special course of lectures and demonstrations is announced in view of the coming transfer of the Submarine Telegraph Company's system to the Post Office. The forthcoming session commences on Monday October 1st.

Exeter.—At a meeting of the Town Council, on Wednesday, Sept. 12, the Navigation Committee reported that they had held a special meeting on the 18th August. The meeting was called in order that Mr. Chidley, solicitor to the proprietors of Trew's Weir Mills, who was then in Exeter, might have an opportunity of explaining to the committee the arrangements they were desirous of making with regard to the proposed works of the Exeter Electric Light Company. A letter was read from Mr. H. W. Michelmore, secretary of the company, enclosing plans of what the company proposed to do on the land adjoining Trew's Weir. The plan showed the waterways, the position of the turbines, and the ground plan of the buildings. The turbines were four in number, each of 24 horse-power nominal, using 3,000 cubic feet of water per minute. The excavation for the races would be floored with Portland cement concrete, with side walls of the same. Care would be taken not to interfere with the wing wall at the end of the weir, and where it was approached by the company's works the intervening space would be filled with concrete. The committee resolved that the suggested interview with Mr. Chidley could not be held until the surveyor had had an opportunity of examining and reporting upon the plans submitted. The secretary's letter and accompanying plans were laid before the ordinary meeting of the committee on the 4th September, when, having heard the observations of the surveyor and the wharfinger thereon, they recommended that the proposals of the company be declined.—Mr. Daw said the committee were almost unanimous in coming to that decision.—Mr. Wreford moved, and Mr. Williams seconded, that the committee hold a conference with the directors of the company, and this was carried by 18 to 12.

The Electric Light at Barnet.—The following extract is taken from the *Barnet Free Press*:—"Up to the 1st of September the streets were lighted by one hundred ordinary gas lamps and four large refuge lamps, two of which were kept burning all night. For these lamps the gas company were paid as follows:—One hundred ordinary lamps at £2. 18s., two large lamps at £16, and two others at £10, or a total of £342 per annum. These lamps have been replaced by seventy-one electric lamps, the charge for which is £5. 8s. each, or a total of £383. 8s. Two of the electric lamps are to be kept alight all night, for which doubtless something extra will have to be paid. At present, therefore, in point of cost, there is a balance of at least £40 in favour of the 104 gas lamps as against the seventy-one electric lamps, and this £40 is *plus* any sum paid for all-night lighting of certain lamps. Ratepayers might not object to additional cost if they obtained an equivalent in improved lighting, always provided that the cost does not become excessive, and that the ratio between cost and light will bear favourable comparison with what may be obtained in the case of gas. But are we getting an equivalent for the additional outlay? Is our town better lighted than it was with gas? These are early days in which to speak of what may or may not be ultimately accomplished with the electric light at Barnet, yet one may reasonably compare the present lighting of the High-street with what is was when gas was the illuminating power, and we venture to say that the comparison is not yet altogether in favour of the electric light. More lamps are required, and, leaving altogether out of account some twenty lamps or so which have not yet been lighted at all, there are portions of the district in which no provision has been made for electric lighting where gas was formerly used. This deficiency must sooner or later be supplied at a further cost to the ratepayers, who welcomed the electric light because they were led to believe that gas could be replaced lamp for lamp by electric light of equal power and at less cost. The fallacy of that belief is now apparent, and it remains to be seen whether the electric light company can make up in effectiveness for the comparative costliness of their light. We would not willingly say a word to damp the ardour of the enthusiasts in electrical science or to discourage their efforts, but we are bound to recognise that the company are held by their bargain, and that up to the present time they have not fulfilled the conditions of their contract in a manner calculated to gain the confidence of the townsfolk. It may be that the present lighting arrangements, being of a temporary character, do not give such perfect results as may be looked for when those arrangements have been finally completed. In any case the company should lose no time in giving effect to both the letter and the spirit of the contract into which they have entered. Electric lighting is on its trial in Barnet, and those chiefly concerned in its success should show themselves in earnest, since the system must stand or fall on its merits."

SKETCH OF THE ELECTRICAL PAPERS IN SECTION A AT THE RECENT BATH MEETING OF THE BRITISH ASSOCIATION.

BY PROF. OLIVER J. LODGE, F.R.S.

Some talk of Isaac Newton, of Euler and Clairaut
Of Kepler and Copernicus, and old Galileo ;
But of all the mathematicians
There's none who can compare
With the row dow dow de dow dow dow
Of the British Engineer.

The above verse may be said to strike the keynote of the recent British Association meeting at Bath, as it appeals to an outsider. The note was struck both in the Presidential Address and in the address of the President of Section G, and it has been further emphasised, no doubt beyond the meaning of either President, by an instructive leading article in the oldest engineering journal. The following extract is from the *Engineer*, of date September 7 :—

"Sir Frederick Bramwell's address is mainly a pleasant discourse on the part which the engineer has played in the world, and is principally remarkable as a well-constructed refutation of the preposterous pretensions put forward by some men of so-called pure science. . . . The theme is so congenial that we feel no keen desire to criticise what Sir Frederick Bramwell had to say. Our only quarrel with him, indeed, is that he did not go far enough, or press his arguments with sufficient insistance. Possibly it was impossible or impolitic to push his arguments home. . . . No one, however, knows better than Sir Frederick that the world owes next to nothing to the man of pure science. In another page we give an abstract of the address, from which it will be seen how carefully Sir Frederick avoided the utterance of a word that might give offence. But we are not tied or bound by any consideration of this kind, and we should be lacking in our duty did we not assert whenever the occasion for assertion arises, that the engineer, and the engineer alone, is the great civiliser. The man of science follows in his train."

Meanwhile, in the quiet and peaceful atmosphere of Section A some good work has been done, and in the calm temperament engendered by such work and by the assured feeling of progress in insight and knowledge, there is a disposition, I doubt not, to grant to the engineer all the credit he, or others for him, can possibly claim, and not to resent even such a singular tone as is sounded in the above-quoted leading article. There is, after all, some excuse for a good deal of self-glorification when the society-transforming consequences of an engineer's labours is regarded ; and yet one would not be surprised if one learnt that great individual engineers—such, for instance, as the builder of the Forth Fridge—were among the most unassuming of men.

I propose to give a brief account of such of the communications to Section A as may be expected more particularly to interest the readers of this journal. It should be always clearly apprehended that when one man gives an account of another's work that other is in no sense responsible for or bound by what is said. It ought to be absurd to have to point this out, but experience shows that it is not unnecessary ; and it is especially necessary to call attention to the fact in connection with a hasty report of a great number of Papers, written without notes and without the respective authors' knowledge or supervision. However carefully one may attempt the task some errors are bound to creep in, and were it not that in process of time all these Papers will be published in authentic form by their writers one would not be justified in making the attempt. But persons not able to be present may find even a partially correct account of what went on at the meeting better than none at all.

First, then, the section was happy in having for its president a man exhibiting an altogether exceptional combination of qualities—profound knowledge, great originality, mathematical and experimental skill both of the first order, quickness of comprehension, and a ready wit. The address with which he opened the business of the section was not unworthy of the man. Its subject was that greatest of all physical subjects, "The Ether," and it largely consisted in a glorification of the quite recent experiments of Dr. Hertz in Berlin, whereby Prof. Fitzgerald shows that the existence of an æther is raised out of the rank of a very probable hypothesis, which it has long been, into the domain of demonstrated facts. He hints also that certain outstanding problems concerning the structure and properties of the ether can most probably be answered by a further discussion and repetition of experiments like those of Hertz. Our engineering friends ought not to sneer at the prominence given to such a refined abstraction or hypothetical figment as the ether may seem to some of them to be, for it is by its means they drive all electric motors, it is it they use in dynamos and transformers of all sorts ; it is the ether which transmits their signals, whether telegraphic or telephonic; and, though this may appeal to them less forcibly, it is through the action of the ether that mankind is enabled to see. Not to mention the as yet incompletely verified hypothesis that it is of ether that Engineers and all other material substances are composed.

On Friday morning the serious electrical business of the section began, and Prof. Rowland exhibited his most recent photographs of the solar spectrum, obtained by a yet more nearly perfect concave grating which he had just completed. The photographs exhibited at a former meeting by Prof. Rowland had far eclipsed anything previously accomplished ; but those now shown were still better, and represent an extraordinary stage of perfection. They are by far the most magnificent things of the sort ever seen. The special appliances in Prof. Rowland's laboratory at Baltimore for this work are so perfect and convenient, that the whole solar spectrum can be photographed on an immense scale in the course of a morning. Terrestrial spectra, such as that of iron, can be photographed for purposes of comparison at the same time on the same strips of glass.

It may be hastily thought that such a subject belongs primarily to optics, but it is not so. Ingenious mechanical devices and optical theorems are made use of in obtaining the result, but the influence of the result is more felt in other sciences. The existence of such a standard of wave-lengths and permanent measurable records of atomic vibration reacts upon several of the sciences. It reacts upon astronomy by furnishing a statement of the present condition of sun and stars, with which future observations may be readily compared ; upon chemistry by exhibiting the relations among the vibration numbers of the elements, whereby hypotheses as to the construction and compound nature of our elements may be tested ; and it reacts upon electricity by affording us some knowledge of the precise way in which the ether is disturbed by electric oscillations in the substance of the atoms, as well as by the motions of electrically-charged atoms themselves.

Lord Rayleigh followed, with an account of an exceedingly delicate and difficult experiment on the question whether an electric current through a liquid influences the velocity of light therein. It is well known that when an electric current flows through an electrolyte an actual transfer of matter accompanies it—two opposite transfers, in fact, as evidenced by the continuous appearance and escape of the travellers, one at each electrode. It is also known by a refined experiment of Fizeau, confirmed by Michelson, that when a beam of light travels down a stream of moving matter its speed is slightly increased, whereas if light travel against a stream of water it is slightly retarded. These things being so, it may be held as probable that whenever the two ions taking part in an electrolytic current differ in momentum a slight effect may be exerted on the velocity of light travelling with or against the current. But then, according to the calculations of Kohlrausch, confirmed by some experiments of the present writer,* the speed of the electrolytic ions is extremely small, the quickest being 30 microns per second, or about 4 inches an hour, for an applied slope of potential of 1 volt per centimetre.

The effect of such a creep as this was not what Lord Rayleigh looked for. It was quite within the range of possibility that the existence of an electric current in an electrolyte should so disturb the ether inside it as to produce quite a notable change in its index of refraction. Were such an effect discovered it would be a distinctly new fact, not taken account of or even rendered probable by existing theories, and it is very well to have the question experimentally examined, and to a certain extent set at rest.

* Birmingham British Association Report, 1886, p. 393.

Digitized by Google

The method adopted was a beautiful interference arrangement of Michelson, whereby a beam of light is split up into two halves, which are sent along a certain route, or circular tour, in opposite directions, are then recombined into one again at the point whence they originally split off, and are examined by a magnifying eye-piece. The result is a set of interference bands more or less well defined. Tubes containing dilute sulphuric acid supplied with an electric current are then placed along the route taken by the two half beams of light, so that one half the beam will be helped and the other half hindered by the current, if it produce any effect at all. The thing looked for is to see if the interference fringes shift along microscopically when the current is supplied, stopped, or reversed. The result is negative, and by considering carefully how much of an effect could have been certainly perceived if it had existed, the definite statement is made that a current of intensity 1 ampere per square centimetre through dilute sulphuric acid does not affect the velocity of light in its own direction by so much as one part in thirteen millions, or by 15 metres per second.

There are two ways of experimenting. One is to order expensive and highly polished optical banks and other apparatus from an instrument maker; the other, to rig up an arrangement with odd bits of glass, cement and portions of telescopes. The born experimentalist adopts the latter plan; considering beforehand where exactness and steadiness is essential and where it is unnecessary, and accommodating his means to his end with forethought and localised precision. It is by this latter mode of experimenting that the just quoted result has been obtained.

A couple of Papers by the present writer followed. One, on the "Measurement of Electromagnetic Wave-Lengths," the other, on the "Impedance of Conductors to Leyden Jar Discharges." The point of the first Paper was to bring forward a case of electric resonance whereby pulses rushing to and fro along a couple of long insulated wires of certain length, synchronised with the known oscillations or alternations in a discharging Leyden jar circuit connected to them. The experiment is thus analogous to an acoustic experiment known by the name of Melde, wherein a tuning fork attached to a long stretched silk string throws it into synchronous vibrations when everything is properly adjusted. And just as the length of the sympathetic string is half the wave length of the sound emitted by the vibrating fork, so the length of each wire in the electrical analogue is half the length of the ethereal waves emitted by the discharging Leyden jar. These waves being essentially light, except that they are much too long to affect the retina. If Hertz had not simultaneously been experimenting in very similar directions, the interest of these experiments might have been greater, but as it is they are perhaps mainly interesting as affording a confirmation of the theory of Kirchhoff, Thomson, and Heaviside, regarding the rate of propagation of telegraphic impulses along a wire. These pulses travel at a speed always a trifle under the velocity of light—under certain perfectly known conditions very much under; but in the most favourable case of two thin parallel wires, transmitting exceedingly rapid oscillatory disturbances (the case of the above described experiment), the velocity of the pulses is, according to theory, exactly the velocity of light; and so it comes out in the experiment. The length of the waves emitted by the Leyden jar circuit can be calculated directly one knows the capacity of the jar and the self-induction of its circuit; the length of the waves sent along the wires can also be observed experimentally; the two determinations are found to be in close agreement.

The following data may be of interest:—

A microfarad condenser, discharging through a good conducting coil of 1 sec-ohm, gives a current alternating 159 times a second, and emits ether waves 1,200 miles long.

A gallon Leyden jar, discharging through a stout wire suspended round an ordinary sized room, emits waves between three or four hundred yards in length, its current alternating at the rate of a million per second.

A pint Leyden jar, sparking through an ordinary pair of discharging tongs, gives a current of 15 million alternations per second, with ether waves some 20 yards in length.

An ordinary electrostatic charge on a conducting sphere two feet in diameter, if disturbed in any way, will surge to and fro at the rate of 300 million vibrations a second, emitting waves a yard long.

Electric charges on bodies of atomic dimensions, if able to oscillate at all, would vibrate thousands of billions of times a second, and produce ultra-violet light.

The maximum amplitudes of current given in these several cases can also be stated if the initial difference of potential be given. For instance, the microfarad case charged to a volt will have a current amplitude of one milliampere; the pint jar case charged to give an inch spark will give a discharge current of maximum strength 2,500 amperes.

The second Paper by Prof. Lodge, "On Impedance of Conductors," has to do with the obstruction offered by conductors of different sizes and materials to sudden rushes of electricity. A series of experiments on the E.M.F. needed to force the contents of a Leyden jar, under given circumstances, through a wire of measured length and thickness arranged in the form of a circle (a single turn about a yard and a half in diameter being usually employed) are briefly described. The numerical results obtained are then compared with the theory of Clerk Maxwell and Lord Rayleigh, and are found to be in very satisfactory agreement.

The noteworthy thing about these sudden rushes, or violently alternating currents, is that they keep wholly to the outer surface of a conductor, and accordingly the obstruction they meet with has next to nothing to do with either the specific resistance or the magnetic properties of the material. A number of quantitative determinations have been made which will be published elsewhere.

The reason why these alternating or rapidly-varying currents keep to the outside of a conductor is merely because the outside affords the easiest path. If they penetrated its substance like steady currents do, it would have to be magnetised and demagnetised in concentric cylinders by them, and this would cause delay and obstruction. By keeping to the outside they avoid having to do this. It is true that they thereby throttle the conducting area open to them very considerably. They would meet with much less frictional resistance if they permeated the whole sectional area of the wire, but then, for these very rapid variations, frictional resistance is of far less consequence than the inertia-like obstruction of varying magnetisation; and, on the whole, they find it better to escape the inertia by keeping to the outside, even at the expense of a throttled and highly resisting path. The whole thing is a compromise, and currents of slower rates of alternation will penetrate deeper, always taking the course which reduces total obstruction to a minimum, until we come to steady or slowly-changing currents, to which the inertia effect of magnetisation matters next to nothing, while friction matters just as much to them as to any of the others; these, therefore, will flow through the whole cross section of the wire with complete uniformity. Regret was expressed both by Lord Rayleigh and by the President that Mr. Oliver Heaviside, who had done so much in the theory of these matters, was not present to join in the discussion.

Next came three Papers by Sir William Thomson, the third of which, as connected with the foregoing subject, it is convenient to take first. Its title is, "Five Applications of Fourier's Law of Diffusion, illustrated by a Diagram of Curves, with Absolute Numerical Values," and its subject matter is the accentuation of the analogy and complete mathematical equivalence existing between the different kinds of diffusion, so that the method suitable for treating one enables problems in the others to be solved. The best-known cases of diffusion are:—(*a*) *The diffusion of substance*, as when a heavy salt-solution creeps up from the bottom of a vessel of water until it becomes, in a century or two, thoroughly mixed; or when a scent diffuses in the air; (*b*) *the diffusion of momentum*, as when motion is transmitted from one part of a viscous fluid to the rest, this being the process by which tea can be stirred, and by which winds and whirlpools are brought to rest some time after the exciting cause has ceased; (*c*) *the diffusion of energy*, better known as the conduction of heat, a frequently quoted consequence of its laws being the gradual penetration of an

Digitized by Google

alternating disturbance deep and deeper into the substance of a conductor—as, for instance, the diurnal and annual fluctuation of temperature finding their way down into the crust of the earth, so that at a certain depth one could find evidence of heat waves six months behindhand; (*d*) *the diffusion of electric potential* in the conductor of a submarine cable, worked out long ago by Sir William Thomson as one of the problems to which Atlantic telegraphy gave rise, and by the solution and complete understanding of which rapid submarine telegraphy became practicable; and (*e*) *the diffusion of electric currents* in the substance of a homogeneous conductor.

It is this last kind of diffusion which is evidently most interesting Sir William at the present time, and he does justice to Mr. Oliver Heaviside's labours in connection with it.

I have been saying above that a very rapidly alternating current keeps to the outside of a conductor, just as a very rapidly alternating force applied to the surface of water in a trough (say by means of a flat board lying on it made to vibrate horizontally) would only succeed in moving the surface water; but this is not a complete account of the matter. When an alternating cause acts at a surface its effect penetrates in waves of diffusion through the mass, dying out according to a certain law of decay. If the alternations are slow the depth of penetration may be very great, as, for example, heat waves in the earth's crust; if they are excessively quick the depth of penetration may be very small indeed. And so for any given frequency of alternation, there is a specifiable depth at which the substance of the medium will appreciably take part in the action, and beyond which no noteworthy effect is produced. The problem, then, is to determine this depth for such rapidities of oscillation as are most common in practice.

The modern supply of alternating currents for secondary generators would seem to have a frequency of something like 150 complete alternations per second, and Sir William Thomson reckons that the depth to which these disturbances penetrate into the substance of a copper conductor is about 3 millimetres, so that portions of the conductor beyond this distance from the surface are almost useless. Hence manifestly conductors for powerful alternating currents should be hollow tubes, or flat bars, or separated wires, and the useful thickness of flat copper bars adapted to carry the present rapidity of alternating currents will be about 6 millimetres, or, say, $\frac{1}{4}$in.*

Of the other two communications of Sir William Thomson it is not easy to give an intelligible account without introducing technicalities; but inasmuch as they afforded a text for a great deal of discussion, both in and out of the section, I must try and give a general notion of what they are about. Their titles are, "A Simple Hypothesis for Electromagnetic Induction of Incomplete Circuits: with Consequent Equations of Electric Motion in fixed Homogeneous or Heterogeneous Solid Matter," and "On the Transference of Electricity within a Solid Conductor." It is not often that the public are admitted to the genesis of scientific ideas, or are allowed to witness a development of opinion going on before them. But in the presence of Sir William Thomson this is no new thing. At his Baltimore lectures a few years back the whole University turned itself with enthusiasm into a research society, and many germs of discovery flourished or faded during the few weeks those lectures lasted. Then, the main topic was an elastic-solid theory of light. Now, we may observe a further step, and without abandoning an elastic-solid theory, which in some form or another is a necessity, Sir William is assimilating, and criticising, and extending, Maxwell's electrical theory. Finding in it certain apparent excrescences and redundancies, he seeks to lop them off and keep only that which is essential. Long-standing students of both Thomson and Maxwell join in, and throughout the meeting there is, among the *dii majores*, discussion and keen competition to see through the fog of symbols, to disentangle their real physical meaning, and to find a right and proper position for the half lopped-off apparent excrescences of Maxwell.

The main point under discussion relates to the mode and rate of propagation of electrostatic potential as compared with electromagnetic potential. Electromagnetic disturbances correspond to shearing strains in an elastic solid; they travel through the ether with the velocity of light—the lines of magnetic force spreading broadside on—and about them there is no difficulty. Difficulties begin with the propagation of electrostatic displacements, which correspond to the disturbances possible in an ordinary fluid, longitudinal not transverse disturbances, having to do with incompressibility instead of rigidity, disturbances which in ordinary matter we call *sound*.

Suddenly confer upon a conductor an electric charge: in all directions there is experienced a rise of potential equal to $\frac{Q}{r}$. How did that potential reach any given place? Was it by end thrust, or pulse of longitudinal compression, like sound? and, if so, at what rate did it travel? Maxwell assumes the ether to be absolutely incompressible, and, if so, the rate of propagation of disturbances corresponding to sound waves in it is infinite. Longitudinal pulses are not, strictly speaking, *transmitted* at all through a medium of infinite incompressibility, they are simply felt at all distances instantaneously.

That ether is *enormously* incompressible is proved (so it seems to the writer, and he has probably acquired it insensibly through the pores from Maxwell) by an experiment which is best called the "Cavendish experiment," referred to (in a poverty-stricken form) in French books by the name of Biot, and popularly known as the "outsidedness" of electrostatic charge. It is also proved (again to the mind of the writer) by the fact established by Laplace that gravitation, if transmitted at all, is transmitted with a velocity too great to be ascertained at present, and certainly much greater than the velocity of light. But that anything is *infinitely* incompressible is an assertion which it is impossible to make on the basis of any experiment whatever.

Accordingly, Helmholtz has taken into account the possibility of a slight compressibility, and has generalised Maxwell's equations by the introduction of a symbol, k, expressing this compressibility. Helmholtz's equations, therefore, enable this quantity to have any value which experiment may hereafter determine for it, including the possible value 0, which would reduce his theory to Maxwell's again. It is the value of this constant, k, the compressibility of the ether, which the President referred to in his address as hoping to be able to deduce by a further analysis of the experiments of Hertz.

But now, directly a possibility of compression and a finite velocity for longitudinal waves is introduced into the ether, a long outstanding difficulty in the theory of light—a difficulty from which it was hoped the electrical theory would be free, though the ordinary elastic-solid theory is not free—at once makes its appearance. This is the old friend (or enemy) of undulatory theorists, the wave of longitudinal compression, or the "pressural wave," as it is sometimes called. Indeed, in the form of a pressural wave—the instantaneous transmission of a thrust to infinity—it must come in even to an incompressible ether, if the transmission of electrostatic potential occurs by end thrust.

This electrostatic potential is denoted in Maxwell's equations by the symbol Ψ, and so the attempt to get rid of it and do without it in the general equations of an electromagnetic field was referred to by the President as the "murder of Ψ." Many deaths, and many bringings to life, this unfortunate symbol suffered in the course of the week, and I would not like to say that its fate is even yet decided. On the last day of the meeting Rowland and Fitzgerald seemed to come to an understanding, but whether Sir William will coincide with it, or will upset the whole thing once more, remains to be seen. As they put it the matter is now like this: The propagation of electrostatic potential does not go on by end thrust at all; it is not really analogous to a pulse of longitudinal compression, though it is apparently and superficially so; and accordingly its rate of propagation depends not at all on the compressibility or incompressibility of the ether, a question on which it has nothing to say one way or the other. An electrostatic field is not developed *sui generis*, but is always the consequence of a previously existing electromagnetic one, which, on subsiding, leaves it as its permanent record.

Plainly an electrostatic field cannot arise without the motion

* These numbers are not authoritative.

Digitized by Google

of some electricity, either with or through a conductor. Now, whenever electricity moves, it at once has magnetic properties, its motion generates a magnetic field. When the motion ceases the field at once subsides, and in subsiding it may produce a succession of diffusing and dying away induction currents in neighbouring conductors; or it may, if the circuit be an incomplete one, leave a permanent vestige of itself in the dielectric as a field of strained ether—this state of strain being what we call electrostatic potential, and the field being familiar to us as an electrostatic field.

Generating it in this way, all distinction between rate of propagation of electrostatic and electromagnetic potential vanishes, they both travel together with the velocity of light; or rather, the thing which travels is the magnetic potential, and its permanent effect *in situ* is the electrostatic potential.

Thus, once more, the difficulty of a longitudinal or pressural wave disappears from the electrical theory of light, into which it had seemed to intrude itself, and Ψ is left to enjoy "a long and useful career," though it is not permitted an infinite or any other rate of propagation in its own proper nature. The question of the incompressibility or compressibility of the ether thus remains unanswered, and, as it would seem, unanswerable, by any such experiments as those of Hertz, or by any experiments on the rate of transmission of electrostatic potential. If any one asks how soon will the pull of a suddenly electrified body be felt at a distance ? one may answer, "As soon as the charging spark is seen." But if it be asked at what rate electrostatic potential travels, the answer is that it does not travel, but is generated *in situ* by the subsidence of a magnetic potential which travels with the velocity of light.

It must be understood that the last word has by no means been said on these great problems, and that what I have here written must be digested with salt. It is proper also to record the conviction expressed by the President that most of these refined points would probably be found mathematically treated somewhere in the writings of Mr. Heaviside.

(To be continued.)

HERTZ'S RESEARCHES ON ELECTRICAL OSCILLATIONS.

BY G. W. DE TUNZELMANN, B.SC.

(Continued from page 589.)

In a note in Wiedemann's *Annalen*, Vol. XXXI., page 543, Dr. Hertz states that since the publication of his Paper in the same volume, he had found that von Bezold had published a Paper in 1870 (Poggendorff's *Annalen*, Vol. CXL., page 541), in which he had arrived by a different method of experimenting at similar results and conclusions as those given by him under the head of Preliminary Experiments.

Induction Phenomena in Open Circuits.—In order to test more fully his conclusion that the sparks obtained in the experiments described in my last Paper were due to self-induction, Dr. Hertz placed a rectangle of copper wire with sides 10 and 20 centimetres in length respectively, broken by a short air space, with one of its sides parallel and close to various portions of the secondary circuit of the coil, and of the micrometer circuit, with solid dielectrics interposed, to obviate the possibility of sparking across, and he found that sparking in this rectangle invariably accompanied the discharges of the induction coil, the longest sparks being obtained when a side of the rectangle was close to the discharger.

A copper wire, *i g h* (Fig. 3), was next attached to the discharger, and a side of the micrometer circuit, which was supported on an insulating stand, was placed parallel to a portion of this wire, as shown in the diagram. The sparks at M were then found to be extremely feeble until a conductor, C, was attached to the free end, *h*, of the copper wire, when they increased to one or two millimetres in length. That the action of C was not an electrostatic one was shown by its producing no effect when attached at *g* instead of at *h*. When the knobs of the discharger B were so far separated that no sparking took place there, the sparks at M were also found to disappear, showing that these were due to the sudden discharges and not to the charging current. The sparks at the discharger which produced the most effect at the micrometer were of the same character as those described in my last Paper. Sparks were also found to occur between the micrometer circuit and insulated conductors in its vicinity. The sparks became much shorter when conductors of larger capacity were attached to the micrometer knobs, or when these were touched by the hand, showing that the quantity of electricity in motion was too small to charge these conductors to a similarly high potential. Joining the micrometer knobs by a wet thread did not perceptibly diminish the strength of the sparks. The effects in the micrometer circuit were not of sufficient strength to produce any sensation when it was touched or the circuit completed through the body.

In order to obtain further confirmation of the oscillatory nature of the current in the circuit *k i h g* (Fig. 3), the conductor C was again attached to *h*, and the micrometer knobs drawn apart until sparks only passed singly. A second conductor, C′, as nearly as possible similar to C, was then attached to *k*, when a stream of sparks was immediately observed, and it

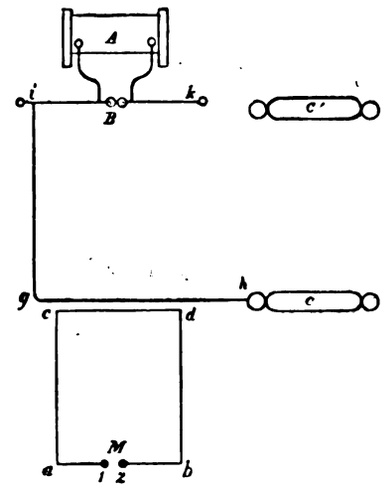

FIG. 3.

continued when the knobs were drawn still further apart. This effect could not be ascribed to a direct action of the portion of circuit *i k*, for in this case the action of the portion of circuit *g h* would be weakened, and it must therefore have consisted in C′ acting on the discharging current of C, a result which would be quite incomprehensible unless the current in *g h* were of an oscillatory character.

Since an oscillatory motion between C and C′ is essential for the production of powerful inductive effects, it will not be sufficient for the spark to occur in an exceedingly short time, but the resistance must at the same time not exceed certain limits. The inductive effects will therefore be excessively small if the induction coil included in the circuit C C′ is replaced by an electrical machine alternately charging and discharging itself, or if too small an induction coil is used; or, again, if the air space between the discharger knobs is too great, as in all these cases the motion ceases to be oscillatory.

The reason that the discharges of a powerful induction coil gives rise to oscillatory motion is that, firstly, it charges the terminals C and C′ to a high potential; secondly, it produces a sudden spark in the intervening circuit; and, thirdly, as soon as the discharge begins the resistance of the air space is so much reduced as to allow of oscillatory motion being set up. If the terminal conductors are of very large capacity, for example, if the terminals are in connection with a battery, the current of discharge may indefinitely reduce the resistance of the air space, but when the terminal conductors are of small capacity this must be done by a separate discharge, and there-

Digitized by Google

fore, under the conditions of the author's experiments, an induction coil was absolutely essential for the production of the oscillations.

As the induced sparks in the experiment last described were several millimetres in length, the author modified it by using the arrangement shown in Fig. 4, and greatly increasing the distance between the micrometer circuit and the secondary circuit of the induction coil. The terminal conductors C and C′ were three metres apart, and the wire between them was of copper, 2 millimetres in diameter, with the discharger B at its centre.

The micrometer circuit consisted, as in the preceding experiments, of a rectangle 80 centimetres broad by 120 centimetres long. With the nearest side of the micrometer circuit at a distance of half a millimetre from C B C′ sparks two millimetres in length were obtained at M, and though the length of the sparks decreased rapidly as the distance of the micrometer circuit was increased, a continuous stream of sparks was still obtained at a distance of one and a-half metres. The intervention of the observer's body between the micrometer circuit and the wire C B C′ produced no visible effect on the stream of sparks at M. That the effect was really due to the rectilinear conductor C B C′ was proved by the fact that when one or other, or both halves of this conductor were removed, the sparks at M ceased. The same effect was produced by drawing the knobs of the discharger B apart until sparks ceased to pass, showing that the effect was not due to the electrostatic potential difference of C and C′, as this would be increased by separating the discharger knobs beyond sparking distance.

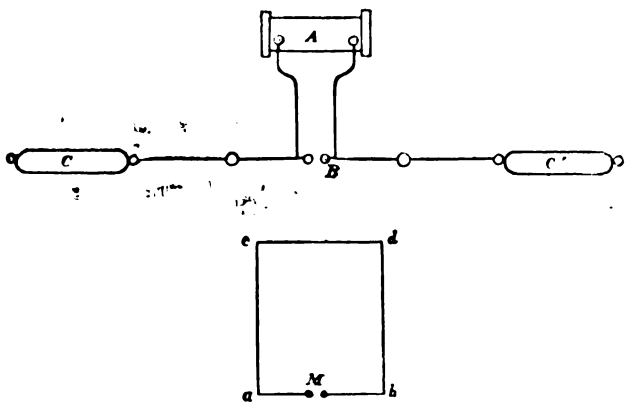

Fig. 4.

The closed micrometer circuit was then replaced by a straight copper wire, slightly shorter than the distance C C′, placed parallel to C B C′, and at a distance of 60 centimetres from it. This wire terminated in knobs, 10 centimetres in diameter, attached to insulating supports, and the spark micrometer divided it into two equal parts. Under these circumstances, sparks were obtained at the micrometer, as before.

With the rectilinear open micrometer circuit sparks were still observed at the micrometer when the discharger knobs of the secondary coil circuit were separated beyond sparking distance. This was, of course, due simply to electrostatic induction, and shows that the oscillatory current in C C′ was superposed upon the ordinary discharges. The electrostatic action could be got rid of by joining the micrometer knobs by means of a damp thread. The conductivity of this thread was therefore sufficient to afford a passage to the comparatively slow alternations of the coil discharge, but was not sufficient to provide a passage for the immeasureably more rapid alternations of the oscillatory current. Considerable sparking took place at the micrometer when its distance from C B C′ was 1 2 metres, and faint sparks were distinguishable up to 3 metres. At these distances it was not necessary to use the damp thread to get rid of the electrostatic action, as, owing to its diminishing more rapidly with increase of distance than the effect of the current induction, it was no longer able to produce sparks in the micrometer, as was proved by separating the discharger knobs beyond speaking distance, when sparks could no longer be perceived at the micrometer.

Resonance Phenomena.—In order to determine whether, as some minor phenomena had led the author to suppose, the oscillations were of the nature of a regular vibration, he availed himself of the principle of resonance. According to this principle, an oscillatory current of definite period would, other conditions being the same, exert a much greater inductive effect upon one of equal period than upon one differing even slightly from it.*

If, then, two circuits are taken having as nearly as possible equal vibration periods, the effect of one upon the other will be diminished by altering either the capacity or the coefficient of self-induction of one of them, as a change in either of them would alter the period of vibration of the circuit.

This was carried out by means of an arrangement very similar to that of Fig. 4. The conductor C C′ was replaced by a straight copper wire 2·6 metres in length and 5 millimetres in diameter, divided into two equal parts as before by a discharger. The discharger knobs were attached directly to the secondary terminals of the induction coil. Two hollow zinc spheres, 30 centimetres in diameter, were made to slide on the wire, one on each side of the discharger, and since, electrically speaking, these formed the terminals of the conductor, its length could be varied by altering their position. The micrometer circuit was chosen of such dimensions as to have, if the author's hypothesis were correct, a slightly shorter vibration period than that of C C′. It was formed of a square, with sides 75 centimetres in length, of copper wire 2 millimetres in diameter, and it was placed with its nearest side parallel to C B C′, and at a distance of 30 centimetres from it. The sparking distance at the micrometer was then found to be 0·9 millimetre. When the terminals of the micrometer circuit were placed in contact with two metal spheres 8 centimetres in diameter, supported on insulating stands, the sparking distance could be increased up to 2·5 millimetres. When these were replaced by much larger spheres the sparking distance was diminished to a small fraction of a millimetre. Similar results were obtained on connecting the micrometer terminals with the plates of a Kohlrausch condenser. When the plates were far apart the increase of capacity increased the sparking distance, but when the plates were brought close together the sparking distances again fell to a very small value.

The simplest method of adjusting the capacity of the micrometer circuit is to suspend to its ends two parallel wires, the distance and lengths of which are capable of variation. By this means the author succeeded in increasing the sparking distance up to three millimetres, after which it diminished when the wires were either lengthened or shortened. The decrease of the sparking distance on increasing the capacity was naturally to be expected; but it would be difficult to understand, except on the principle of resonance, why a decrease of the capacity should have the same effect.

The experiments were then varied by diminishing the capacity of the circuit C B C′ so as to shorten its period of oscillation, and the results confirmed those previously obtained, and a series of experiments in which the lengths and capacities of the circuits were varied in different ways, showed conclusively that the maximum effect does not depend on the conditions of either one of the two circuits, but on the existence of the proper relation between them.

When the two circuits were brought very close together, and the discharger knobs separated by an interval of 7 millimetres, sparks were obtained at the micrometer, which were also 7 millimetres in length, when the two circuits had been carefully adjusted to have the same period. The induced E.M.F.'s must in this case have attained nearly as high a value as the inducing ones.

To show the effect of varying the coefficient of self-induction, a series of rectangles, *a b c d* (Fig. 4), were taken, having a constant breadth, *a b*, but a length, *a c*, continually increasing from 10 centimetres up to 250 centimetres; it was found that the maximum effect was obtained with a length of 1·8 metres. The quantitative results of these experiments are shown in Fig. 5, in which the abscissæ of the curve are the double lengths of the rectangles, and the ordinates represent the corre

* *See* Oberbeck, Wiedemann's *Annalen*, Vol. XXVI., p. 245, 1885.

Digitized by Google

sponding maximum sparking distances. The sparking distances could not be determined with great exactness, but the errors were not sufficient to mask the general nature of the result.

In a second series of experiments the sides *a c* and *b d* were formed of loose coils of wire which were gradually pulled out, and the result is shown in Fig. 6. It will be seen that the maximum sparking distance was attained for a somewhat greater length of side, which is explained by the fact that in the latter experiments the self-induction only was increased by increase of length, while in the former series the capacity was increased as well. Varying the resistance of the micrometer circuit by using copper and German silver wires of various diameters was found to have no effect on the period of oscillation, and extremely little on the sparking distance.

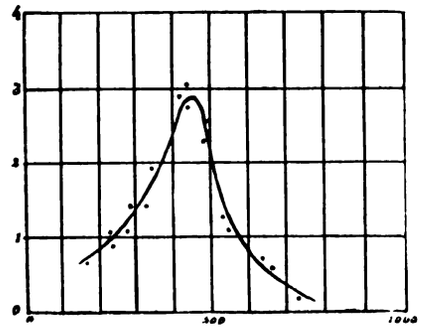

FIG. 5.

Curve showing relation between length of side of rectangle (taken as abscissa) and maximum sparking distance (taken as ordinate), the sides consisting of straight wires of varying lengths.

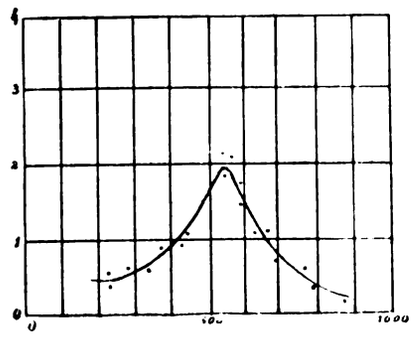

FIG. 6.

Curve showing relation between length of side of rectangle (taken as abscissa) and maximum sparking distance (taken as ordinate), the sides consisting of spirals gradually drawn out.

When the wire *c d* was surrounded by an iron tube, or when it was replaced by an iron wire, no perceptible effect was obtained, confirming the conclusion previously arrived at that the magnetism of the iron is unable to follow such rapid oscillations, and therefore exerts no appreciable effect.

(To be continued.)

DYNAMOS WITHOUT COMMUTATORS OR BRUSHES.

BY TH. MARCHER (OF MÜLHEIM).

The first recorded attempt to construct a continuous-current dynamo without the impedimenta of commutator and brushes is due to M. A. F. Gravier, who took out a patent in France for a dynamo of this class. In 1882 a Mr. E. Newton obtained a similar patent in England. In 1883 L. Hajnis, of Prague, took out a patent in Germany for a dynamo on this principle; but in which some of the defects of the Gravier machine were avoided. In 1887 the Cronstadt Electrical Manufacturing Company also designed a dynamo without commutators. Since then but little seems to have been done in this direction.

I will, in the first place, briefly describe the original Gravier machine, from which he subsequently developed the non-commutator type. In Fig. 1 N and S are the field-magnets; *a a a* and *b b b* are the armature coils, which are mounted on radial cores, as in the Lontin type; and $+f$ and $-f$ are the brushes. When the armature revolves in the direction shown by the large arrow currents are induced in the coils in the direction shown by the small arrows. The armature poles *a a a*, therefore, become S magnetised, and the poles *b b b* N magnetised. Now imagine a second armature of the ring type, interposed between the above-mentioned armature and the poles N S, this second armature having no coils at A′ A″ and B′ B″ (Fig. 2). The magnets *a a a* will produce in this armature a current flowing in the direction *c i*, and the magnets

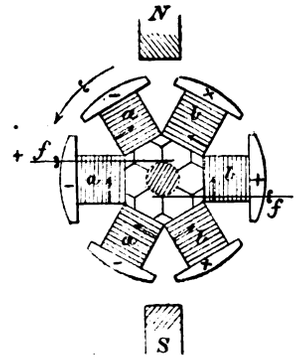

FIG. 1

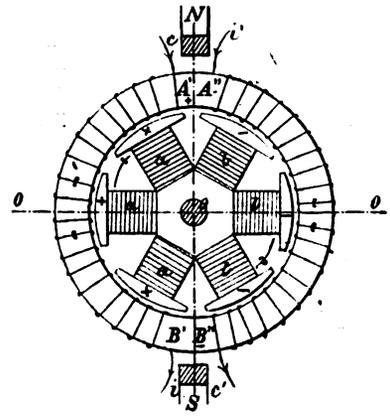

FIG. 2.

b b b will produce a current flowing in the reverse direction, *i′ c′*. Now, these two currents induce poles at A′ A″ and B′ B″ similar to those of the field-magnets, N S, at the adjacent points. If, therefore, sufficient residual magnetism was present, the magnet N S could be dispensed with, and the pole A′ A″ and B′ B″ would suffice. Gravier, however, was unable to get any good results from this form of machine, and subsequently designed one without commutator, collector, or brushes. In this dynamo (Fig. 3) Gravier had a revolving armature *i*, a revolving system of magnetisation, N S, a fixed armature I I, and a fixed system of magnetisation *n s*. The theoretical outcome of this arrangement is as follows:—The magnets *n s* induce currents in *i*, which excite the magnets N S, which in turn induce currents in I I; the current thus obtained passes into the external circuit, and also round the magnets *n s*. One method of winding is shown in Fig. 4. The Hajnis machine consists of the same four essential parts, namely, fixed armature and field-magnets, and revolving armature and field magnets, the revolving parts being mounted on the same shaft. This arrangement is shown diagramatically in Fig. 5. M M M M are fixed magnets, A A are revolving armature coils, B B B B are revolving magnets, and P P is the fixed ring armature. From each individual coil of the revolving armature connections are made to the corresponding magnet coil, each armature coil being one behind the

Digitized by Google

respective magnet coil. The action of the machine is easily understood.

To test the practical value of the system I built a dynamo, somewhat as shown in section in Fig. 6, where M_1 M_1 are the

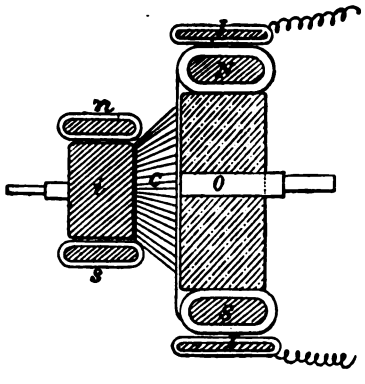

Fig. 3.

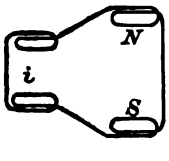

Fig. 4.

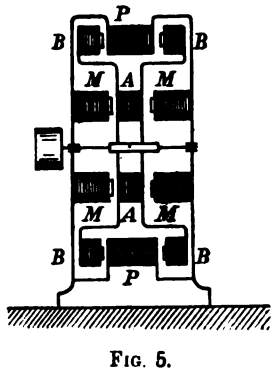

Fig. 5.

fixed magnets, I I the fixed armature, R R the revolving armature, M_2 M_2 the revolving magnets. The armature cores were both laminated in the customary manner. The experiments I carried out showed clearly that (as might have been expected)

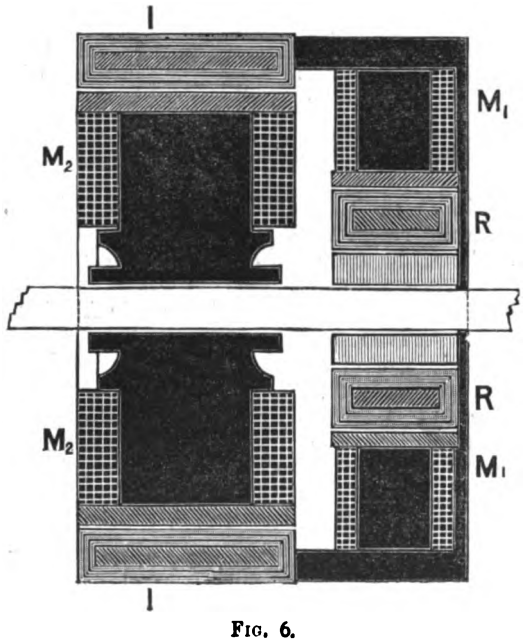

Fig. 6.

it was also necessary to laminate the revolving magnets to avoid eddy currents, and to magnetically separate the fixed magnet from the fixed armature. It would have been interesting to have carried the experiments further, and to have tested the efficiency of a machine constructed on this principle compared with that of an ordinary dynamo, but this I was unable to do at the time. Owing to the additional transformations of energy which take place in a dynamo of this kind, it is probable that its efficiency would be comparatively low; the avoidance of commutators and brushes would, however, I think, quite compensate for this inevitable defect.

LETTERS FOR LEARNERS AND UN-PROFESSIONAL READERS.

BY H. D. WILKINSON.

Chapter IX.—*Magnetic Fields.*

(Continued from page 571.)

Section II.—Electro-Magnetic Fields.

128. *Magnetising Force.*—The field of force set up in the interior of a coil of wire through which a current is flowing is found both by experiment and theoretical deductions to be proportional to the product of the strength of current and the number of turns of wire. If an iron bar be wrapped round with a given number of turns of wire, and a current of known strength passed through the wire, we have a definite field of force produced by the current in the coil which is capable of "exciting" or magnetising the iron. Hence we speak of the *exciting power* or *magnetising force* of the current, and in practice express it in *ampere-turns*. So long as the product of the number of amperes and number of turns is constant for a given volume of wire, the magnetising force is constant whatever individual values the current or number of turns may have. This is the same thing as saying that the current must vary inversely as the number of turns for the same magnetising force. For example, if we have one electro-magnet, A, wound with 50 turns of thick wire, and another, B, wound with 1,000 turns of fine wire, the volume or weight of wire being the same in the two coils, the current strengths in the coils must be in the proportion of 1,000 to 50, or as 20:1 respectively, in order to produce the same magnetising force on the iron in each. It is sometimes more convenient to express the number of turns or length of wire in terms of the resistance. We have already seen (para. 63) that the length of wire wound on a coil of fixed volume or weight varies as the square root of the resistance; therefore, for a given magnetising force the product of the current and the square root of the resistance of the coil must be constant; or, in other words, the resistance must be inversely proportional to the square of the current. Hence, in the above example, the resistances of the two coils A and B are respectively as $1 : (20)^2$, or as $1 : 400$. Further, since the volume is constant, the cross-sectional area of the wire multiplied by the number of turns is constant, and therefore the sectional area of the wire on each coil is inversely proportional to the number of turns on each, and the diameter of the wires are inversely proportional to the square root of the number of turns. Hence, in the above example, the diameters of the wires on coils A and B are in the ratio of $\sqrt{20}:1$ respectively. This is without taking into account space taken up by thickness of insulation. Similarly, the length of wire on each varies as the number of turns—viz., as 1:20 respectively.

129. *Variation in Field due to more or less complete Magnetic Circuit.*—Now let us measure with the magnetometer the strength of the external magnetic-field when the magnetising force is constant and the amount of iron in the magnetic circuit are varied. For this experiment two bobbins were taken (Fig. 109), each 20 centimetres long, and wound with No. 30 copper wire, to a resistance of 156·5ω. This represented, therefore, about 2,180ft. of wire wound on each (No. 30 measures 13·95ft. to the ohm at 60° F.). Also, the mean diameter of each coil being 4·25 centimetres, the mean length per turn of wire was $4{\cdot}25\pi = 4{\cdot}25 \times 3{\cdot}14 = 13{\cdot}3$ centimetres $= \frac{13{\cdot}3}{30{\cdot}48}$ ft. Hence the number of turns on each bobbin was

$$\frac{2180 \times 30{\cdot}48}{13{\cdot}3} = 5{,}000 \text{ turns approximately.}$$

Digitized by Google

The two bobbins of wire were then connected in series to produce opposite poles at N S when the battery was connected. The cylindrical iron cores were 23·2 centimetres long and 2·5 centimetres diameter, and the two keepers or yokes, one of which, Y, is shown, were each 11 centimetres long and 2·75 square centimetres in sectional area. The parallel axes of the bobbins were placed 5·5 centimetres apart, and a potential difference of 42 volts connected to the terminals, maintaining, therefore, a current of

$$\frac{42}{156{\cdot}5 \times 2} = 134 \text{ milliamperes}$$

through the two coils, and a constant magnetising force on each coil of $\cdot134 \times 5000 = 670$ ampere-turns.

The results obtained from the magnetometer readings are tabulated:—

——	Magnetometer deflection.	Magnetic Moment. C.-G.-S. units	Strength of Poles. C.-G.-S. units
Coils without iron cores ...	·2	—	—
Iron cores inserted.....	100	8,508	1,547
Yoke added at end A.....	440	38,030	6,915
Yoke added at end B.....	180	—	—
Last yoke removed and larger one substituted	0	—	—

The moments were determined in the manner already described (para. 125, 1st method), the perpendicular distance between the needle and the polar line of the electromagnet being 36·3 centimetres, and the deflection due to the coils alone being subtracted from each reading. The strength of pole was found by dividing the moment by the distance

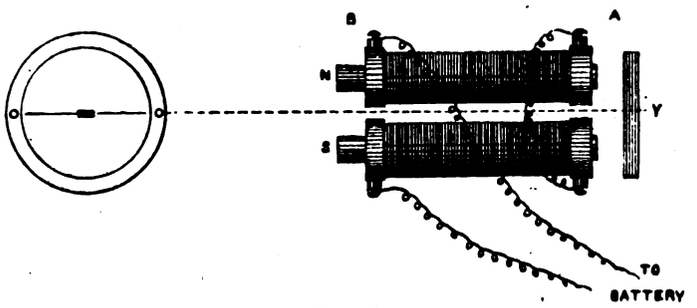

FIG. 109.

between the pole centres, 5·5 centimetres. The conclusions to be drawn from the above may be stated thus:—

1. A magnetic field is set up by the current in the coils alone.

(The deflection of two divisions at the distance of the coil from the magnetometer corresponds to a pole strength of about 30 C.-G.-S. units.)

2. The field is enormously increased by the insertion of iron cores.

Lines of force are evidently *created* by the presence of the iron in the field, since the magnetising force remains constant.

3. The field is still further increased by bridging across one air space by an iron yoke. Lines of force are again created, both through the interior of the iron and the remaining external air space, by making a more continuous iron circuit. We should therefore conclude that,

4. On completely closing the magnetic circuit by adding the second yoke at B, the field in the mass of the iron is still further increased, but that this tends to short-circuit the external field through the air. The magnetometer, however, being still deflected considerably, we should conclude that

5. The mass of iron is not sufficiently large to carry the whole of the field so created, and therefore there is some leakage of lines of force through the air, which affect the magnetometer. This is borne out by adding a larger mass of iron ($15{\cdot}2 \times 5 \times 1{\cdot}5$ centimetres) in place of the small yoke at B, which effectually short-circuits the field—that is, causes the flow of lines of force to be entirely within the iron mass.

(To be continued.)

DISRUPTIVE DISCHARGES AND THEIR RELATIONS TO UNDERGROUND CABLES.*

BY E. G. ACHESON.

From among the numerous problems that are earnestly calling for solution before perfection can be claimed in underground systems of electrical distribution for arc lighting, I selected as the one presenting probably the greatest importance, and, consequently, the one most desirable to solve, *the determination of the cause and cure of the frequent puncturing of the insulation, especially at the terminals, of lead-encased conductors, when carrying high potential currents.*

In a communication to the electrical press, under the title "The Influence of the Condenser on Disruptive Discharges," a detailed description of a series of experiments on the discharge between points in air was given, they having been made with varying E.M.F.'s and condenser capacities.

These experiments resulted in the formulation of the general law expressed in the equation

$$\frac{(\text{E.M.F.})^2 \times (\text{charge in coulombs})}{a} = d,$$

or

$$\frac{(\text{E.M.F.})^3 \times (\text{capacity})}{a} = d,$$

where a is a constant for the dielectric and d is the spark length, the charge being expressed in coulombs and the capacity in microfarads. In the same article the value of a was taken as 135 and d was expressed in inches.

While these experiments may serve as a basis or foundation to build upon, much more must be known before they will meet the requirements of the engineer operating with high potential currents, and with the object in view of obtaining at least a small portion of this required information, my experiments were extended into the more practical part of the subject, and furnished the results I have embodied in this Paper.

The most probable condition of a discharge in a cable would be between the cylindrical conductor and a point or projection on the lead covering; hence the first point to determine was the striking distance between such a cylindrical body and a projection or point.

Experiments were made with a point and the side of a wire, two sizes of the latter being used, a No. 8 and a No. 16 B. and S. wire gauge. There was no difference between the results obtained with the two sizes. The length of the spark was found to be about 55 per cent. when compared with that produced between points with the same E.M.F. and capacity.

This difference gives a new value for the constant a, which is found to be 263.

The equation for the spark length between a point and a cylinder will therefore be

$$\frac{(\text{E.M.F.})^3 \times (\text{capacity})}{263} = d \text{ (inches)}.$$

The following approximate values of a have been determined for the conditions and dielectric specified, d being expressed in inches.

Dielectric.	*Spark between.*	*a.*
Air	Points.....	135
Air	Points and wire.....	263
Paraffin and cotton	Points and wire	5,822
Ozite and cotton	Points and wire	7,759

The conditions governing the disruptive discharge, through the insulation of the covered, grounded cable, are so numerous that it would be quite impossible to exhaustively consider them, even if the necessary data were at hand, within the limits of this Paper. It will therefore be necessary to confine the subject to the more important conditions and the exposition of the law by means of a case that might be found in practical work.

Consider, for example, an arc-light circuit consisting of a dynamo and 30 lamps, connected in series by a lead-covered underground cable. For the purpose of illustration and calculation it is assumed that the lamps are separated a uniform distance of 300ft.; the size of the conductor, a No. 4 B. and S. wire gauge, insulated with one-tenth of an inch of cotton and paraffin; the capacity per mile is 0·704 microfarad, and the E.M.F. at the brushes of the dynamo 1,500 volts. Also, as an assistance in calculation, it is supposed that the drop in the E.M.F. occurs in the lamps only.

The capacity of each one of the 31 sections of cable separating the lamps and dynamo, and which are numbered in regular order from 1 to 31, will be 0·04 microfarad, and the capacity of each division, from conductor to conductor across the circuit, as between sections 2-30, will be,

$$\frac{\cdot04 \times \cdot04}{\cdot04 + \cdot04} = \cdot02 \text{ microfarad},$$

or, in this case, one half that of one side.

* Paper read at the Convention of the National Electrical Light Association recently held at New York.

Digitized by Google

With these conditions each division, composed of the paired sections, as 1-31, 2-30, 3-29, and so on, will have a potential tending to break through the insulation of the lead, and thence across the intervening medium in the direction of the broken lines, of a value of 1,500 volts at 1-31, and decreasing by 100 volts for each succeeding division.

These various potentials will, provided the insulation is perfect and the leads well grounded, induce a static charge between the conductor and the lead of each section, of a value measured by the potential across the division, and the specific inductive capacity and thickness of the insulating material.

In the case under consideration the thickness of the insulation and the specific inductive capacity are such as to induce a condenser capacity of ·02 microfarad, and with an E.M.F. of 1,400 volts, as would exist between 2-30, the charge would be $1,400 \times \cdot02$ (m.f.) = ·000028 coulomb; and if the conductors forming the two sides of this division should, while in this charged state, be insulated from each other, as might be done by breaking the electrical continuity at both ends of either one of the sides, the energy stored within it would be able to produce a disruptive charge through air, from the conductors to a point, or *vice versâ*, equal to

$$\frac{(1400)^2 \times \cdot000028}{263} = \cdot2087 \text{ inch.}$$

This is almost $2\frac{1}{10}$ times the thickness of the insulation; but the thickness of cotton and paraffin composing the insulation of the cable that this energy would pierce would be

$$\frac{(1400)^2 \times \cdot000028}{58\cdot22} = \cdot0094 \text{ inch}$$

or less than one-tenth of the thickness of the insulation.

Two questions now present themselves. First: are the sides of division 2-30, or any one of the others, liable to become insulated from each other, or attain a condition favourable for a discharge, for will there not always be a path open for discharge around the circuit, either by way of the lamps or the dynamo? The second question may be stated thus: Is it probable, with the conditions of the case above taken, that the insulation will ever be pierced, seeing that the discharge through the insulating medium cannot be greater than ·0094in., whereas the thickness of the insulation is 0·1in.

It is evident that from accidental causes, such as the breaking of the circuit at two points, it is possible to have the two sides of the division insulated from each other; but such accidents are not liable to occur, especially when it is remembered that the breaks would have to be made simultaneously. To make the probability of this action occurring worthy of consideration, other means of producing it must be looked for and found.

On a circuit using coils shunted round the arc, the electrical continuity is established at each end of the two sides of the division by one of these coils and the arc.

From the experiments of various experimenters, prominent among whom may be mentioned Prof. Hughes and Dr. Oliver J. Lodge, it is concluded that the self-induction in these coils would be of such a value as to offer an almost insurmountable barrier to the flow of the charge through them, and this being the case the discharge, if it occurs at all, must be through either the arc or the insulation of the cable. To determine whether the charge would pass off through the arc, the apparatus shown in Fig. 1 was used.

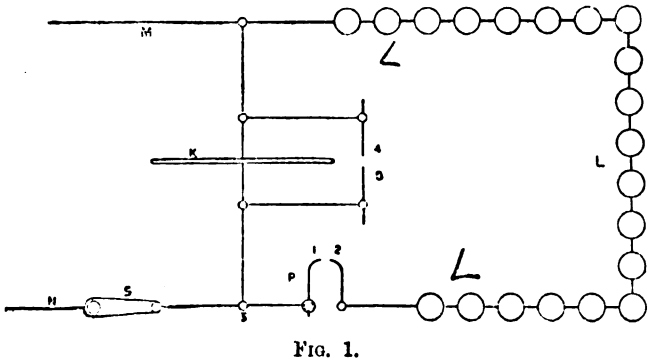

FIG. 1.

Twenty incandescent lamps, L L L, of 100 volts each, were connected in series to the lines M N; in the line N was placed the switch S and the contact points 1 and 2, the former being mounted in the revolving post P, thereby permitting of the points being opened. The condenser K was connected across the circuit from the line M at a point 3 between the switch and the contact points on the line N; around the condenser were placed the points 4 and 5, with suitable means of regulating the distance between them. M and N were connected to the sides of a transformer supplying an E.M.F. of 2,067 volts. The points 1 and 2 being in contact, no amount of rupturing of the circuit at S and adjusting of the space separating 4 and 5 would cause a discharge to occur between them; but upon opening the points 1 and 2, and thus establishing an arc in the circuit, the opening of the switch, S, would cause a heavy discharge between 4 and 5.

From this experiment and Dr. Lodge's results with circuits containing self-induction, the conclusion must be drawn that conditions favourable to a disruptive discharge are exceedingly likely to occur when upon opening an arc light circuit the various sections of the cable become, so far as the static charge is concerned, insulated from each other.

In considering the second question the fact is at once recognised that where the constant a for the dielectric surrounding the conductor is that of the cotton and the paraffin, a disruptive discharge would, under the circumstances cited, be impossible, and the answering of the question in the affirmative will therefore turn upon the probable lowering of the value of a.

Anyone familiar with insulations as applied to conductors knows that all of them, with the exception of rubber and gutta-percha and their compounds, will permit water or moisture to penetrate them, and as the hydro-carbons and water do not form chemical compounds, the one being insoluble in the other, this passage of the water must be a purely mechanical action, and furthermore, openings, cracks, or crevices must exist in order to permit of its passage. In many cases the cracks are visible to the eye, while in others they can only be detected by submerging the insulated conductor in water for a time and then testing electrically. But even after proving the existence of these cracks, it remains to be determined that the static charge will be influenced by them.

As one means of testing the case, a plate of glass ·072 inch thick was broken into two pieces, and the two parts immediately fitted into their former positions and held together by clamps. The crevice or space separating the parts was infinitesimal in width, as will be evident to anyone who may have made a similar experiment. The restored plate was placed between two discharge points, in such a position that the line joining the points passed through solid glass. Under these conditions I was not able, with my facilities, to cause a disruptive discharge to take place through the plate; but upon moving it so that the line joining the points would lie in the plane of the fracture, a disruptive discharge occurred with an E.M.F. of 2,067 volts, and a capacity in the circuit of ·00322 microfarad.

While this demonstrates the minuteness of the path required for a discharge, it is hardly a parallel case to what would exist in an insulated conductor where the insulation was built up out of many overlapping windings of fibrous material, and then treated with an insulating compound, for in this case the cracks or crevice produced by temperature variations and the bending incident to handling and laying of the conductor will not be direct lines or planes from the conductor to the metallic casing, but angle or zigzag lines, following the interstices of the fibrous structure. This difference would result in the lengthening of the path of discharge, but scarcely to an extent sufficient to raise the resistance to discharge to the value of the insulating material in a perfect state; and so long as the value is below that of the insulating material, the value of the constant a is also lowered, and it is therefore reasonable to assume that the conditions may become such as to warrant an affirmative answer to the second question.

Unfortunately, both of the two grand divisions of conductor insulators, the fibrous and the non-fibrous, have their faults, for while the fibrous has the, in some circumstances, serious fault of cracking, the non-fibrous has the even greater fault of losing its insulating qualities and running off the conductor when heated, as might occur by an accidental overloading of a circuit, and when it is confined, as in a lead covering, it permits the conductor to become decentralised and eventually come in contact with the lead casing. Between the two insulators, with the faults specified, inseparably associated with them, there would, for high potential currents, be little or no choice, but, fortunately, means have been devised whereby the existence of the cracks or crevices in the fibrous insulating envelopes when properly protected from water by a metallic casing is immaterial, as they are sheared of the power of diverting the discharge into the paths opened by them. These ends are accomplished by the simple expedient of causing the discharge to occur at such a place and in such a manner as not to pass through the insulating envelope.

This may be done in a great variety of ways, but the most simple one that has suggested itself to me is shown in Fig. 2, where A is the lead cover, I the insulation, C the conductor, and P a wire connected to A and extending out beyond I, its end, K, being adjusted in relation to C so as to leave an air space slightly less than the thickness of the insulating material I. Under these conditions, when a charge occurs it will invariably be at K and not through I.

While this simple arrangement illustrates the action and answers as a means of protection, it is evident that some device more durable and capable of adjustment would be preferable. A design meeting these requirements is shown in Fig. 3.

Digitized by Google

In the figure A is the lead covering, I the insulation, and C the conductor. Mounted on the lead A and held in place by the band V is the metallic arm P, carrying at its outer end the pointed rod R. Another pointed rod R′ is held by a projection on the ring B, which is mounted on the insulating bushing D. A fusible wire F connects the ring B to the metallic sleeve or collar E. The distance between the points R and R′ can be adjusted, and the rods held in position by suitable screws.

It is evident that the operation would be similar to that of the device shown in Fig. 2. The electrical potential between the conductor C and the lead covering A before attaining a height sufficient to discharge through the insulation I, will discharge across the air space between the rods R and R′, for these rods, being in electrical connection with A and C, will attain their potentials, and the points of the rods will, according to a known law, have an electrical density above that of A and C, or that requisite to produce a discharge across the intervening air. The fusible wire F is inserted as protection against injury to dynamos and cables in case of a ground existing on the other side of the circuit.

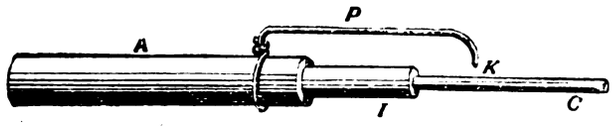

FIG. 2.

There are several points, apparently trivial, but really of much importance, relating to the design and material of construction of a device for discharging a cable.

The distance, measured on the exposed surface, separating the points of support of the discharging arms or rods, should be as great as possible, as there would be a loss of energy across this space in case the distance was small and dampness existed.

Another point to remember is that the constant a should have a known value, and therefore the most appropriate design, for the discharger is one employing points to discharge from an unvarying intervening medium, such as air.

In order to obtain some definite information on the question raised by Mr. Leggett at the Pittsburg meeting, as to the effect on the insulation of a short bend or indentation in the lead of a cable, I caused a very deep dent to be made in a cable, so deep, in fact, that it would at once have been condemned in practical work; and then connecting it into the working circuit, an attempt was made to cause a disruptive discharge to pass through the compressed insulation at the point of indentation; but the attempt was unsuccessful, the discharge preferring to occur at any other point.

Another experiment was made to determine the effect of bending the cable backward and forward several times in the same place. A length was selected in which the discharge always occurred at either one of the ends, and after the bending operation had been performed a number of times, I was able to produce the discharge through the bent portion in preference to the terminals.

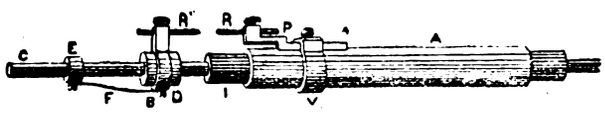

FIG. 3.

These tests show the superior strength of the insulation in the more condensed or homogeneous forms, and the weakening effect of much bending.

In this connection it may be well to inquire more fully into the tendency of the discharge to occur at the terminals of the lead.

It is a well-known fact that the greater number of the grounds or burn-outs that occur on arc-light circuits are at the terminals of the lead or at the joints, and it is precisely at these points that the charge, acting under well-established and familiar laws, would be most dense, and, owing to the presence of the edges or points for the electricity to flow from, the disruptive discharge will, under ordinary circumstances, take place between the edges or points and the conductor within the insulation. Owing to the special facilities offered at these places for the passage of the discharge, it is probable that in many cases burn-outs occur under the influence of a charge that would be unable to produce a discharge through the continuous portions of the cable.

In order to reduce the probability of a discharge occurring at terminals and joints, I would suggest that the lead whenever cut be made bell-shape in order that all edges or points be turned away from the conductor.

It may be appropriate at this point to consider briefly that vexed question, which way does the spark pass?

From the experiments and conclusions of Faraday I have made the following deductions:—

1. When the charged bodies are of the same size and form the *spark discharge* will, other things being equal, be *from* the positively-charged body.

2. Other things being equal, less potential is required to produce a *brush discharge* than a *spark discharge*, and when it does occur it will be from the negatively charged surface.

3. In all cases where the charge of electricity is on, or closely associated with, the discharging surfaces, a diminution of either surface will facilitate a discharge, and when any considerable difference exists in their areas the discharge will always be *from* the smaller surface.

4. A spark from a small body to a large one will be from eight to ten times greater in length when the small body is charged positively than it would be with a negative charge.

In general the direction of the discharge between the conductor and the lead, through the insulation, is subject to the form of the surfaces of the conducting bodies, a slight burr or point on either one being sufficient to determine the direction of the spark.

In a series of very interesting articles by Mr. G. L. Addenbrooke in the London *Electrical Review*, the subject of spark length disruptive discharges and the advantages of a perfectly continuous and unbroken dielectric are extensively treated. The influence of the capacity of the cable is, however, entirely neglected. Special stress is laid upon the advantages of a continuous envelope of insulation, and those using rubber-covered conductors are particularly cautioned against handling or bending them when the temperature is lower than 45° Fahr., as fissures or cracks are then liable to occur and permit of the passage of discharges. This, I confess, was information to me, and puts a certain limitation to the qualities I have given above to rubber, and which was written before this statement of Mr. Addenbrooke came into my hand.

As the experiments referred to in this Paper have extended over a considerable period (not less than six months), there have naturally been a number of questions and points presented from outside sources. Others have been led into the field to experiment, and with the equally natural result of obtaining in some cases effects that they have construed to be at variance with those I have secured. I have one case in mind where the experimenters found it impossible to produce a disruptive discharge so long as the lead of the cable was insulated from the ground; but the grounding of it made the production of the discharge feasible, and they concluded that the theory of a disruptive discharge was not correct. This is a repetition, under different conditions, of the very old experiment of attempting to charge a Leyden jar with the jar insulated. The first condition to be arrived at in the charging of a jar is the grounding of one of the surfaces.

A disruptive discharge through the insulation of the cable cannot occur without a charge being first formed; hence it is absolutely necessary that a ground be made to the lead.

The resistance of the ground connection to the lead is to a very great extent immaterial, as the charge is cumulative, and the energy expended in the discharge is only that held in the charge; hence though the ground resistance may be many megohms in value, and the charging process extend through a considerable time, there will eventually be a storage of energy on the surface of a value sufficient to rupture the insulation at the first change in the charging current.

The spark discharge is all but instantaneous in its action, and with the word restricted to this immeasurably short space of time it is necessary to have the energy on hand, as it were; there is no time to generate it, electrically, at the dynamo and convey it over long or even short distances.

The subject of disruptive discharges, with various resistances and self-induction placed in the path of energy, is beautifully treated in a Paper read by Dr. Oliver J. Lodge before the Society of Arts, April 17, 1888.

One word more before closing this subject. It is safe to predict that, the disruptive discharge being provided for, little or nothing more would be heard of the much-talked-of pin-holes in the lead and the moisture-absorbing terminals, the undergrounding of arc-light cables would become a thing of certainty, and our municipal governments relieved of a great bug-a-boo.

Cologne.—A recent examination of the lightning rods of Cologne Cathedral showed that the rod attached to the north tower had been struck; the flash must have been a violent one, for the platinum point was fused to a distance of 10 mm. During the last four years, the lightning conductors have protected the cathedral on five occasions. It is officially stated in Germany that fires due to lightning are steadily on the increase, and that since 1840 accidents from this cause have more than tripled.

The rates for the United Kingdom remain as follows:—	5 0	... 10 0	... 19 6

TO ADVERTISERS.

"The Electrician" offers exceptional advantages to Advertisers. **It has the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application to this office.

Trade Advertisements *intended for the current issue must be handed in not later than First Post on Thursday morning.*

Small Prepaid Advertisements *(for Rates see page XI.) are accepted up to 4 p.m. on Thursday.*

TECHNICAL PRINTING.

"The Electrician" Printing and Publishing Company (Limited) *beg to inform Electricians and Electric Light Engineers that they make a specialty of Technical Printing, and have a Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electrical Catalogues and Electro-Technical Literature generally.*

The Electricians' Directory.

Royal 8vo. Cloth Boards, 3s. 6d. Boards, 3s.

At the end of December in each year is issued The Electricians' Directory and Handbook. *The Directory was established in 1883, and has now attained considerable proportions. Every care is taken to make the names and addresses of all persons engaged in the Electrical Industries absolutely accurate. Useful Tables and Electrical Formulæ are given, together with popularly-written Biographical Notices of the leading Electricians, accompanied in many cases by Portraits.*

THE DIRECTORY FOR 1889 IS IN PREPARATION.

THE DISCUSSION ON LIGHTNING CONDUCTORS AT THE BRITISH ASSOCIATION.

The conjoint discussion between physicists and practical electrical engineers at the British Association meeting relating to the views recently put forward by Prof. Lodge on the subject of Lightning Conductors was certainly a very happy idea; and though its importance to the pure physicist was overshadowed by Prof. Fitzgerald's brilliant address, it was certainly, from the point of view of the electrical engineer, the most important outcome of the recent meeting.

The proposition put forward by Mr. Preece in his opening statement that "There is no authentic case on record where a properly constructed conductor failed to do its duty," accompanied by the statement that the principal object which he had in view was to defend it against all comers, was, as it stood, hardly called in question; but, as Prof. Lodge subsequently observed, the point in dispute was "what is it that constitutes a properly constructed conductor?" and though this question was not set at rest by the discussion, which, indeed, was not to be expected, many important points were raised on which further experiment is desirable; and we cannot doubt that a great impetus has been given to the investigation of a subject of the utmost practical importance.

Mr. Preece's contention that the magnetising power of lightning flashes militated against the oscillatory theory of the discharge gave rise to some suggestive remarks from Lord

Digitized by Google

RAYLEIGH and Sir WILLIAM THOMSON which, like most observations from these authorities, are worthy of careful attention.

Mr. PREECE's warning, read in the light of Prof. FORBES' commentary upon his mode of expressing it, against unpractical mathematical speculations based upon no secure experimental foundation, is a much needed one, and will, we trust, meet with the attention it deserves. To the younger electricians this warning is especially valuable. Rejoicing in a comparatively ample mathematical equipment, they are apt to forget that while, as was pointed out by the late Prof. J. STEPHEN SMITH in an address to the London Mathematical Society, mathematics is the one branch of science which has never had to retrace a step or plead guilty to an error; yet mathematical processes, however ingenious, can only enable us to discover what lies hidden in the data to which they are applied, and can therefore never by themselves lead us to a single physical truth.

Mr. PREECE was, however, not so happy in his selection of instances of blunders committed by mathematicians; for, as was pointed out by subsequent speakers, in each of the cases which he cited for illustration it was an engineer, and not a mathematician, whose prediction had been falsified. There are not many mathematicians, we should think, who would be willing to accept Dr. LARDNER as a representative of their science, and indeed we should be inclined to ascribe his being made to pose in that unwonted capacity to the amusing playfulness which helps to make Mr. PREECE such an agreeable antagonist, and his speeches so pleasant to read.

His contention that a lightning flash was analogous rather to the bursting of the dielectric in a Leyden jar than to the external discharge in which oscillations may occur, was, we should say, the most important objection brought by Mr. PREECE against the validity of Prof. LODGE's conclusions, and Prof. FITZGERALD appeared to be of the same opinion. Prof. LODGE, in the course of his remarks, somewhat ruthlessly demolished the arguments advanced by Mr. PREECE in his inaugural address to Section G in favour of regarding electricity as a form of energy. The instances which he quoted of the failure of lightning conductors of the most approved pattern, though not touching Mr. PREECE's opening assertion in the form in which he had stated it, certainly established the impossibility of maintaining that existing conductors never fail.

The fact to which Prof. LODGE called attention, that the sparking between the secondary terminals of an induction coil is facilitated by exposure to light, was one which may not improbably prove of value in helping to throw further light on the nature of electrical phenomena.

The photographs of lightning flashes which had been collected by a Committee of the Royal Meteorological Society and were exhibited by Mr. ABERCROMBY possessed considerable interest, and M. JANSSEN's suggestion that the unexplained "dark flash" might be due to over-exposure, not on account of an unusual lightness in the flash, but because of its having an unusually long duration, was a valuable one and will be worth following up by experiment. Mr. TRUEMAN WOOD thought that if the dark flash had been due to over-exposure, it would have shown over the white one, which it did not; and Lord RAYLEIGH afterwards pointed out that it might be due to a formation of oxides of nitrogen, as suggested by Prof. STOKES, by a decomposition of the oxygen and nitrogen of the air, as those oxides, being opaque to the chemical rays of the spectrum, would cause the path of the flash to appear as a black line in the photograph.

Sir WILLIAM THOMSON endorsed Prof. LODGE's conclusion that the protection of powder magazines should be carried out by making the walls, roof, and floor of iron and banishing lightning conductors altogether, the iron floor, of course, being protected by means of a covering of wooden boards to obviate the possibility of sparks arising from persons walking upon an iron floor.

In the report of the Lightning Rod Conference, which was drawn up in December, 1881, while the importance of having all ironwork on the roofs of buildings in perfect metallic connection with the lightning conductor is insisted on, it is asserted that the possibility of such metal work inducing the charge to desert the conductor when struck by lightning could only occur if it were of inadequate conducting power, or imperfectly earth-connected. The results of the discussion, to say the least, throw considerable doubt on the truth of that statement. We also take it that no sane person who has studied the discussion will care to try the experiment of holding on to a conductor during a thunderstorm, in spite of the statement in the report alluded to, that "a man may with perfect impunity clasp a copper rod an inch in diameter, the bottom of which is well connected with moist earth, while the top of it receives a violent flash of lightning." The further statement that such a conductor might with impunity be surrounded with gunpowder is one which, we trust, will not be made the subject of an experimental trial.

IMPROVEMENTS IN THE TELEPHONE SYSTEM OF GLASGOW AND THE WEST OF SCOTLAND.

BY D. SINCLAIR, Engineer, National Telephone Company.

(Concluded from page 597.)

A comparatively new thing in telephone exchange business is the introduction of telephone call boxes. These are fixed at convenient places, and connected with the exchange system. Some companies charge their subscribers and the public alike for the use of them, but in Glasgow it has always been an advantage held out to intending subscribers that they could have the use of these boxes free of charge, and that consequently from any district of the city they could speak to their office. This system is very much taken advantage of.

With the idea of allowing subscribers to talk free of charge, and at the same time make non-subscribers pay for communication, a simple automatic call-box has been brought out by Mr. Smith, of Glasgow, and myself. The invention is little more than two years old, and we already have ninety of them at work in Glasgow and the West of Scotland. Nothing could be more successful than the manner in which these instruments have done the work required of them. A marked feature in the arrangement of the call-box is that no money is put in until the party wishing for the connection has spoken to the exchange and has ascertained that he can have the connection which he wants. If the line is clear the customer has next to put the toll into the box. The operator is able to tell whether or not this is put in, and Figs. 9A, 9B, 9C show diagramatically how this is accomplished.

If a local connection is wanted, *i.e.*, a connection in the same town, threepence is the charge, and the operator joins a battery on to the wire with a single-stroke bell in circuit. As the pennies drop into the box they momentarily disconnect the line, and the bell sounds once for each penny as it falls into the box. If sixpence is wanted for a connection by trunk wire to another town, the coin, in falling into the box, disconnects the local circuit of the telephone at the call box, the operator hearing a smart click in her telephone. I am aware that electricians can tell me that this click can be produced otherwise than by putting in the sixpence, but the users do

not know this, neither do they try, and if they did, the operator, after a little experience, knows at once if the least symptom of tampering takes place.

Up to this point I have only spoken of single wires, between which there is always a certain amount of overhearing by induction from one wire to another; but this is by no means of such vast importance in telephone exchange business as many have made of it. In Glasgow there are hundreds of single wires on which there never has been any practical trouble from overhearing by induction. The number who have suffered from this annoyance is very small indeed, certainly not more than one per cent. of the total number. Our experience roughly is, that where two or three wires only run on a line of poles for three miles and over, the effects from induction are such as to interfere with the proper use of the telephone. On shorter wires, and where greater numbers exist on the same

poles, the induction is not of such a character as to interfere with the proper and business use of the telephone; it is true that there is not perfect quietness, but who in a busy city can command it, in the streets, in the offices or anywhere else?

For wires running together for long distances and on all trunk lines we use twisted metallic loops. The manner in which we join local single wires so as to speak through loop wires is shown on Fig. 10.

For this purpose we use an induction coil, with the secondary in the loop circuit and the subscribers' lines at each end through the primary circuit to earth, thus acting as a translator in the same manner as the induction coil in every telephone acts as a translator from the local circuit to the line wire. This arrangement works very well on our longest lines of between 80 and 100 miles. After considerable experimenting on the line between Glasgow and Edinburgh, the best results I got were with the wire joined as in Fig. 11. This differs from the ordinary method in having a battery of ten cells placed in the loop circuit at each end. The batteries are so joined up as to cause a continuous current to flow in the loop circuit all the time the speaking is being done.

The subject of inductive disturbances between telephone wires is one that is always before telephone engineers.

Time and experience have yet much to say on this subject. The results of the experience which I have so far gained I would sum up by saying that I know of no telephone circuit that is perfectly clear of all disturbances but the twisted metallic loop circuit. I know of no arrangement or condition of telephone wires or circuits where facilities are provided for the disturbing inductive effects to go to earth that they do not do so, and always in proportion to the facilities so provided—*e.g.*, a fifty-wire cable of, say, 200 yards in length, having telephones joined on two of the wires, with all the ends of the other wires insulated, will show that speaking by induction between these two wires is almost as strong as speaking direct on either of the wires; but when the other forty-eight wires are put direct to earth, either at one or both ends of the cable, the overhearing by induction practically ceases to exist. If any resistance is introduced between the forty-eight wires and the earth the overhearing between the two wires increases in proportion to the resistance so introduced.

ON A SYSTEM OF ELECTRICAL DISTRIBUTION.*

BY HENRY EDMUNDS.

The problem of the distribution of electricity has considerably occupied the attention of engineers lately, and several methods are in practical use, which may be classified as follows:—The direct low tension, in which currents of large volume are transmitted, requiring correspondingly large conductors. This system has the advantage of extreme simplicity, but is limited in its operations to short distances from the source of supply. Another is the secondary generator or converter system, in which alternating currents of smaller volume but much higher tension, are used—lessening considerably the weight of conductors, and getting over the limit of distance, enabling comparatively small wires to supply electiric energy over a large area, but attended with increased danger to life and property from leakage, and neutralising the saving of cost in copper in the increased cost of insulation and protection of the conductors. Both these systems are, however, subject to the annoyance of fluctuation in case of varying pressure, or total extinction of light, due to stoppage of machinery, when all work would cease. And if in order to minimise such accidents the generating plant be duplicated, the already large cost of machines, whose maximum output is only occasionally demanded, is enormously increased, thus adding to the capital invested and interest expected thereon.

In order to obviate the difficulties inevitably connected with any system of direct supply, of being always dependent on the continuity and regularity of the motive power, accumulators or storage batteries have been proposed, as it is seen to be necessary to have the equivalent of the gasholder to the retort, or the water cistern or reservoir to the spring or pump, in order to have a reserve independent of the source. This brings us to the question of how to supply batteries to the best advantage, and to examine into the methods hitherto employed on a large scale in connection with the public supply of electricity for lighting or other purposes.

In 1882 and 1883 I was in New York with the Brush Illuminating Company of that city, taking charge of the demonstration there of Mr. Brush's new system, which consisted in the employment of storage batteries, located in groups in series to each other, charged from a common main, carrying a 10-ampere current (the same being used to operate their arc lamps at night), devices being employed to automatically disconnect the batteries from the charging main when fully charged, and *vice versâ*, the idea being by this method to obtain double duty from their existing illuminating plant, and enabling them to charge batteries by day and run arc lamps direct at night, the charged batteries at the same time supplying current for incandescent lighting. But in actual practice serious difficulties soon presented themselves. The current employed for charging was too small, and there was not time to charge the batteries sufficiently during the hours of day for any great demand there might be made on them at night. Suggestions were made to obviate this by charging a larger number of small cells in series, and discharging in multiple. But this demanded correspondingly higher voltage pressure in the mains and at the generating station, which presented very serious practical difficulties. Batteries being so charged could not be used to supply light locally at the time of charging, thus removing the great *desideratum* in electric service, viz, continuous supply; and, further, the risk of breakage and damage therefrom was greatly increased. Besides, batteries under charge have an increased voltage, which either injures the lamps or causes annoyance by fluctuation. Ultimately, after great cost and expense, this promising system was abandoned, and, I learnt when in the United States a few weeks ago, has never been revived.

In England, also, experiments on a large scale were made at Colchester about the same period. Here batteries were charged with a high pressure changing current of small volume—duplicate sets of cells were employed, so that one set was being charged from the main while the other was discharging locally. But again difficulties presented themselves in practice. The pressure at the station or the charging mains, being at least equal to the sum of all the batteries in series, was either very high or else limited; the number of groups on circuit that could be charged at one time, also the freshly charged cells having a higher E.M.F. than those that had been discharging, caused serious fluctuation in the lights during the change from the main to the local. And as the cells automatically changed their position from the main to the local only when they had themselves arrived at a certain condition of charge, sometimes the local cells had got over discharged, causing serious damage through buckling and deterioration generally. The result was that the Colchester system was ultimately abandoned.

Having thus far glanced at the history of electrical supply, I now turn to the method proposed and patented by myself, known as the Edmund's System of Electricity Distribution, such as is now being employed in actual practice by the Cadogan Electricity Supply Company, London. This system differs essentially in every point from any of the plans hitherto tried or in operation at the present time, and may be thus described:—

A number of groups of cells, which we will call the local batteries, are placed at different points or centres where supply is required in the district, each battery having its individual number of cells according to the voltage required locally and the amount of current to be supplied. Unlike the Brush method referred to, these local batteries are electrically distinct and independent of each other and of the charging main; neither is there a duplicate set to be changed as at Colchester, but instead we employ an additional group with each of the local batteries, which we will term the main batteries, the number of cells of which are a divisor of the number employed

* Paper read before the British Association meeting at Bath, September, 1888. Section G.

Digitized by Google

locally—generally one-third. For example, suppose the local voltage be 48 volts, 32 cells would be employed, which we would subdivide into four groups, eight cells in each, and for purposes of identification we will call these groups *a*, *b*, *c*, and *d* respectively. Groups *b*, *c* and *d* are connected in series in the local (*see* diagram), giving 48 volts. Group *a*, being in the main, being charged for a limited period of time—in practice two minutes—is then removed from the main charging circuit and placed in the local discharging circuit, when, say, group *b* is removed from the local into the main to be charged ; *b* now in turn exchanges places with *c* and *c* with *d*, so that each group *a*, *b*, *c*, *d* follows each other in turns from the main to the local or local to main, whereby in every eight minutes each group has received its increment of charge from the main and has supplied the same in turn to the local, and so on continuously, until in twenty-four hours each group has received its full charge of current, enabling the battery to maintain its maximum discharge for eight hours, the current employed in practice being 70 amperes, and the size of cells proportionate. Incidentally we find many advantages due to charging cells in this manner. We can maintain a constant potential on the local circuit, so that we have not the interference and fluctuation due to charging and discharging at the same time. The high-tension main is never at any time in electrical contact with the local circuit, thereby freeing the system from leakage to earth and its attendant danger. Also the cells are kept in much better condition by continually receiving short increments of charge and having periods of rest from discharge. The loss due to difference of potential between the charging and discharging current is minimised, it being found in practice we can continue charging the cell to its maximum capacity with a mean voltage of 2·25, instead of 2·5 per cell, as is required where cells are charged continuously. This, on a large scale, is a considerable element of economy where there are a number of cells in the charging main. Also we find that an approximately constant potential on the local circuit enables us to run lamps at a higher efficiency without the risk of rupture due to sudden rises of pressure ; and, so far as we can judge, the life of the batteries is considerably lengthened by this mode of intermittent charge and rest. And, in addition to all these advantages, we have a great saving in the generating station in cost of plant, only one-third the power being required to operate the same number of lights for eight hours that would be necessary for any direct system, and much less electric force or pressure on the charging mains to supply the same number of lamps, thereby saving cost of installation and chance of leakage.

The additional advantage of being able to run a smaller station for 24 hours in the day is obvious, as we do not have any idle plant, with interest thereon. The current being always constant in volume enables a single main of one size throughout to be used, preventing complications, and only requiring increase of pressure as the work extends, which pressure would be only one-third the Brush or Colchester systems referred to for the same number of cells in the local centres, or could at their pressure charge three times the number of batteries. For example, where batteries are used in 100 centres on the Brush or Colchester plan, each centre giving 50 volts, requiring at the station a charging potential of over 5,600 volts exclusive of the line, while with the distributor plan it would only require a charging potential of under 2,000 volts for the same work, with this it would be only 1,800 or 2,000 volts, according to the length of the line.

The apparatus for carrying out this system I call a distributor (Fig. A). It combines in one instrument a time mechanism causing changes to occur at regular periods of, say, two minutes, by energising an electro magnet at each period, rotating a shaft carrying cams that cause levers to make the necessary contacts for changing the position of the cells from local to charge and *vice versâ*, a polarised switch, whereby the current is prevented from entering the batteries in the wrong direction, and a voltage regulator which causes the batteries as a whole to cut themselves out of the charging main or otherwise, according to their being fully charged or requiring charge. A simple form of meter registering the current is supplied. The diagram of the cycles of operation will explain what takes place, and I have constructed several distinct instruments for effecting these cycles, some with levers and mercury contacts, one with rotary brush contacts like a compound commutator, and the one shown in cut which we are now using, in the designing of which I have received great help from my assistant engineer, Mr. Albert Howard.

The manner of effecting the cycles is explained by diagrams 1 to 6 A, B, C and D represent the accumulators at one point of lighting, which are divided into four equal groups. For instance, imagine there are 32 cells in one house, then A group would consist of 8 cells connected together in series, and B C and D the same.

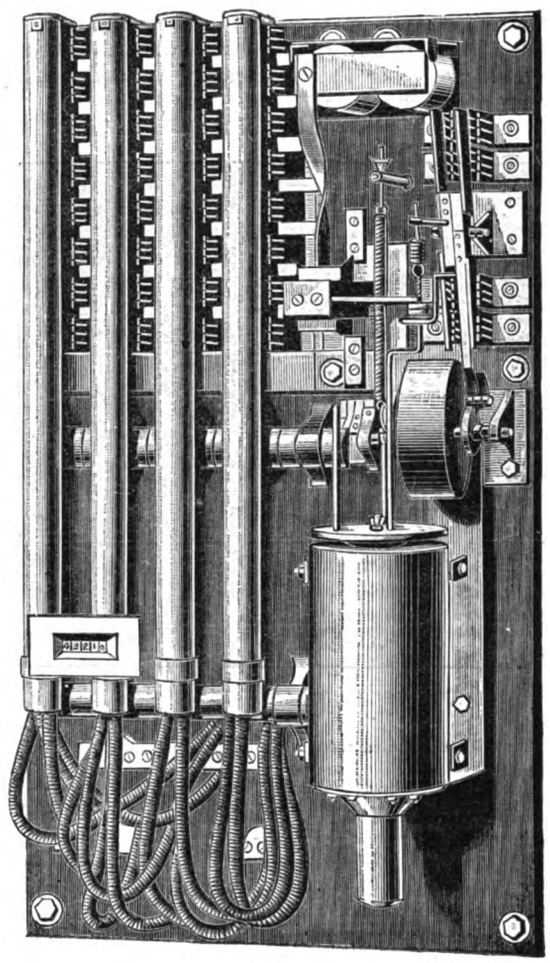

FIG. A.

In diagram 1, A is receiving a charge from the central station, over the main cable B, and batteries B C and D are connected together in series and furnishing current to the lights B. After this state of discharge has been in operation for a fixed interval of time, the distributor begins to work automatically and makes the various connections necessary, as follows :—

Fig. 2. A resistance, I, has been switched into the main circuit in parallel with battery A.

Fig 3. A has been switched entirely out of circuit, leaving the main current of 70 amperes, which have never been interrupted, flowing through the resistance Y.

Fig. 4. A has been switched into parallel with B, in the local or discharge circuit. This is done without the slightest alteration in the lights, as the electromotive force remains the same as before.

Fig. 5. B has been cut out from the discharge circuit, leaving the lights on to A C and D.

Fig. 5. B has been connected into the main charging circuit in parallel with the resistance Y.

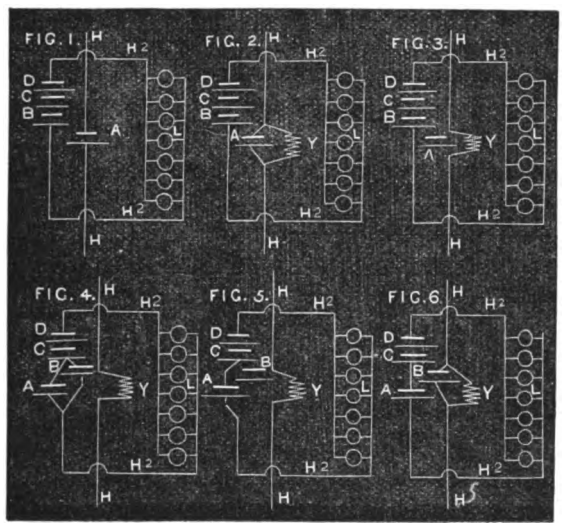
The resistance Y is then disconnected, leaving the charging current flowing through B, which receives a charge for the fixed interval of time and is then switched back into the local

Digitized by Google

circuit, while C receives its increment of charge. In this way each section of the batteries passes through equal periods of charge and discharge.

The time occupied in the mechanical movement of the entire cycle is three-quarters of a second, and the period during which the charge is on can be varied at will.

Such a system as I have briefly described lends itself to many purposes in connection with electricity supply. For instance, in the working of a railroad switches and signals, electrically, a distribution at each block station would enable a whole line of rail, say 200 miles, to be supplied from one source, the pressure on the main being only a small fraction of the sum of the local pressure, or in electric tramway work, a charged main, well insulated, of high pressure, could supply a number of points *en route*, which in turn could each, independently of the other, supply large-volume, low-pressure currents locally, saving risk of breakdown and consequent interruption of traffic.



But more particularly is it useful in detached house and surburban lighting, for it solves the problem of giving each house its own individual supply of electricity continuously day and night, totally independent of continuous or regular working at the central station or of interference from other work on the same circuit, being at the same time absolutely safe from the danger of shock, and, above all, supplying the electric light at a reasonable cost.

ON THE MEASUREMENT OF ELECTRICITY IN A HOUSE-TO-HOUSE SUPPLY.*

BY W. LOWRIE.

The supply of electricity from central stations has for years received a large amount of attention, but until within quite recently a practical house-to-house supply was impossible, owing to the enormous weight and cost of the copper conductors or mains required to convey large currents at low tensions to any considerable distance. The sectional area had to be very great, to avoid a high percentage of loss due to resistance. This objection, which was fatal to any extensive venture in a house-to-house supply of electricity, has now been overcome by the introduction of high tension, alternating current, and secondary generator or converter system. By the employment of this system the current is so greatly reduced, and therefore the size of the mains is so lessened, that even in very long distances any loss due to their resistance may be reduced to a practicable minimum without any serious outlay of capital.

One of the most important features in a house-to-house supply of electricity is a reliable method of a meterage to the different consumers; now, even in the case of the old systems of low tension continuous-current circuits, the difficulties of meterage have hitherto not been satisfactorily overcome, the greatest difficulty in these systems being the very high percentage of loss due to the passage of very large currents through the resistance offered them by the coils or other mechanical appliances which have to be introduced into the circuit rendering it impossible to obtain the full luminosity of the lamps; or in the case of an electro-deposition meter the enormous quantity of copper carried from plate to plate, and consequently their large area and thickness, which is necessary, and also the difficulties connected with the accurate weighing of these very heavy plates, are insurmountable objections. Still more difficult has it been considered to meter alternating currents, for they will neither deposit metals nor decompose liquids; and if any attempt is made to construct a mechanical meter retardation is set up against the current to so great an extent in the coil or coils necessary to control or act as a motive power to suitable mechanism that here again insurmountable objections are met with. But it is the very fact of this inability of the alternating current to deposit metals or decompose liquids, which has hitherto been considered fatal to any system of meterage, which enabled Messrs. Lowrie, Hall and Kolle, the inventors of the new system herein described, to form a most efficient and reliable method of electro-deposition meterage. This new system is the differentiation of the main or alternating electromotive force. This desired effect can be brought about in many ways, the one used now by Messrs. Lowrie and Hall in their house-to-house lighting system at Eastbourne being by the introduction of a constant electromotive force into the said main or alternating circuit, which, whilst it reinforces the main electromotive force in the half-alternation in a direction positive to it, retards it in that direction which is negative to it, so producing a subsidiary or resultant extra current to the main or alternating current in that half-alternation which is positive to the constant electromotive force. This subsidiary current must be necesarily exactly proportional to the main current, or, what is the same thing, to the resistance of those appliances in which the electrical energy is expended. Thus, by putting a deposition cell in series with the source of the constant electromotive force, the amount of deposit will become available as a current measure. So that the fact of the current being an alternating one allows the use of a deposition cell (when the addition of a constant electromotive force has been made), for where, as before pointed out with a continuous current, the passage of copper would be excessively large. By the application of this invention to an alternating current this passage may be reduced to a minimum so long as it remains sufficient for a practical measurement, for this said passage depends alone on the magnitude of the subsidiary electromotive force.

Having now described their method of obtaining an alternating current, in which the maximum current in one half of an alternation is greater than that in the other half in the opposite direction, we will proceed to describe the practical method of obtaining from it the efficient method of meterage at present adopted by Messrs. Lowrie and Hall, and to give a detailed description of the appliances and also the methods of obtaining constants, &c., and other matters appertaining thereunto. The main is severed as it proceeds directly from the dynamo, converter, or other source of electrical energy to the lamps or other appliances in which the energy is expended, and the meter put across the break, so that the entire current which has to be metered passes directly through it. The current on entering the meter passes through a secondary cell, whose electromotive force = 2 volts, so producing the necessary differentiation in the positive and negative directions in half of an alternation. That is to say, that supposing the electromotive force of the dynamo or converter to be 100 volts and the mean current to be 10 amperes, then in the half-alternation positive to the constant cell at its maximum point, total electromotive force = 202 volts, therefore the maximum current $= \frac{202}{10} = 20{\cdot}2$ amperes, while in the other half-

* Paper communicated by Mr. W. H. Preece, F.R.S., to the British Association meeting (Section G) at Bath, September, 1888.

Digitized by Google

alternation total resultant electromotive force = 198 volts, therefore the current = $\frac{198}{10}$ = 19·8 amperes, so giving an effective current of ·4 amperes. But this current lasts for only one-half of an alternation, in the same way that an alternating current does, in consequence of its necessary fall from its maximum positive point to a neutral point in order to rise to its maximum negative point, so that, although at its maximum point the effective current = ·4 amperes, yet its average current is only ·2 amperes for all the time, or, which is the same thing, a current due to 2 volts only. So it is evident that the resultant current may be considered as one merely resulting from 2 volts constantly acting through the circuit resistance. The application of this effective current takes place in a depositing cell, which is a cell in which the electrodes are of copper, alternately connected together, and the solution a slightly acidulated saturated solution of recrystallised sulphate of copper in distilled water.

The meter exhibited is one for a twenty 16 candle-powder 100-volt lamp installation, or for a maximum current of 12 amperes, the area of the plates being 48 square inches, giving an area of 4 square inches per ampere, which, with the strong solution used, gives a resistance quite neglectable.

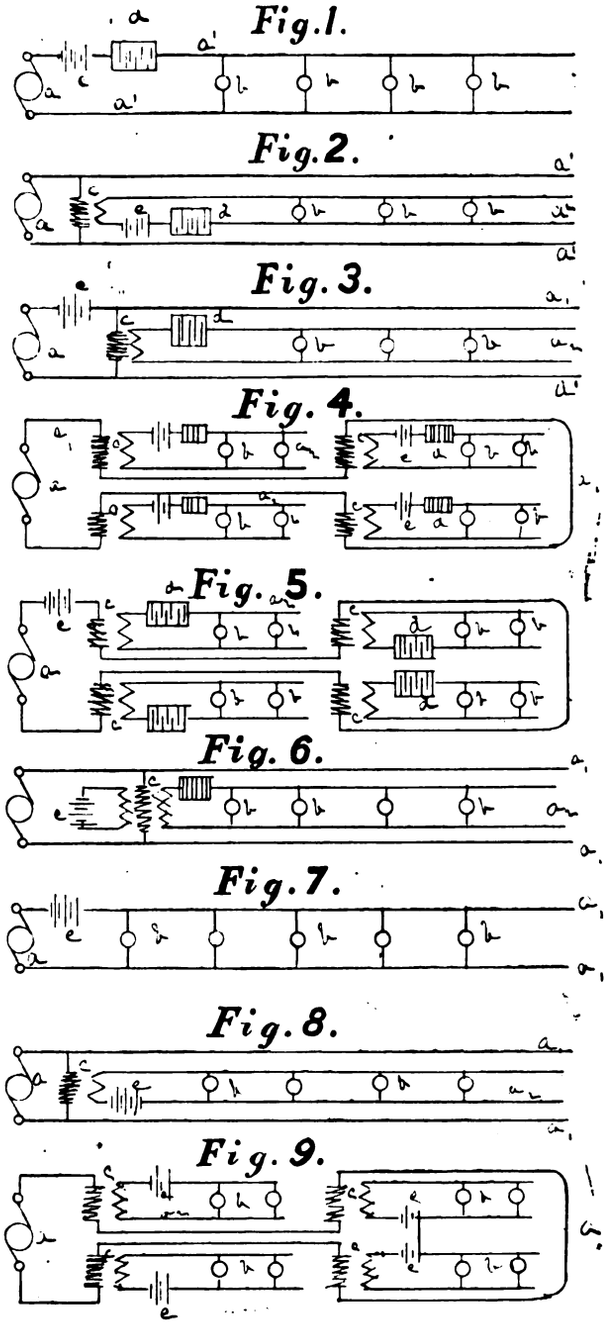
The capacity of the secondary cell is to register 400 units without recharging. The depositing cell is composed of an alloy unacted upon by the solution; the plates are kept at equal distances by distance pieces, by which, also, the connections are made between the alternate plates. They are also kept at equal distances by slots in vulcanite pieces supported by metal bridges, the exterior sides of the plates being coated with an insulating enamel, so that no deposition can take place upon them.

By an examination of the sample meter, a very simple method of removing the plates for weighing purposes, &c., without danger of injuring the deposits, will be seen; their removal being effected by releasing the nuts at the ends of the distance pieces and the plates slid out. The whole is contained in a cast-iron case, with the cover screwed down, the cables entering through insulating washers, the insulation of the secondary cell and depositing cell from the containing case being effected by an insulating frame.

To obtain the constants in the constant electromotive force and depositing cell system, take for example an electric lighting circuit with an electromotive force of 100 volts, and for a constant source of electromotive force a secondary cell of an electromotive force of 2 volts. Then with an alternation in a positive direction to the cell, total E.M.F. = 102 volts; and in a negative direction, resultant E.M.F. = 98 volts. So giving a difference of potential of 4 volts for half the time of an alternation, as before explained. Therefore, in so far as the chemical action is concerned, the electromotive force of the cell (*i.e.*, 2 volts) may be considered as working constantly through the resistance of the lamps. From this the constants of grammes per unit or units per grammes are easily arrived at thus:—In a 100-volt circuit with 10 amperes flowing work = 1,000 watts; and since resistance of exterior circuit = 10 ohms, therefore the subsidiary current from the secondary cell = $\frac{2}{10}$ = 0·2 ampere; therefore the effective quantity of electricity passing through the electrolyte, with 1,000 watts in exterior circuit for one hour (*i.e.*, 1 unit) = ·2 × 3,600 = 720 coulombs. Therefore, the constant for a copper deposition meter is during one unit of exterior work 720 × ·000327 = ·23544 grammes of copper are deposited.

The requisite capacity of the secondary cell is only one-half that of the capacity calculated from the number of ampere-hours required to deposit the copper. Since the discharging current, when the current is positive to the cell, is that resulting from 4 volts for half an alternation, more than 98 volts (*i.e.*, 2 volts from the cell × 2 volts from the dynamo), and on the negative alternation the cell is charged resulting from an E.M.F. of 98 volts. So that the charge of the dynamo neutralises the discharge, leaving a 2-volts discharge for only one-half the time. Given pure copper sulphate and distilled water and good copper, it is obvious that the meter must be absolutely accurate. But in consequence of slight impurities, which must necessarily occur, an error certainly of not more than 2 per cent. may be deducted, so giving an accuracy, under ordinary conditions, of at least 98 per cent.

The use of copper in the depositing cells is quite optional, as any metal and solution may be used by which any practical electro deposition may be obtained; copper, however, is considered at present by the inventors to be the most convenient and cheapest electrode. Various forms of self-reading or self-recording depositing cells are made, the usual form being a dial pattern, the needle of which is actuated by the alterations of the weights of the electrodes. Another form is that of a gas meter, in which the electrolyte is decomposed by the passage of the subsidiary current, a graduated gauge-glass enabling a consumer to see approximately what his consumption may have been.



In the following and other diagrams which will be described, a indicates the generator, a_1 the main circuit, a_2 the secondary circuit, b the lamps or other appliances in which the electrical energy is expended, c the secondary generator or converter, d the depositing cell, e a constant electromotive force.

Fig. 1 is a diagram of an electric lighting circuit coupled directly in parallel with the dynamo, as in the old low-tension

Digitized by Google

system, with a constant electromotive force e, and the depositing cell d placed in the circuit, so that all the current which has to be measured passes through them. The differential action of the current causes an electro-deposition of metal by the influence of the electromotive force e on the alternating or main electromotive force, which being exactly proportional to the amount of electricity passed through b, becomes a measure of the same as before described. Fig. 2 is a diagram of a secondary generator or converter system in which the primary circuits are coupled in parallel, the primary circuit a_1 inducing currents in the secondary circuit a_2 by means of a converter c. The depositing cell d and the constant electromotive force e are placed in the secondary circuit a_2, thus becoming a measure of the current as before described in relation to Fig. 1. In a secondary generator or converter system the secondary cell may be introduced into either the primary or secondary circuit, the depositing cell being, in all cases, between the secondary coil of the converter and the apparatus in which the electrical energy is expended. Fig. 3 is also a parallel secondary generator or converter system, in which the electromotive force, e, is placed in the primary circuit a_1, and the deposition cell d is placed in the secondary circuit a_2. The differentiation of the electromotive force produced by the constant electromotive force e in the primary circuit a_1 is reproduced by induction in the secondary circuit a_2 by means of the converter, c. Electro-deposition results in the depositing cell, as before described. The diagram (Fig. 4) indicates several converters, $c\,c$, placed in series in the primary circuit, a_1, which induce currents in several secondary circuits, a_2 a_2, arranged in parallel with the appliances in which is expended the electrical energy. Both the constant electromotive forces $e\,e$ and the deposition cells $d\,d$ are placed in the said secondary circuits, and thus become a measure for the electricity passed, as described in the preceding figures in each individual secondary circuit. Fig. 5 is also a series secondary generator or converter system, having the constant electromotive force e in the primary circuit a_1, and the depositing cells $d\,d$ in each individual secondary circuit $a_2\,a_2$, the same differentiation of the electromotive force produced by e being reproduced by induction in the secondary circuits $a_2\,a_2$ by the converters $c\,c$, as hitherto described in connection with Fig. 3. Fig. 6 is a parallel converter system; the constant electromotive force e in this case is used in a separate winding of the converter c. This, in combination with the primary circuit a_1, produces by induction, in the converter itself, the differentiated current in the secondary circuit a_2, electro-deposition resulting in the depositing cell d, as described previously in connection with Fig. 3. We may mention that, to obtain this differentiation, instead of a secondary cell, a primary cell or a dynamo may be used, or any other means of obtaining the desired effect.

The following is an example of another method of meterage, and an apparatus connected thereto operating in the manner above mentioned, but using no deposition cell, the measurement being taken in the constant electromotive-force cell itself:—Let it be required to measure the current duration of a number of lamps in a lighting circuit. We place in the lamp circuit, and in series between it and the generator, an electrolytic cell, which comprises two dissimilar metals, placed in an acid or alkaline solution. When an alternating current is passed through this cell and the lamp circuit the passage or flow of the current is alternately retarded or reinforced by the normal electromotive force set up in the cell itself, which subsidiary electromotive force causes a wasting or loss of weight of the positive electrode. As the resistance of the lamps in the lamp circuit varies according to the number and kind used, and the duration of the flow of current through the same, so does the current vary in the cell which acts upon the positive electrode. This current is directly proportional to the electromotive force of the cell and the resistance of the lamp circuit; the wasting away of the positive electrode therefore becomes available as a current meter.

Fig. 7 is a diagram of a similar low-tension circuit to that described in Fig. 1, but without the deposition cell d. In this arrangement one of the electrodes of the constant electromotive force e loses weight proportional to the electricity passed through the lamp circuit b, and this loss becomes a measure of the same as before described. Fig. 8 is a diagram of a similar secondary generator or converter system as that described in Fig. 2, but without the deposition cell d. The electromotive force e in the secondary circuit a_2 has one electrode losing weight in the same manner as before described in the example of a low-tension system given in Fig. 7. Fig. 9 is another series converter system similar to that described in Fig. 5, but without the depositing cell d, the measurements being in this case obtained by the wasting away or deposition of the metal forming the electrodes of the cells $e\,e$, producing the constant electromotive force which causes the differentiation in relation to Fig. 7.

This differentiation may also be produced by mechanical means. One of these is the addition of a subsidiary coil upon the armature of the alternating dynamo, which is so arranged and commuted that it is cut out of the circuit during the second half of an alternation, or it may be so commuted that in the second half of the alternation its electromotive force is in the opposite direction to that of the dynamo, so giving double the differentiation of potential that it would in the other case. The current is commuted at the neutral point of the alternation, so that no high-tension break occurs at any time.

Another method is to pass the alternating current, through a solenoid having a magnetically saturated iron core, the result being that in the half-alternation positive to the direction of the exciting current no retardation takes place, whilst that in the negative direction is retarded. To this latter method, that described in Fig. 6 more properly belongs, except that in that case the exciting current is from the constant electromotive force e round the separate winding round the iron instead of round a separate coil having an iron core.

In a secondary generator or converter system, where differentiation is effected by these means, the same differentiation is reproduced by induction, and an electrolytic cell, or other means of measurement, is put in direct series between the converter and those appliances in which the electrical energy is expended. This also can be applied in the diagrams 1 to 5, the arrangements described being substituted for the constant electromotive force e.

ELECTRIC LIGHTING IN AMERICA.

In the Mechanical Section of the British Association on Monday, the 10th inst., Prof. GEORGE FORBES gave an address on "Electric Lighting in America." He said:—A visit to the United States of America shows one the enormous progress central station electric lighting has made in that country, and when we land again in England we are equally struck with the dimness of the lighting everywhere. In America there is not a single town I am acquainted with where you can walk through the streets at night without seeing abundance of arc lights in the streets—I do not mean in the chief towns only, but out-of-the-way places in the distant parts of the States where gas has not penetrated; there the electric light has fixed its position, and is being used frequently (applause). There is not only lighting but developments of electricity everywhere. A most curious paper was shown to me yesterday. It was the journal of a village in Alaska, and the same paper which treated in a scientific manner of the introduction of electricity for various purposes into the village also treated on the desirability of having laws passed to expel the Indians from the city at 9 o'clock every evening (laughter). At the time I was attending the Electric Light Convention at Pittsburg last February it was estimated there were 300,000 arc lamps being lighted from central stations in America. The progress, however, has not only been made in America of late years in arc lighting (it was a fact that especially struck Englishmen the way arc lighting had developed in earlier times; but it was thoroughly established there when the British Association were there four years ago), the progress that struck us most was the central station lighting for incandescent lights. At the time I am speaking of, February of the present year, it was estimated that there were two and a-quarter millions of incandescent lamps in use in the United States. The rate of manufacture has increased to my knowledge enormously since that short time ago. There are four or five manufacturing places in the States at this moment, each capable of turning out ten thousand incandescent lamps every day (applause). And I have no doubt the incandescent lamps in the United States are now to be counted by millions per annum. Of the incandescent central stations, there are two classes which attract our attention. Those upon the three-wire system, in which the current is supplied

Digitized by Google

to the main conductors for the towns, and the lamps are connected by branches to the system of positive, negative, and intermediate mains. This system was largely adopted in the Edison central stations, which gave us the greatest interest—I think it was in the year 1884—when we were over in America, and they have continued to advance by the use of the three-wire system, which has developed to a very great extent indeed. But I feel quite sure that the greatest progress which has been made in central station lighting in America since the Association visited that country has been by the work which Mr. Westinghouse has done in that country (applause). Mr. Westinghouse has made his name famous by increasing the safety of electric lighting, and by in all parts of the world introducing the railway brake that bears his name. He saw the results which had been attained by Gaulard and Gibbs by alternating currents, and distributing the electric light by means of that alternating current of very high tension; that it could be passed over conductors in the streets, the conductors being of thin diameter and cheap construction; and that at the consumers' premises this high-tension electricity could be reduced in tension by means of converters on the induction principle, and passed into the houses at a harmless pressure, and suitable for the ordinary incandescent lamps at present used. I cannot fail to take the opportunity presenting itself to me to say what I feel of the energy and determination by which Gaulard and Gibbs, in spite of adverse criticism, persevered and continued to improve their invention, and proved to the world it was possible to have a commercial system of lighting by means of these converters. Mr. Westinghouse, on seeing this system, took it up, and the result is that he has established in the course of a few years an enormous business in central station work. It is now a possibility in America—not a possibility only, but a daily occurrence in America—for a town to write an order for a central station to be sent at ten days' notice. They do not order a dynamo, mains, and a set of conductors and other apparatus independently, but complete central stations are now being sent out from Mr. Westinghouse's factory at a stated and uniform rate. In December of last year, some of the manufacturers of incandescent lamps drew up a long list of the number of lamps used in different parts of their country, and I have abstracted from it some notes which show me in December of last year Mr. Westinghouse's alternating-current plant was supplying 153,285 lamps, occupying 152 distinct sets of plant, and there were forty-two sets of this plant of more than a thousand lamps each. At the present moment there are central stations being supplied by this apparatus. It has been said that in this country we do not go ahead so much as in America. Theories have been suggested for it. Prof. Ayrton's most admirable reason seems to go a long way in explaining it—viz., we have two definitions of inertia, one English and the other American. The English definition is resistance to motion, the American resistance to stopping (laughter and applause). In electric lighting we have been stopped a great deal by that, I was going to call it, iniquitous Electric Lighting Act (hear, hear, and applause). I regret extremely in the interests of the public, and of electric lighting generally, an Act has been passed this year which has not yet put electricity on the same footing as gas. It is a matter of extreme regret to all those who have learned the benefit of the electric light that that Act should have been passed (hear, hear), and so the due recognition of the value of the electric light has been delayed (hear, hear). I do not think the Electric Lighting Act is the only thing that has delayed our progress, because I see in electric traction and other developments of electricity the Americans have gone ahead a very great way indeed. I certainly do not put it down to want of capacity on the part of our manufacturers. The best dynamo machines are ordinarily designed in England; the best arc lamps we have are made in England; but while this is so in England, in the States they are determined, as long as they have something which they know will work well, to make it work till something better is produced. It is not in this that the want of English progress is to be found, but in men of capital who are also technically instructed (hear, hear). It is the extension of technical instruction among the moneyed classes which has developed engineering enterprise in America so much. I will now try to describe some of the leading features of the Westinghouse central stations which I visited, and perhaps this may be of use in helping us to draw some conclusions as to the lines on which we are to be developing in our own country. I do not in the least wish to say American arrangements are the best. In many points I see objections, and there are many places where I wish to see improvements; but we have in the system I am going to describe thoroughly successful working arrangements, and although we in this country may not adopt in all points such arrangements, still, I feel it would be of use to us to learn what is being done on the other side of the water. It is a curious thing, for example, in America there is no work hardly being done with accumulators. There is an example in which we lead the way, as compared with the Americans. I was struck with this in 1884, and still more in the present year. Accumulators do not seem to work in the American atmosphere. At any rate, people had been importing numbers of them, and yet they were not recognised as the satisfactory apparatus which we have thoroughly come to consider them in this country. They are looked upon as uncertain as they were four or five years ago with us. The system, then, chiefly depends on apparatus called by the name of a secondary generator, transformer, or converter. It is simply an induction apparatus, with two coils—a primary and a secondary. The primary coil, in contradistinction to the ordinary induction Ruhmkorff coil we have known so much, is of high resistance, a large number of turns of wire; while there is a very small number of turns of wire in the coil of the secondary part, which goes to the lamps. The alternating current produces induction; in passing through the primary coil it produces induction which re-acts upon the secondary coil, there being produced an induced current of lower tension going into the houses. The two coils are completely separated, and when properly constructed it is quite impossible the high tension can ever reach the secondary circuit. Consumers of electricity have nothing to fear from a dangerous potential being distributed from the central station; the wires in the houses are perfectly insulated from it. The wires from the central station are carried generally on poles; there are feeders to the separate districts. The converters are generally attached to the outside wall of the house to be supplied, but are often attached to the poles carrying the feeders. They are sometimes placed inside the house. The secondary wires inside the house, to which the lamps are attached, are laid in the usual manner, and connected with the secondary poles of the converters. The dynamos run day and night without cessation. We hear a great deal about the impossibility of running machinery day and night without breakdowns. I cannot help saying (endorsing the opinion that I have found existing in America) that this scare of danger has been greatly exaggerated in this country. When we see our huge ten thousand and fifteen thousand horse-power engines travelling over the ocean, with all their eggs concentrated in one basket, and performing the journey, lasting days and days, and even weeks, without a breakdown, it seems absurd, when we are able to subdivide our power, as in a central station, there should be any serious danger of a breakdown in a properly organised central station. As a matter of fact, I assure you under the American plan of running without accumulators, central stations have been running for years and years; it is of the utmost rarity that such an accident happens as to stop the general lighting. It occurs *very* rarely indeed. The Edison station, which has been running so many years, has only once broken down, and that was an accidental occurrence owing to the current being turned on too greatly on a foggy day. That was the only time when the current has been interrupted and there has been a breaking down. And every station reports the same thing. The one view in America is undoubtedly that there is no danger of breaking down in a properly organised station, with a proper number of dynamos, and plant and apparatus well laid down. It happens that in the department of furnaces and boilers there is much of special interest in many of the Westinghouse stations. This arises from the fact that over a great part of Western Pennsylvania, nature supplies fuel as natural gas from wells in that region, and it is carried in pipes to a considerable distance. But this is a circumstance so peculiar to the district it requires only a short notice here. I was surprised to learn from Mr. Dowson (Mr. Dowson read a Paper at a previous day's meeting on "Gaseous Fuel") that he did not expect to use fuel gas for heating the boilers of steam engines. In Pennsylvania it has been found so valuable a fuel for boilers there that it has been determined in many outlying districts to supply fuel gas for this purpose in preference to using coal furnaces. The gas, with its due proportion of air which produces the high temperature of a Bunson burner, is admitted by pipes with a sufficient number of nozzles into the combustion chamber and subsequently passes through the tubes of the boilers. The gas is nearly free from carbon; the hydrogen, which is paramount, undoubtedly weakens the iron of the boilers, but practice showed that this action does not go far, and the iron acquires a final condition in which it does not deteriorate, but seems capable of indefinite use. In the best stations the admission of gas and air to the furnaces is regulated by means of a valve controlled by a lever, which in its turn is subject to the pressure of the steam in the boiler. The combustion is proceeded with at a rate which depends on the pressure in the boiler, and the pressure in the boiler is automatically kept constant in 24 hours. The attendance of one man to a station of several thousands of horse-power is quite sufficient. As to the steam engines I need not say much. I do not know that the Americans can teach us anything in steam engines. I may say there are some points in connection with the class of steam engines to be used which are of importance. It has often been thought it would be desirable to introduce economical engines of large type, such as our marine engines, in central station lighting. Practical experience has hitherto decided the question in an opposite manner. It is found to be more economical and safer to have a number of dynamos in a station which are driven by separate engines of high

Digitized by Google

speed, the power being in America always transmitted to a belt with no counter-shafting. On the question of subdividing power there should be no doubt at the present moment. It has been proved over and over again by experience. It does not seem probable at first sight a number of independent engines could be more economical than a single one. The explanation lies in the special conditions of central station lighting. It is only necessary to observe that the maximum load in a lighting station is many times as great as the average load. Thus, if a single engine is adopted for the maximum load, it is working unloaded during a great part of the 24 hours. The consumption of steam to the power developed is very high, and the engine is not an economical one. With independent engines none need do work much under its best load, and when the load increases other engines and dynamos can be switched in, and are always worked at or near the best economical conditions. Twenty per cent. more work is required where counter-shafting is introduced; the load of the engines and dynamos is sometimes only one-eighth the maximum load. It was found desirable to use an engine whose economical load is somewhat under its maximum load. Additional power is speedily added. A breakdown of an engine or dynamo does not stop a station. One of the most annoying accidents in electric central stations—in fact, *the* inconvenience—is that due to the short-circuiting of the mains. The more so is that the case in American stations in which conductors are all passed overhead. It frequently happens through the falling of broken telephone wires on the mains. In this case a small independent engine is brought up, and no damage done. With a large engine, and the whole network of conductors connected with it, the dynamo grinds on, and may be destroyed unless the cause of the short-circuiting is burned up. Now, a word or two about dynamos and converters—the actual apparatus used in America. I attribute a great deal of manufacturing success of American electric lighting plant to this—when they have fixed upon types of machines they are going to make they stick to these lines, and lay down machinery which will enable them to produce these types cheaply, and having thought out a system thoroughly in the beginning they do not require to make a completely new type of machine for every order that comes in. They are thus able to manufacture machinery cheaply, and in such a way that every part is replaceable. At this moment I confess if I had to choose between two dynamos of which one was a little better than the other in efficiency, but one was manufactured in this manner and the other to a special design, I should be very much inclined to lean in favour of the one which is made by machinery, and of which all the parts are interchangeable, and of which I could get any one of the parts by return of train on telegraphing for it. The convenience of working is much greater. I have, for the benefit of those who are electrical engineers and manufacturers here, put down the facts in connection with the three types of alternating dynamos used in Mr. Westinghouse's works:—

DYNAMOS.

Type.....	1.	2.	3.
No. of lamps	650	1,300	2,600
Current	35	65	130
*Resistance armature	·76	·37	·15
*Resistance field	14·5	7·0	3·6
Lbs. of wire (armature)	17	30	60
Lbs. of wire (field)	420	—	—
Total weight ..... in lbs.	4,800	9,000	—
Volts.....	1,050	1,050	1,050
Revolutions per minute.....	1,600	1,000	1,000

* At 30° Centigrade.

No. 3 has an armature about 2ft. in diameter and 2ft. long. It runs 1,000 revolutions per minute. The weight of the armature is 200lb. I need make but little reference to the figures. The voltage is the same in each case, but the number of lamps varies—650, 1,300, 2,600. In this country there is a tendency to use a higher voltage—2,000. In Westinghouse's system they use 1,000 volts at the converters. Mr. Westinghouse's system reduces the electrical pressure in the same proportion as has been most general in Europe—in the ratio of 20 to 1. The 1,000 volts in America is reduced to 50 in the lamps. In this country 2,000 volts is reduced to 100 volts in the lamps. Here there arises a question which must be decided immediately now central stations are being put down in this country—what electric pressure you are going to use. The advantage in the higher pressure is that you are able to save the copper to a very large extent indeed while we are able to use lamps of only 50 volts instead of 100 volts. This is looked upon by Westinghouse as the greatest advantage gained by the introduction of the Gaulard and Gibbs system—that he is able to use lamps of 50 volts instead of 100 volts. The higher the voltage of the lamps the shorter their life, and a 50-volt lamp is a far more perfect thing than a 100-volt lamp. We are greatly troubled with the expense of lamps compared with their life. This is a serious item in the general supply of electricity, and a 50-volt lamp appears the more economical one. Electrical engineers will attach to this point an importance making it worthy of consideration. It may even be said we ought to go still further, and reduce the voltage still more. There is another point which will occur to the electrical engineer, whether it is not desirable to use the lamps which the Bernstein plan perfects—that class of lamps of low voltage placed in series in houses. One of the most serious difficulties of introducing electric lighting central stations is the cost of the wiring of the houses. By putting lamps in series the cost is much diminished, and it becomes a question of this—will the difficulty of cost not be prevented occurring by the beautiful device of Bernstein? The primary current of the converters would be put in series in the same way as originally proposed in the Gaulard and Gibbs system, and we should then be doing what they were striving to do in the series arrangement: not to have two primary terminals inside a house at a potential—1,000 to 2,000 volts—that is dangerous. In the house there would be no two conductors of a greater potential than 50 or 100 volts. If at the same time we are using the low-volt lamps we should still have the long life to lamps that Mr. Westinghouse has attained; there are grave reasons for considering an arrangement of lamps in series—of primary coils in series. I am not here to put forward suggestions on what we may do in England; I only wish to tell you it is being done in America. I wish to guard myself against saying that they have the best arrangements at every possible point. I think the construction of the Westinghouse dynamo is pretty well known in this country, and it is needless for me to speak of it. Probably we are agreed the old type of alternating dynamos has probably seen the end of its days. It will not be likely to be constructed in that manner very much longer. One of the chief difficulties seems to be when you have a large number of coils revolving in the space between the poles you are obliged to make a considerable clearance, and that causes you to use great power. I am speaking to electricians just now. Mr. Westinghouse makes a small clearance only, and gets an advantage in that way. Part of the perfection of his dynamos—it is very good—is obtained by the extremely good insulating arrangement. Mica is chiefly used. Shellac is given up altogether, and they use copal coach varnish with linseed oil, which I am told is a splendid insulating material, and I have heard from one or two gentlemen in this country since I mentioned it to the Society of Telegraph-Engineers it has been tried with great success. I will not, then, speak any more about dynamos, details of which can be obtained elsewhere. I now put down the type of converters which are used by Mr. Westinghouse. There are only five types used—5, 10, 20, 30, 40 lights.

CONVERTERS.

Converter	1.	2.	4.	6.	8.
Number of lights.....	5	10	20	30	40
Wire on primary	25	22	19	17	16
,, secondary ..	11	8	8	8	7
Turns on primary	900	700	480	400	560
,, secondary ...	45	35	24	20	28
Resistance primary ...	4·8	21·9	9·9	7·	5·
,, secondary..	·04	·043	·0197	·0176	·0107
Weight finished ... lb.	50	60	95	—	160

Thickness of iron plates ·006 to ·0065in. Paper insulation ·0025in. Number of plates in No. 8 converter, 1,350.

In this country there has been a tendency to make converters much larger, but for ordinary use in houses I must say I think Mr. Westinghouse's system seems to be simplicity itself, more especially as we find it necessary in our houses to wire the houses in such a way as would suit our meters. Our meters at the present time can, however, range from one lamp to a dozen lamps, or even to fifty lamps. Probably, for this reason, Mr. Westinghouse has determined the size of his converters in the way he has. There are some points about them worthy of attention, in which they differ from the English ones I have seen. In the first place, by the use of one thousand volts a far cheaper converter is made, and there is great safety in the plant required for a house. It is so much cheaper to make a thousand-volt converter. Then, again, the number of alternations—the rapid alternations of the Westinghouse plant. There are 16,000 alternations per minute. In this country there has been a tendency to make the alternations less than that. We know the iron you are obliged to put in a converter depends on the number of alternations. The greater number of alternations the less iron, and the quantity of iron affects the resistance. You are able to use a much smaller converter by the higher number of alternations. The only thing is if you have a smaller number of alternations the construction of the dynamo becomes easier, but it takes up more space, and the converter is larger. The iron which is used in the converters is Welsh Taggard iron. In the use of these converters 50deg. Centigrade is the maximum rise in temperature allowed. Mr. Westinghouse

Digitized by Google

asked me to make some tests of the efficiency of his converters. It is supposed the converters have not a high efficiency when working at half load. I may mention the efficiency I have found varies very slightly in the different types, owing to the iron being better in some than in others. Mr. Westinghouse in some converters is able to get at half a load 95 per cent., which is a splendid result, and, I think, is a greater efficiency than most people have considered to be possible. I do not think we need trouble to consider the average waste of efficiency in the use of converters when properly designed as more than 10 per cent. I must also say that Mr. Westinghouse has got in his lamps 600 watts developed for the brake horse-power by his engine; that is a very good return for these alternating-current dynamos, and it shows the alternating-current dynamo is to-day much superior to the older one. The wire is nearly all overhead in the States, and this, of course, differs from what we want to do here. The wire which is used in the streets is called simplex wire. It is made by a firm in Boston. Ought the conductors to be merged into one heavy main with all the dynamos feeding it, or should the mains be divided with several to each dynamo, or ought we to have intermediate arrangements? These points we must settle in future. I do not express any opinions now. The experience of the Westinghouse Company leads to the subdivision of the mains as much as possible, because the short-circuiting of the mains leads to only one dynamo being affected. The chief trouble of the mains is short-circuiting, and by limiting the range of the district over which that danger exists much security is added to the general system. Whether alternating dynamos do good work in parallel—can we put a number of dynamos on to one main? This is another question. It can be done. It is interesting to see the way in which it is done. One dynamo is working a main, and we wish to switch on another dynamo. Both are set to work, and the two wires to be attached to the same wire of the main are so connected that the current is passed through little connecting terminals of the two dynamos in such a manner that the phase of one dynamo is exactly the same as the phase of the other; the lamp goes out because the two lamps are connected both with the positive or negative conductor. Then when we are wanting to switch in a second dynamo, we watch this lamp and it goes through the phase of brightening, dimming—brightening, dimming—as the phase of the two dynamos coincide and come into opposition. You have simply to take the switch and practise with your hand to get the time, and when you have the time you switch it on when the lamp is out, and then you have the two dynamos working perfectly in unison. But the answer to the question whether dynamos would work in parallel is not quite complete. They work successfully when fully loaded, but when doing less than half load they do not work in parallel well, they are very troublesome. As a matter of fact, the tendency of the Westinghouse plan has been to subdivide the mains as much as possible, and put several different feeders on to one dynamo. There are several conclusions one may draw as to what is likely to be the practice in this country, but I would rather not deal with that question. I have no doubt there are many gentlemen here who will speak as to the practice in Europe on the subject—in the way of alternating-current distribution. There is one thing which will probably be spoken of—the high speed of the Westinghouse dynamo. I believe there is a needless opposition to high speed amongst engineers in this country. High speed is dangerous, undoubtedly, if it tends to disruption on the part turning at high speed. But if we have a perfectly uniform cylinder of iron revolving, I have no objection to turning at any speed as long as I know the shaft will not give way. The Westinghouse dynamo, from its construction, is capable of turning at the high speed indicated without any serious danger (applause).

After the address by Prof. Forbes, a Paper by Mr. Edmunds on his system of distributing electricity was read, and Mr. Lowrie's Paper on "The Measurement of Electricity in a House-to-House Supply" followed. The three Papers were discussed together.

DISCUSSION.

The PRESIDENT (Mr. Preece) said he knew Mr. Lowrie's arrangement was in use, but it had been kept very quiet. It was rather a novelty if he understood its action aright.

Sir WM. THOMSON acknowledged the great advance made in electric lighting in America, and said their own country had been very slow in obtaining practical results such as were obtained in America. Glancing at the two systems—the alternating-current plan and the constant-current system—Sir William said one way of carrying out the direct-current system was to use accumulators to allow high-potential current to be carried by small wires to a distance, and to distribute the supply to the public by dividing the accumulators. It was possible one system might prevail for a time, and another system prevail ultimately. Lamps had become such a comparatively small part of cost of a system of electric lighting, that the durability of a 50-volt lamp would not be the determining reason that would lead to the adoption of that standard. He believed in other respects 100-volt lamps had advantages. It seems quite probable also that lamp makers, if asked with sufficient urgency to do so, will succeed in making 8-candle 100-volt lamps, which shall be at least as durable, with the same number of watts per candle, as any 50-volt lamp or 100-volt lamp hitherto made.

Mr. E. P. SELLON, as a manufacturer of incandescent lamps, said there was no doubt the lower E.M.F. lamps had a longer life than the others, and that their first cost was more economical.

Mr. S. WALKER said the earlier forms of incandescent lamps were not reliable. Defects had now, however, been got rid of, and 100-volt lamps were as good as the other. He thought they had far better save their copper and use a 100 or even 200-volt lamp. They could not help acknowledging the skill and energy shown in America in electrical work.

After further discussion,

Prof. FORBES said: Before I pass on to answer the questions raised on my own communication I would like just to make one remark about Mr. Lowrie's Paper, "On the Measurement of Electricity in a House-to-House Supply." Where Mr. Lowrie spoke of meters he says hitherto the waste of energy has always been too great, and that automatic current meters have not been successful. I cannot let that statement go unchallenged. There is an automatic current meter which has worked extremely well—a meter I showed the Association last year. In reply to Sir William Thomson, I would say no one must think because I have been speaking of the alternating current I am advocating it. I am not wishing to advocate anything the Americans adopt. I merely wish to lay before you what is being done in America, and not that it should be looked upon that everything there is right by any means. I think we should do a great many things ourselves, and improve on the American system. I quite agree with what Sir William Thomson says about accumulators. I always felt that they were very desirable when they had the qualities they now possess. They are now working extremely well. They have fulfilled the conditions, as far as was required, very well; but still are far too costly, unfortunately, and I hope within a short period we shall be able to have the cost reduced. Sir William Thomson has asked me about the working in parallel of the alternating-current machines. Of course it was known by Mr. Wilde they could be run in parallel. I know in the old days in the Grosvenor Gallery it was tried with Siemens' machines; dynamos were run with different belts from the same engine, and could not be got to work in parallel. The Westinghouse dynamo can work in parallel, and several others. Dr. Hopkinson had shown in his Paper read before the Civil Engineers Institute that it can be done. The self-induction machines run better altogether than those which have not much self-induction, and that is, I think, one reason why Mr. Westinghouse's runs well and Mr. Siemens's did not. The machine I have described having been once started in unison, as I stated, will keep in unison, the belt slipping slightly if one goes too fast. It is the slip of the belt which allows them to check each other if the engines do not run perfectly. At the same time the check is much greater when the maximum current is passing through, and it is only when they are doing a good deal of work the unison is perfect. If much under half-load they get out of synchronism. This is shown by the lamps flickering; the electromotive force of the two dynamos would in that case be nearly opposing each other sometimes. There is, I assure you, no difficulty in running in parallel.

Mr. KAPP: There must be a period when the lights are out.

Prof. FORBES: No; you may put on one dynamo and take off another without hindrance. The Alleghany River separates Pittsburg from the town on the opposite side of the water, and when one centre is hard up for electric current it is helped by power being switched on on the opposite side of the river. Then the question comes up about the 100-volt lamps being preferable to the 50-volt. I will not express any opinions, seeing there are various opinions about it. I will leave it to public discussion elsewhere. In America it is believed the durability of a lamp is much greater with the smaller potential. As to the insulation in the converters, I am sure it is impossible to have connection between the primary and secondary coils. The converter does not get so hot that you cannot put your hand on it. I mentioned that 50deg. Centigrade rise is allowed.

Mr. PREECE (President), in thanking the readers of Papers, said he thought too much blame must not be put on the 1882 Act, which had not in any way interfered with the action of corporations. The fact was there was so much about electrical systems that was unsettled that corporations did not see their way clear to risk the money of the ratepayers (applause). He should recommend a strong committee of the Society of Engineers to consider the question of 100 or 50-volt lamps, and as to the different voltages, so as to have some uniformity arrived at. He believed Mr. Edmunds's system would compare very favourably with other systems.

Sir William Thomson on the Objects of the British Association.—In a letter to *The Times* this week Sir William points out that the object of the Association "is the advancement of science. It contributes to this object in a manner altogether peculiar to itself, by bringing together from all parts of the world persons engaged in scientific investigation, and giving them facilities for helping one another in their work, and being helped in it by what they see and hear. No one not following the course of scientific progress, generally or in some particular department, can fully understand how much of practical impulse is owing to the British Association for the contributions made in the course of the year to the scientific societies and magazines, in which achieved results of scientific investigation are recorded and published."

BRITISH ASSOCIATION.

DISCUSSION ON LIGHTNING CONDUCTORS.

On taking the chair in Section A of the British Association, on Tuesday, September 11, 1888, Prof. FitzGerald called upon Mr. W. H. Preece to open a joint discussion with Section G on lightning conductors.

Mr. W. H. PREECE, F.R.S., said it was a most remarkable thing that if they wanted to know much about atmospheric electricity and its effects they would have to go back to the works of Benjamin Franklin, 140 years ago. Scarcely anything in this direction had been done since then. Up to the year 1881 there was not even a code of rules extant in the United Kingdom to guide people in protecting their buildings from the destructive effects of atmospheric electricity. It was proposed in 1878 to establish a conference of various societies to discuss the effects of atmospheric electricity, and to form a code of rules for the erection of lightning conductors. All the manufacturers in this country, all the architects who were members of the Institute of British Architects, and the whole of the press of this country, were invited to assist the conference. The conference divided itself into several sections; all works, English and foreign, were examined and abstracted, all rules and regulations then published were compared, and at the York Meeting of the British Association in 1881 a report was adopted. The work of the conference was collected and published; and there existed at the present moment, published by Spon, in Charing Cross, one of the most admirable works that ever had been collected on atmospheric electricity and its effects. If anybody really wanted to know what to do they could not do better than obtain that book, because they would find there the work of nearly everybody who had laboured in this field. This report was divided into three parts. In the first part was discussed the purpose which a lightning conductor is intended to serve; in the second part there was a statement of those features in the construction and erection of the lightning conductors, respecting which there had been or is a difference of opinion, and the final decision of the conference thereupon; in the third part there was drawn up a code of rules for the guidance of those who erect these conductors. The report itself was most decisive and most important; there was a true ring about it—the ring of men who knew what they had done, and what they were writing about. He could not help reading to the meeting, because it would form the basis of a good deal that would be said in the course of the discussion, how a lightning conductor was defined in the report. "A lightning conductor fulfils two functions; it facilitates the discharge of the electricity to the earth, so as to carry it off harmlessly, and it tends to prevent disruptive discharge by silently neutralising the conditions which determine such discharge in the neighbourhood of the conductor. To effect the first object a lightning conductor should offer a line of discharge more nearly perfect, and more accessible, than any other offered by the materials or contents of the edifice we wish to protect. To effect the second object the conductor should be surmounted by a point or points; fine points and flames have the property of slowly and silently dissipating the electrical charges; they, in fact, act as safety valves. If all these conditions be fulfilled, if the points be high enough to be the most salient features of the building no matter from what direction the storm cloud may come, be of ample dimensions, and in thoroughly perfect electrical connection with the earth, the edifice, with all that it contains, will be safe, and the conductor might even be surrounded by gunpowder in the heaviest storm without risk of danger. All accidents may be said to be due to a neglect of these simple elementary principles. The most frequent sources of failure are conductors deficient either in number, height, or conductivity, bad joints, or bad earth connections." The paragraph ended with this most decisive and clear assertion—an assertion that he was there to defend—that "there is no authentic case on record where a properly constructed conductor failed to do its duty."

They had there defined the functions of a conductor, and lest it should be thought that the conference had neglected the teachings of modern theorists it would be only right to point out that it was asserted in the report "we will assume the conductivity of equal lengths and weights of iron in the case of steady currents of electricity," and, further on, "that the suddenness of lightning discharge modifies the conductivity." This report was signed by Grylls Adams, Ayrton, Latimer Clark, E. E. Dymond, Carey Forster, D. E. Hughes, Hayter Lewis, W. H. Preece, G. J. Symons, and John Whichcord. They all had had a great deal of experience in the performance of lightning protectors. He, personally, had now under his supervision at the present moment 500,000 lightning conductors, and throughout the Post Offices of this country their apparatus was protected by about 30,000 or 40,000 lightning protectors. If 500,000 lightning conductors and about 40,000 lightning protectors were not sufficient to give a man a little experience, what would give a man that experience? (applause).

A gentleman of the name of Mann—Dr. Mann—had practised the protection of buildings by electricity to a very large extent in South Africa, and had made himself much associated with the introduction of the system. He was an active member of the Society of Arts, and in order to commemorate his memory his widow gave a sum of money to the Society on condition that they gave lectures on some subject in which he was interested. The Society at once thought there was no better subject than atmospheric electricity, in which Dr. Mann took so much interest, and they had no hesitation in selecting as their mouthpiece for that occasion one who had lectured in that hall with great effect, and whose power they were all prepared to bow down to; that was Prof. Oliver Lodge (loud applause). Prof. Lodge was selected to deliver lectures at the Society of Arts to crack up or eulogise the report of the conference (laughter). But they had produced, he was sorry to say, a veritable Balaam, who rode upon the British Ass, and instead of going there to bless, he ended by cursing the work of the conference (renewed laughter). If all the vaticinations of Prof Lodge were true, the work of that committee and the work of the last 140 years would be useless—no lightning protectors could possibly protect, and no discharge could possibly be led to earth.

These were strong assertions. He thought that Prof. Lodge had in his Papers before the Society of Arts,* and in his Paper published in the *Philosophical Magazine*,† committed certain fallacies which it would now be his (Mr. Preece's) duty to bring before the Association. In the first place Prof. Lodge assumed that a lightning rod formed a part of a flash. Well, it did not; nobody had ever seen, to his knowledge, a flash of lightning strike a conductor. The function of a lightning conductor was to prevent the possibility of its being struck by a flash, and if it were struck by the infinitesimal part of a flash then, he said, that the lightning protector was not a lightning protector; it had some defect in its construction that ought to be remedied. But supposing it did, then the lightning protector would form but a very small portion indeed of the path of a lightning discharge from the cloud to the earth. A great deal depended upon the height of thunder clouds. They saw in text-books ridiculous assertions about the length of lightning flashes. Now who could measure the length of a lightning flash? There had been several extremely accurate measurements of the height of thunder clouds. In South Africa Dr. Mann measured them, and his measurement made the height 650ft. The most accurate measurements had been made by M. Lacoine, an eminent Frenchman, in charge of the Ottoman telegraphs in Constantinople; he made the height of a thunder cloud and therefore the length of a flash about 325ft. There were these two measurements which he believed to be accurate. During the past summer months he had been rusticating and enjoying himself amongst the mountains of North Wales. He saw there several thunder clouds, but he saw no lightning. He took several fiducial marks there upon the mountains; he had the 500ft. line and the 1,000ft. line and the 1,500ft. line in his mind's eye. All those thunder clouds seemed to be 500ft., and he felt almost certain that nearly all our flashes of lightning do not average more than 500ft. In consequence of the researches of Sir William Thomson and of measurements made by Dr. Warren de la Rue and Hugo Müller, the striking distance across the layer of air for steady currents in one direction was pretty well known. It was something like 30,000 volts per centimetre, or somewhat approaching that—he did not quite remember the exact number. Now, if a flash of lightning were 500ft. long, and it varied directly as the striking distance, then Prof. Lodge's measurements as given in his Papers would be fairly accurate. But there was every reason to believe that the striking distance did not vary directly as the length, especially in the case of alternate currents which were modifying their conceptions in every direction of the action of electricity. Mr. Acheson, in America, had been making some very careful observations on the striking distance across air when currents were produced by transformers, and he made out that the striking distance varied not directly, but as the cube of the electromotive force into the capacity.‡ If that be so, then it would follow that the electromotive force forcing a current of electricity through the air and producing a flash was very much less than they had hitherto considered it to be. Again, a flash of lightning always goes along a path that has been prepared for it; a flash of lightning does not go fooling about waiting for a convenient house to strike (laughter); it does not come down upon a flagstaff or a telegraph pole or an unfortunate horseman with a sudden rush. Experiment, as well as theory, gives indications that wherever lightning flows there some preparation has been made for its passage.

There was next an assumption made which he also considered to be a fallacy, namely, that a flash of lightning is instantaneous. They all knew the experiments that were made to show revolving wheels—the spokes of a revolving wheel suddenly appeared whenever a spark passed, and most of them believed from this that a flash of lightning was really instantaneous. There was no proof of its instantaneity. What they saw was the flash, which was merely a flash of light indicating the path. How long the current lasted they could not tell. But there are dark and invisible flashes, if he might so call them. There are dark and invisible charges of electricity, and there are cases on record where people have been struck and killed underneath trees where no light of any kind whatever has been seen.§ He argued on the non-instantaneity of lightning flashes from their effects on telegraph wires. We had spread all over this country an enormous network of telegraph wires, and whenever a lightning flash took place anywhere some wire was sure to be affected somewhere, and wherever lightning took place it might not strike the wire—it sometimes did, but whether it did or did not apparently does not make very much difference in the effects observed, for they always got currents of sensible duration. Take the case of ships. Ships have often been struck, especially when their lightning conductors are a little defective, and there it had been observed—he would not say invariably but frequently observed—that the compass needles were turned about and went playing about whenever the ship passed through an electric storm. It was quite impossible that the compass of a ship which had a very slow rate of vibration could be deflected or turned round unless there be a considerable duration in the flash. That was a point on which the photographs taken would give a considerable amount of information, and he hoped that Mr. Abercromby would show them some of the beautiful photographs he had collected.

He now came to, perhaps, the hardest nut to crack of all in the questions they had to discuss, one that he approached with a certain amount of diffidence, because it was supported by very high authorities, and that was the assertion that a flash of lightning is oscillatory in its character—that is, that it does not flow straight from the cloud to the earth and then disappear, but that it goes slashing backwards and forwards—somebody said a million times in a second; but he was not going to discuss that (laughter). At any rate, that the flash goes flying backwards and forwards with considerable frequency. He would say at once that this assertion of the oscillatory character of a lightning flash was based more on mathematical reasoning than on absolute observation. He was not going to say much on the mathematical part of this question—first, because he did not think it would interest the meeting, and, secondly, because he did not think he was quite equal to it himself. He did not pretend to be a mathematician, although compelled in the discharge of his duties to make use of mathematics in some shape or other every day of his life. He made mathematics his slave, and he did not allow mathematics to make him its slave (applause). He was sorry to say that there were those amongst mathematicians who certainly allowed mathematics to make them its slaves, and they get into quagmires and sloughs of despond out of which they had great difficulty in struggling. If he were speaking as a member of the committee of Section A he should feel a little hesitation in saying one word on the question of mathematics, but he was speaking as president of Section G, and he appeared before them as an engineer. He might tell them that engineers had no very great respect for mere mathematical development unless it was proved by absolutely true experiments (applause). He would give them two or three instances which explained why engineers had a little hesitation in accepting mere mathematical developments. Some 50 years ago or more—he forgot the date—it was proposed to cross the Atlantic by a steamer; it was mathematically proved that it was impossible for a steamer to cross the Atlantic (laughter) Some 37 years ago the Menai Straits were spanned by a tubular bridge. The greatest mathematician of the day, one of the luminaries of Cambridge, proved that it was impossible that that bridge could stand, and he used all his power to induce the Board of Trade to stop the opening of the bridge. He had himself heard no less an authority than an Astronomer Royal prove absolutely and completely—to his own satisfaction, not to others—that it was impossible to lay a cable across the Atlantic. He had also heard a gentleman at that table, one of their greatest authorities, calculate by the conditions then at his fingers' ends the speed at which currents were likely to pass across the Atlantic; but it was found that a little condition was wanting which changed the whole aspect of the question. Instead of their being able to speak across the Atlantic at the rate of about eight or ten words a minute, it was found to the surprise of everybody that when the cable was laid they were able to speak at the rate of twenty words a minute. These were instances to show why mathematical developments devoid of practical experimental proof should be received with a considerable amount of caution (applause), and he thought, therefore, that this theory, beautiful as it was, of the oscillatory character of a lightning flash, must be received with great caution. There were several facts against the theory. There was no doubt whatever that electro-magnets were powerfully excited for a sensible duration by lightning flashes. They knew that needles were magnetised and demagnetised; they knew that electrolysis could be produced by lightning flashes; he had pointed out to them that the mariner's compass was caused to fly about. Sounds were produced; he had stood in the telegraph office and he had heard distinctly letters of the alphabet signalled by a flash of lightning. He had introduced into his Presidential Address this quotation from Job: "Canst thou send lightnings that they may go and say unto thee 'Here we are'?" Now, he had heard the letter "R" most distinctly sounded (laughter).

The PRESIDENT: Have you heard the three "R's"?

Mr. PREECE: Only the first R—we have stopped at that (renewed laughter). Now, the letter R involved three currents—three oscillations were required to make it. He had also heard the letter C; that involved four currents. There was a case on record in the A B C instrument of Wheatstone of the letter G having been made. Now, the letter G required eight alternations to be made in order to be recorded. And there were other facts. Hence he said that these durable effects in telegraphs were contrary to the oscillatory theory of the flash, unless the frequency of these oscillations be very small indeed; he said there were very great doubts as to whether it was true for lightning flashes. It might be true for condensers, it ought to be true for Leyden jars, but they were not dealing with Leyden jars, they were dealing with flashes of lightning, which, if they were analogous to anything in a Leyden jar, were analogous to the bursting of the dielectric, and not to the external discharge where oscillations may occur. They had in a Leyden jar the dielectric with its charges of negative and positive electricity on each side of it under a considerable state of mechanical stress; when that stress is suddenly removed, as it is by a spark, then it is not difficult to conceive that there may be mechanical oscillations in the dielectric; but he could not conceive that those took place in a flash of lightning, which bursts through a mere layer of air. Speaking once more of oscillations, they had distinct evidence of slow oscillations in a flash of lightning, and he thought the photographs would also give some evidence of that. Prof. Elihu Thomson, in America, a very careful observer, and one of the ablest men on the other side of the Atlantic, had recently, during a thunderstorm, by wagging his head or his glass about, seen six distinct flashes pass exactly over the same path. They had other evidence in favour of slow oscillations, but at present they had no evidence whatever of these rapid oscillations, and if they did not exist then the whole of Prof. Lodge's ingenious theory fell to the ground. On this point he would read one little quotation from Faraday's researches, who showed how, when a spark flew across an air space, the whole of the electricity disappeared. Faraday said, "The ultimate effect is exactly as if a metallic wire had been put into the place of the discharging particles, and it does not seem impossible that the principles of action in both cases may thereafter prove to be the same." He thought that statement of Faraday had a most important bearing on the theory of electricity.

Now he would deal with another and extremely important point that Prof. Lodge had raised, which was one of immense value. He would tell them at once that, while he was attacking Prof. Lodge with all his power and force, he was also going to pat him on the back with equal power and force. There was no man who had worked so thoroughly and so honestly in this direction, and there was a true and a real pleasure in carrying on a discussion with a man who worked with the harmony and the good feeling that he showed (applause). Prof. Lodge had given some very beautiful experiments to prove his case. He took two Leyden jars, and they were charged with a Holtz machine, which was one of those new influence machines that produced static electricity with great ease and with great power; they were most charming instrumeuts when they were in the form that Mr. Wimshurst makes, and no electrician and no laboratory should be without them. One of the great advantages of this question being raised by Prof. Lodge was this, that it was dragging them all back to the early experiments they made in their youth when they first studied electricity, and experiments in static electricity were the most interesting and the most charming form of electricity that could be dealt with. [Mr. Preece then drew the following diagram on the blackboard.]

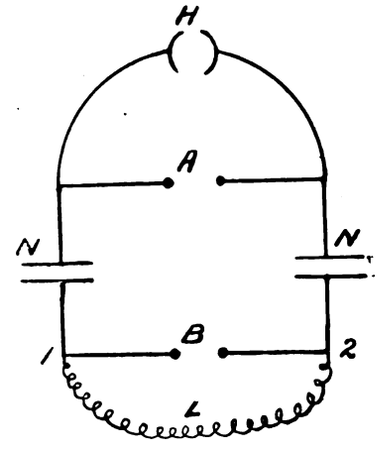

FIG. 1.

Here they had a Holtz machine, H, which charged each side of one condenser with positive electricity and the other with negative. The experiment was this: If the points 1 and 2 be connected with what Prof. Lodge called an alternative path, L, either iron or copper, then the distance through which the flash across the balls B flies is very much longer than it is when there is no alternative path. The real discharge itself is determined by the balls A. When the flash occurs through the discharge of those condensers then there is simultaneously a spark between B and between A, but it is the discharge between A that determines that between B. Prof. Lodge said that owing to this oscillatory character of the discharge there was in the alternative path L self-induction, a kind of obstruction, a real obstruction to the discharge that causes the charge to fly back through B rather than go through the conductor. The spark was much longer with copper than with iron. Prof. Lodge's experiments were perfectly exact. He (Mr. Preece) had repeated them in every shape and form that he could; he had had them repeated by others, and in all cases Prof. Lodge's experiments were found to be absolutely exact. He did not question them, and could not question them; they were true. What he did question was the deduction from these experiments, and there was a very great difference between an experiment and the deduction from that experiment (applause). In order that the alternative path should influence the charge or discharge there must be self-induction in that wire, and there must be frequency in the oscillatory character of the charge or of the discharge. Prof. Lodge argued solely on the discharge, and arguing on the discharge, then, his conclusions were right, but he did not take into consideration the charge. The oscillatory character may be true or it may not be true. For the purposes of this argument he would say it is not true, and therefore Prof. Lodge's theory fell to the ground. Here, however, in the charging current, they had a Holtz machine which charged up by a series of consecutive minute charges of electricity; they had in reality a frequency of charge—little charges were sent pulsating through all this system. Here they had a wire possessing self-induction—in one case a wire of copper, and in another case a wire of iron. Prof. Lodge said that because the length of the spark is greater with copper than with iron, therefore copper has more self-induction than iron. He (Mr. Preece) said that because the charge is a pulsatory charge, and because they had a greater spark with copper than with iron, there is a greater self-induction in iron than there is in copper. The increased spark in the case of copper is due to increased charge in the condenser; iron throttles the charging current. So that by arguing from the discharge as Prof. Lodge did, he made out the self-induction of copper to be greater than iron; on the contrary, by arguing from the charge he had himself made out that the self-induction is greater in iron than it is in copper, which is, of course, true; therefore by taking it from those two points of view they arrive at diametrically opposite results.

Digitized by Google

There were many objections to this self-induction theory. There was no doubt whatever that Prof. Lodge in this inquiry had started an entirely new and fresh hare which electricians were bound to hunt up and follow and kill. He felt satisfied that Prof. Lodge was on the brink of some discovery in connection with static electricity. He did not think his explanations were right, and he did not believe in the influence which Prof. Lodge assumed of self-induction; in fact, he looked upon the way in which lately self-induction had been brought into account for every unknown phenomenon as being very much what the Americans call a species of bug. The Americans used that term not in the sense that we did; sometimes we call it a bug-a-boo. Now, self-induction is used in innumerable senses and in different ways. Prof. Lodge himself (who was one of their shining lights on this subject, and his Papers, whether they were right or wrong, were most charmingly written and were excessively interesting), with all his care, could not avoid speaking of this self-induction in various ways; for instance, in his Paper he sometimes called it electro-magnetic inertia, sometimes electro-magnetic capacity, sometimes self-induction, sometimes self-induction of the conductor, sometimes self-induction of a discharge, and he also called it inductance and electric inertia. As practical men in the telegraph world they had been familiar with self-induction for the past twenty years—they knew it, they called it electro-magnetic inertia, and its effects upon the wires were always spoken of as retardation. If they possessed in everyday language two terms so well known as electro-magnetic inertia and retardation, he could not for the life of him understand why every fresh writer on electricity should apply a new term to this well-known phenomenon. For instance, its effects are expressed by a very simple formula, and to this it is very desirable that some name should be given. Practical men had, without hesitation, accepted a term applied to it by Lord Rayleigh, and they spoke of it accordingly as "throttling." Self-induction has a kind of throttling effect on a current of electricity. Some people called it choking, but why it should be called impedance, why it should be called hindrance, and why it should have all the other names applied to it at the present moment, they could not possibly understand. He said that Prof. Lodge had made a discovery—he did not know what it was—but that Prof. Lodge, in being possessed by his mania, he would call it, for self-induction—he had self-induction before his eyes, and nothing else—had neglected to study Prof. Poynting's Paper to the advantage that one would expect. If he had studied Prof. Poynting's Paper, which showed that energy passed through the dielectric, and not through the conductor, he might have applied that principle to his experiments, and proved, with equal satisfaction to himself, that the peculiar effects he produced were due to something or other in the dielectric. He himself was not sure that Prof. Lodge would not find, on further inquiry into the matter, that there was something in the contact between the dielectric and the conductor. They knew that a conductor in contact with the dielectric, in contact with air, was subject to an electromotive force. They knew, for instance, when a row of people were collected together and a spark was passed through them that those who suffered were the two end ones. There were several instances on record where horses had been ranged in a row and the two extreme horses had been killed, while the intermediate ones were not touched. That showed that there must be some effect between the surface of the terminals and the air, of which at present they were ignorant. He thought that was a point that deserved experinent; wires could be obtained coated with various dielectrics. He could supply Prof. Lodge (if he still continued the experiments) with any quantity of wire covered with gutta percha, with paraffin, with bitumen, or with any other compound that was in the market. Then, again, there was something analogous to the transformation of energy in these experiments of Prof. Lodge. Let his explanation be absolutely true, let there be self-induction held in this alternating current, he (Mr. Preece) could not conceive from analogy any single effect of self-induction that would cause the E.M.F. between the two balls at B to increase from 100,000 to 140,000 volts. They had to account for a great increase of E.M.F. Prof. Lodge indicated in his Paper, read in Section A on Friday, that a spark of one inch, at a distance of three yards (he thought) increased to 14 inches. Here they had an increase of E.M.F. that would be something like an increase from 100,000 volts to 1,000,000 volts, and they could not account for that by any known phenomenon connected with self-induction. He thought those points rather tended to shake one's confidence in the oscillatory character of lightning, and in the influence of self-induction in determining the efficiency of lightning protectors.

The next fallacy of Prof. Lodge that he wished to touch upon was the assertion that a lightning protector protected no area whatever. If a lightning protector raised above a building did not protect the area around and about that building, what earthly use was there in the lightning protector. They knew from evidence in this book [Report of Conference] that areas are protected, and he had in a Paper in the *Phil. Mag.* worked this out in a way which he thought could scarcely be controverted.

Again, Prof. Lodge asserted that extended points are needless. The report of the Conference said that extended points are necessary. Of course those two views were diametrically opposed to each other. The authors of the report took their stand upon the experience of the past, and Prof. Lodge took his stand upon his mathematical assumptions.

Then Prof. Lodge advocated iron, as did he (the speaker); but he did not like, and he did not think any of them much liked, sudden conversions; they were not always agreeable. The most extreme Radical in that room did not feel very comfortable when he found that Mr. Gladstone was committed to Home Rule; so Prof. Lodge, when he suddenly turned round and became an advocate of iron, committed a very serious conversion. He found in *Nature* on November 3rd, 1887—only last November—this:—"A lightning conductor should not be a round rod, but a flat strip, or a strand of wires, with the strands as well separated as convenient, and though I have not mentioned the special effect of iron, I may as well say here that iron is about 90,000 times worse than copper."

He had already said something about mathematical developments; he thought that one of the serious errors committed by those who relied upon mathematical developments was that of hasty generalisation. This subject was dealt with last year by the President of Section A. He made his friend, Mr. Querelous, say that in dealing with mathematical developments you had only to write down equations and scribble away till you got something or other (laughter). There was no doubt that all the disputations of the learned never brought to light one effect of Nature before unknown; they were always discovered by experiment. But there was no question of this, that mathematical developments, in the hands of such masters as Lord Rayleigh, Prof. Fitzgerald, Sir William Thomson, with such experimentalists as Hertz in Germany, Prof. Lodge himself, and many others, were gradually opening their minds to the true character and the true nature of electricity. They were gradually reaching a time when they could speak of the mechanical theory of electricity. Prof. Fitzgerald made the subject of his address the fact that we had now absolutely proved the existence of an intervening medium for the transmission of these oscillations and these vibrations. They had in all the effects of atmospherical electricity indisputable proof of the fact that they were dealing with energy in some form or other. He had made this calculation—he wanted to know, as they all wanted to know, where this wonderful energy came from that was so destructive in a flash of lightning. They saw trees rent, buildings thrown to the ground, and terrific effects produced. Where did this energy come from? It was a very simple calculation to show that if they took aqueous vapour, which came in clouds from the ocean, and brought it in contact with a stratum of cool air, the aqueous vapour would be condensed into rain and would fall. If that rain fell at the rate of one millimetre per acre per hour it developed energy equivalent to 600 horse power per acre. If that was spread over a county they would get to millions of horse-power. They could readily see that in that simple operation of the condensation of moisture they had a source of power which only required further investigation on the part of mathematical physicists and experimentalists to develop into a true mechanical theory of electricity. He had always held the belief that sooner or later we should trace an electric current to be a mere vibration—a mere oscillation of the molecules that compose the mass of the conductors. He had carried out in Dr. Warren de la Rue's laboratory and with his great battery a series of the most brilliant experiments deflagrating pieces of wire. These pieces of wire were laid flat between white paper, and the result of the deflagration was shown upon that white paper. Here they had distinct indications that the passage of the current through the conductor assumed the form of waves. Prof. Hughes, one of their best experimenters, and one of the most marvellous men with his fingers (applause), had also been working steadily at this question. The notion that he had gone upon was that in order to account for heat, in order to account for light, in order to account for electricity, and in order to account for the difficult crux of the whole question—the duality of electricity—they would have to prove that the result of the motion in an electric current is spiral—that it is of the character of a right and left-handed screw.

He would say, in conclusion, that he had done all he possibly could to prove that the position taken up by the Lightning Rod Conference was the true one. He had feebly shown Prof. Lodge's views to be in some respects fallacious. He felt satisfied of this, that whether the result of the discussion established the truth of the position taken up by the Lightning Rod Conference, or whether Prof. Lodge would be able to succeed in defending himself, at all events it would have this advantage, that it would bring to their minds what they were all anxious to have brought before them, the true theory of electricity shadowed forth by Prof. Fitzgerald in his inaugural address, an address which he believed would mark this meeting of the British Association at Bath as an epoch in the history of electricity (loud applause).

Prof. OLIVER J. LODGE, F.R.S., on rising to reply, confessed that he had nothing whatever like the experience of Mr. Preece to base his statements upon; so far from having half-a-million lightning conductors under his supervision he had not even one. He had not a lightning conductor to his house, nor was there at present one to the college at Liverpool with which he was associated. He had asked for one to be put up; but lightning conductors seemed at present to be so expensive that the answer he generally got was that it is cheaper to insure (laughter). He thought there must be some fallacy in the argument (which ought to be treated in Section F) that because an insurance company is willing to pay if a thing is damaged, therefore it is nobody's business to protect it from damage. He did not know where the fallacy was; he felt sure there was one. However, manufacturers often acted on that principle. It was perfectly true that if his views were correct very few buildings were effectively and thoroughly protected at the present time; but then it was also true that if they were correct lightning conductors would in the future be bought for—he was going to say as many shillings as they are now bought for pounds; but at any rate they would become much cheaper, and that of itself would be no slight advantage, if, of course, they were equally effective.

Mr. Preece had poked some fun at mathematicians, but as he could hardly pretend to be a mathematician in that room he would not say anything in reply to it—in fact, it was quite unnecessary. At the same time, he was quite willing to argue the point without any introduction of mathematics and without a single symbol. As far as the term "self-induction" is concerned, if electro-magnetic inertia is preferred, he had not the slightest objection to use the latter phrase; it was a very good term, and the only possible objection to it was one of caution, namely, that it might seem to imply a little more than we certainly knew. For himself he felt that we should be quite certain, sooner or later, that self-induction is due to inertia—electric inertia—inertia of electricity, if they might say so. In using the term electro-magnetic inertia they might

Digitized by Google

possibly be understood as implying a knowledge which at present they did not certainly possess. When they did possess it they would be a great deal further on towards the certain statement that electricity is a form of matter. He did not think Mr. Preece recognised how near he went, when he spoke of electro-magnetic inertia, to the assertion that electricity is a form of matter. Mr. Preece's argument (in his Presidential Address) was that electricity is a form of energy because you could buy and sell it, but they might as well argue that sugar is a form of energy for the same reason. Mr. Preece also argued that electricity is not a form of matter because they could make it do work; the hydraulic engineer might equally well argue that water is not a form of matter because with water they could do work.

Mr. Preece began by saying that there is no authentic case on record of a properly-constructed conductor failing to do its duty. He had read carefully the Report of the Lightning Rod Conference, to which Mr. Preece drew attention, and there had found a large number of entire failures. There was one very noteworthy one which was often quoted—a brass rod an inch thick on a steeple in Italy which was smashed all to pieces and the spire destroyed, the flash being seen, he believed, by a number of people. There were a heap of other cases. In his lectures last spring he quoted as the best protected building in the world the Hotel de Ville at Brussels, on which M. Melsens had spent so much time and trouble. That building was elaborately protected. It was protected by innumerable conductors, with admirable earths made in a variety of ways, bristling with points all over the top—everything, in fact, carried out in the most approved style, regardless of expense. But in the month of June that building was struck and set on fire.* The fire was put out. He was sorry that he did not know more of the particulars, which had not been published. He thought, however, that they ought to be published, because that was a building the protection of which had had books written about it—M. Melsens himself wrote a book about it. It should be very instructive to find out, when a thoroughly protected building was struck, how and why it was struck, and what damage was done, and all about it. He did not think, although he spoke from a limited experience, apart from reading, that it could possibly be asserted that existing conductors never fail.

Next Mr. Preece had a hit at him where, he admitted, Mr. Preece had the advantage. Mr. Preece quoted a sort of Midlothian speech of his (laughter), in which he had made an entirely erroneous statement (renewed laughter); but he was not introducing that as a statement of a mathematical calculation, or anything of the sort; it was a mere parenthesis thrown in, and it was very hastily done. Of course, one ought not to do those things, but still if one wrote much one would be very apt at some time or other to make hasty statements. He did not speak of his phase, when he thought that the magnetic permeability squared entered into the expression, as a personal matter, but it was instructive because it must be a condition of mind through which many people had gone. When the Society of Arts asked him to give a lecture on lightning conductors, he thought to himself, "Yes, I will tell them about self-induction," because he knew that the Lightning Rod Conference had not called attention to that, under the name magnetic inertia, or any other. He happened to be writing a Paper which appeared, he thought, in *Nature*—he was not sure where the quotation made by Mr. Preece came from—and in that Paper, having regard to the magnetic permeability of the two metals, copper and iron, he had stated that in regard to the magnetisability of its substance iron was 90,000 times worse than copper. He meant to say, therefore, that although iron was cheaper, was more difficult to melt, had a higher specific heat, and in a variety of ways was better than copper, yet, in regard to this electro-magnetic inertia, it was enormously worse. Before actually giving the Mann lectures, however, he made a few experiments on this point, and to his surprise he found that, so far from being worse, iron was often rather better; and that even a thin wire of iron carried off the discharge better than a thick wire of copper. This experiment naturally and at once effected his conversion. The experiment referred to was that of the alternative conductor; it might be of iron or copper, or any other metal, of any thickness they wished to experiment upon. The top part of the arrangement sketched by Mr. Preece was of no particular interest; at least, they need not attend to it now—the bottom part was the thing. The B spark measured the E.M.F., which drove the current through the alternative path. They should adjust the B part until the flash produced there did not know which way to go—whether to go through the wire or through the air. Half the sparks failed when that is attained. With a spark micrometer at B they measured the distance, and thus obtained the E.M.F. which is on the verge of succeeding in driving the contents of the jar through the wire. He tried first a thick copper wire, and afterwards he tried a thin iron wire of the same length; he found that a greater distance of spark, a greater E.M.F., was needed to drive the contents of the jar through the thick copper wire than through the thin iron wire. Whatever explanation might be given of an experiment of that kind, a direct intimation from heaven could be no clearer. For some reason or other the copper and the iron are at least equally good. He did not press the point that iron is *better* than copper, and he had never stated that copper has more self-induction than iron—that would be a mad thing to say; but it might happen, for some reason or other, that the copper obstructed the current more than iron. He preferred, however, to say that the two metals were equal.

Mr. Preece said that when the Society of Arts asked him to come and bless the Lightning Rod Conference he turned out a Balaam. They did not ask him to bless the conference, they asked him to give a lecture on lightning conductors, so that there had been no breach of contract. There were three parties in the little drama to which Mr. Preece referred—Balak, Balaam, and the ass (laughter). Balak was the gentleman who asked the prophet to come and give a lecture; Balak was therefore the Society of Arts, or, say, Mr. Trueman Wood. Balaam was the prophet, who went and said what he ought to have said. He did not not know who the third party was, unless—(great laughter)—unless he was the party who spoke against the prophet. Mr. Preece said that the function of a lightning conductor was to prevent a flash from striking the conductor—that is to say, that a lightning conductor never ought to be struck, or it failed; but they are struck, because they get melted, and yet in an earlier sentence Mr. Preece said they never failed. He did not know which of those statements was to be taken as correct. If a lightning conductor could prevent a flash from occurring by its point action, well and good; but he had shown in the lectures (he would not trouble them by repeating a statement of the experiments) that there were cases where a point had no protective action whatever, when it can be struck by a thick and heavy flash. There were other cases where the point acted with a brush or fizz and neutralised the electric charge without a flash. But they could not always depend upon it doing that, and so the lightning rod had two functions—one preventive if it can, and the other to carry off a flash when it cannot help receiving it. But they must remember that a flash—at least the electric charge—has always a certain amount of energy, and that it has to be dissipated somehow. It is not a question of a certain quantity of electricity which has to be conducted to earth and then there is an end of it; there must be a certain amount of energy, and they must dissipate it somehow. They could not expect to *hocus pocus* energy out of existence by saying they would conduct the charge down to earth; the quicker they tried to conduct it down to earth the more surging and violent disturbances they were likely to get. It might be better to let it trickle down slowly by using a moderately bad conductor than to rush it with extreme vehemence down a good conductor (hear, hear). Just as it would be safer to let a heavy weight suspended in a dangerous position slide down rather than to let it drop as quickly as possible.

Concerning the length of flashes, he wished he had first-hand information, but he had none; it was one of those things which meteorologists must determine. It was very important to know the length of the flash. He had seen it stated in books that the flashes were a mile long and perhaps more. Mr. Preece thought they were only 500ft. long; that was a matter of fact which could be investigated, but that was a matter upon which he had no direct first-hand information. As to whether the spark length is proportional to the distance or not, he would say that the experiments with oscillating currents to which Mr. Preece magnanimously called his attention yesterday, were conducted with alternating dynamos between points. Now the area of cloud and the area of earth below it are not points; they are flat surfaces, like the coats of a Leyden jar.

Mr. PREECE: They were alternating transformers.

Prof. LODGE replied that they were alternating currents as used in practical commercial work discharging between points. There the law did not seem to hold; but then it ought not to hold, so that would be all right. But between flat surfaces it ought, and the spark length ought to vary with the difference of potential between the two flat surfaces. At the same time if there were points on the earth's surface which were big enough, and if these points determined the flash, then the law of proportionality would not hold. However, the laws concerning discharge in dielectrics were well known and were scarcely matters for argument. The circumstances of an oscillating current did not apply as regards the length of the spark, because until the discharge occurred there was no oscillation; it was a mere static charge. The earth and the cloud above it are exactly like the coats of a Leyden jar, which are preparing to spark into one another, and which do spark into one another when the difference of potential rises to a certain maximum, and the air between is broken down.

The duration of flashes was another point on which much valuable work might be done by meteorologists and photographers. He had seen lightning flashes which certainly appeared to last two or three seconds. He could not imagine that it was one flash which was doing that; he thought it was a series of multiple flashes succeeding one another very rapidly. If any kind of flash can be shown to last long it is an argument that that kind is not oscillatory. The fact that they deflect a compass needle did not prove anything about it; it did not prove anything concerning their duration either, because a ballistic galvanometer is deflected by a momentary kick. A momentary blow given to a thing can deflect it, the blow having ceased long before the motion has ceased which it produced.

There was a difficulty which Mr. Preece did very well to advert to; that was the magnetising power of lightning, and he thought it was the strongest point Mr. Preece had adduced. A flash magnetises steel bars, deranges the magnetism of a ship's compass, conspicuously produces magnetic effects. An oscillating current ought not to produce these effects. An oscillating current with decaying amplitude is used by Prof. Ewing to demagnetise steel, not to magnetise it. The oscillating current would have a gradually decaying vibration. That would demagnetise things, but it ought not to magnetise. It does magnetise them; therefore how can it be a current of this kind? But then the same difficulty would be felt with the Leyden jar discharge. The Leyden jar discharge is certainly oscillatory, because it has been seen to be so, when the sparks have been analysed in a revolving mirror. And yet it magnetised steel needles when sent round them. He did not fully understand that point, and he hoped Lord Rayleigh would say something about it. Mr. Preece was quite right in saying that the whole theory depended upon the existence of oscillations. As far as the theory was concerned, he (Prof. Lodge) had merely called attention to these oscillations (which were well known in the case of Leyden jar discharges, and of which the mathematics had been worked out), and pointed out that they applied also to lightning, which he did not think had been much noticed. A pendulum is an analogue of them. Raising the pendulum represents the charging of a jar; charge it more and more, and then discharge it—that is, let it go. When you let a thing go, it naturally swings before coming to rest; it need not, it may meet with too much friction. Suppose it were oscillating in treacle; he would pinch it hard, so as to represent the oscil-

* See *The Electrician*, September 7th, 1888, p. 550.

Digitized by Google

lation in treacle; it would then have a dead-beat motion down. It may be a slow leak, the discharging of a condenser through a leak, in which case it would come down very slowly. Those are cases in which there is no oscillation, and it entirely depends upon the friction—the viscosity it meets with. If the friction is very great, if it is like a leak, then it would go down slowly, and there would be no oscillation. If the friction is small, and if there is inertia, then it must oscillate. Mr. Preece admits the inertia. Suppose a Leyden jar going to spark, it possesses potential energy like a raised pendulum or bent spring; the instant it sparks a current rushes round. They had then a circular current, which was well known to deflect compass needles, to produce magnetic effects. That is the electro-kinetic inertia—represented by the ordinary inertia of the spring or pendulum when it passes the middle position. You have, first, a static charge; then, while it is flying past, you have a current and magnetic effects and kinetic inertia, which carries it on to its other extreme position of static charge; and so you have these oscillations gradually dying out on account of the friction. If they made it oscillate in water instead of in air, the oscillations would die out quicker. They would die out for two reasons: partly because of friction, which generates heat, partly because it produces waves. If they made it oscillate in water the surface would be disturbed, and waves would travel along; part of the energy would go in heat, and part in waves—that is, producing radiation, or light as they might call it if it were only quick enough to affect the retina.

He did not know what was the energy of a lightning flash, and he wished there were some means of determining it, as its determination would be interesting and important. As to whether lightning was likely to be oscillatory or not, that was a matter of the resistance or friction compared with the capacity and the inertia of its discharger. The smaller the capacity the more likely it is to be oscillatory; the bigger the electro-magnetic inertia the more likely it is to be oscillatory. The capacity discharged in a flash he said is small, and he said so for this reason, that the quantity of electricity discharged is not great; it is well known that the quantity of electricity concerned in a lightning flash was small; the quantity of electricity then existing in the portion of the cloud that is discharged is a small quantity, but the potential of it is enormous. It is able to spark 500ft.—possibly a mile; whatever its real length of spark may be. That meant an enormous potential. When they had a very small quantity raised to an enormous potential it meant that the capacity cannot be great, capacity being the ratio of the two. There was no reason for supposing that the capacity of a condenser discharged in a lightning flash is anything bigger than a Leyden jar—nothing like a microfarad or condensers of that sort. They had some means now of measuring the wave length produced by a discharge, and in that way they might determine a good deal more about them. He would mention as being interesting, perhaps, that the radiation of the waves produced by a microfarad condenser through a coil of self-induction one secohm, as Profs. Ayrton and Perry called it—he preferred to call it a quad—the waves produced by that discharge—ether waves—waves of light, if it is oscillatory, will be 1,200 miles long. They had nothing like that capacity discharged in a portion of thundercloud, which has a capacity of only about, as he guessed it, 10 metres electrostatic units. Mr. Preece had offered to supply him with covered wire in order to repeat these experiments on the alternative path. That was another instance of his magnanimity which he would have the greatest pleasure in taking advantage of, and Mr. Preece might expect on his return to London to have a letter reminding him of his promise, because he (Prof. Lodge) might, perhaps, want large quantities of covered wire for this purpose.

Finally, there was the theory of the protection of area. Mr. Preece said, "If it does not protect an area, what is the good of it?" That was not an argument. He knew Mr. Preece's theory on this point, because it had been published in the *Phil. Mag.* But the area, on Mr. Preece's view, was so extremely small that they might almost give it him without much argument [illustrating on the black board] (Fig. 2). Suppose A B is the lightning conductor and D E the ground; take a base-line equal to the height of the conductor, then take a point at the other corner of the square, then describe a circle with this point C as centre; and, of course, do the same thing on the other side. Now the protected area would be the portion (A D E), and that was not much (applause). If they applied that to every point of the house they would want a lightning conductor to every point, but Mr. Preece meant that therefore you must send up a rod to a gigantic height, so as to bring the house into the protected area. Even then they would not be safe. Why did he object to such a bit of protection as that? Mostly because he thought that areas of protection directed one's attention to side issues—to a thing which it is better not to think about, because there is no certain area of protection. Take another rod (F G) completely enclosed in this area of protection, and lead it up from the ground to near to the lightning conductor so as to leave a little spark space. If "area of protection" has any meaning, that rod ought to be protected, but he said that when a lightning flash (that was merely an assertion, and they need not believe it) struck that conductor A B they would almost certainly get a spark down to this supplementary rod F G, which would take its share and assist in conveying the current; therefore, it is not protected. If a man held a lightning conductor when the flash passed down it he would most likely be killed, and if it passed through gunpowder—well, he did not know about gunpowder, because gunpowder got blown about. It did not matter about the earth: let the intended conductor have a good earth and this supplementary one a bad earth, still the same effect will occur; a spark is likely to occur if the distance be not too great. He said that is so because he had made experiments in the laboratory after this fashion, amongst others. He took a rod which might be of copper as thick as they pleased, he put it in circuit with a Leyden jar, sending the discharge through the rod. This was a solid rod of copper; take a Wollaston platinum wire, or any other wire, as fine as possible so as to make the contrast greater, and arrange it to make a kind of tapping circuit; arrange so that the bottom end shall be in contact with the rod, and the top end an eighth or a sixteenth of an inch away. There they had a splendid conductor, better than any lightning conductor ever was. They would have no trouble about earth, as they had a little tapping circuit close to it—the Wollaston wire, which they could hardly see. It seemed absurd for any portion of the discharge to leave this inch-thick conductor to jump across a sixteenth of an inch of air space, and to make for the little thread of wire. Nevertheless a portion of it does, and from every spark that goes through the conductor a side branch goes to that little wire.

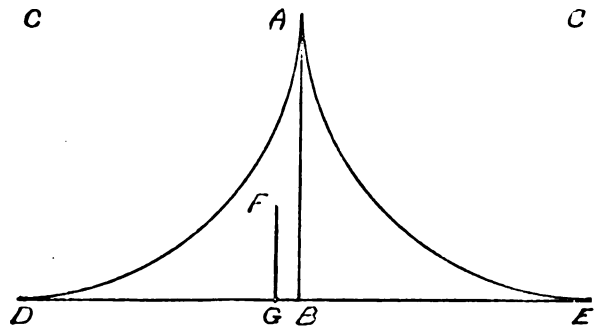

Fig. 2.

There was one point where Mr. Preece might have attacked him, but where he did not think Mr. Preece had made out the full strength of his case, namely, the question—What are the conditions of a flash? He (Prof. Lodge) had assumed that a flash behaves or may behave like the discharge of condensers in a laboratory; but it was a question whether a cloud discharge was of this kind. A cloud is not a good conductor; it consists of globules of water separated from one another by inter-spaces of air, it may be compared therefore to a kind of spangled jar; when a spangled jar discharges there is no guarantee that the whole of it discharges, it discharges out in a slowish manner; it may be that you have first a bit of discharge, then another bit, and so on, so that you may have a kind of dribbling of the charge out of it, and you may thus fail to get these oscillatory and sudden rushes. At the same time he did not think that they could always guarantee doing this with cloud discharges, and it would not be safe in arranging for protectors to protect for only one case, and that the easiest; they must provide for the possibility of a sudden and violent discharge. Still the conditions of actual lightning were to be ascertained by observing lightning and not by experiments in the laboratory.

There are many other known points to which attention might be called, and which would have application in practice. Thus there was the momentum of one spark exciting others; and he was sure there were multiple flashes. Mr. Abercromby had a photograph where the flash is breaking the air down in all directions at once. It is most extraordinary the way in which there seems to be a sort of *rot* set up in the air so that when one flash begins the whole region smashes up in all directions. There was another recently discovered point which could only now be just called attention to, namely, the effect of the light of one spark in assisting others to form. A spark of an induction coil here will be able to start the spark of another induction coil up in the gallery merely by its light; if it is closer it will do it better, but it will do it at very considerable distances. When they considered the very bright light of a lightning flash this effect must have very important consequences. There was no doubt that once a flash occurred the light of it must make all conductors in the neighbourhood—all the air in the neighbourhood—very easily able to break down, and so may give rise to a multiplicity of flashes from all the neighbouring points. That was why he said the idea of areas of protection was misleading. If one flash caused a lot of others you had better not have the one if you can help it. Therefore he said do not run up great long rods to precipitate flashes near powder magazines, or anywhere where it is dangerous, but try to avoid them if possible. If there must be one they must be very careful indeed to have all the other conductors arranged so that the sparks along them do not matter, because if one flash occurred they were likely to get others.

Mr. Glazebrook had just asked him to describe the effect of light in producing a spark. There was no difficulty in it; they merely wanted two induction coils. Take a common induction coil and separate its terminals until they just cannot spark into one another; let the coil be working, but let the sparks just fail to pass. Light a bit of magnesium wire and they would instantly begin to go; take the magnesium wire away and they will stop. Instead of magnesium wire have another coil or a Holtz machine, or anything else, to make the light. Let one be just on the verge of sparking, and let another instrument in another part of the room begin sparking; if the light of that spark can fall upon the space between the terminals of the first, especially upon the cathode of this space, these sparks will begin to pass too. The light of a spark, or ultra violet light in general, seems to make air conduct; a more accurate statement would be that it seems to diminish the transition resistance between the metal and the air, especially upon the surface of the cathode (loud cheers).

CORRESPONDENCE.

SOME EXPERIMENTS ON ELECTRO-MAGNETIC ACTION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Several of my scientific friends have asked me the meaning of the remark on p. 548 of your issue of Sept. 7th, wherein you credit me with having shown that "knots can be tied in a line of (magnetic) force." May I take the opportunity of describing through your columns the experiments which I narrated to you two months ago, and upon which your remark was founded.

Early in the year 1885, in considering the nature of the process by which the variations of an electric current in a circuit set up electromotive forces in a neighbouring second circuit, it occurred to me that if this process were in reality due to action in the intervening medium, and not to action at a distance merely, then it should be affected not only by the material (magnetic or otherwise) of the intervening medium, but also by the structure given to that medium. This idea of structure simmered in my mind for some days, and early in February of that year it took a more definite shape. Every electrician knows how the mutual induction between two circuits is augmented by giving them a common core of iron. Could I not, while using iron, by giving to the pieces of metal employed a particular structural form, actually diminish the mutual induction which existed between the circuits when air only intervened? Nay, could I not by the same means neutralise, or even *reverse*, the ordinary inductive action?

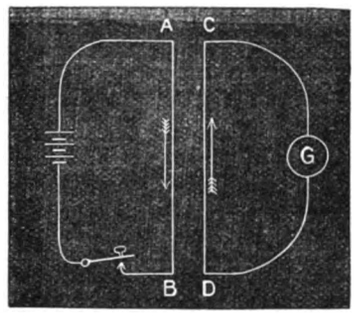

FIG. 1.

To test the matter I determined to begin with two adjacent parallel conductors forming portions, the one of a primary, the other of a secondary circuit. If these are represented respectively by A B and C D, in the diagram, Fig. 1, then in the

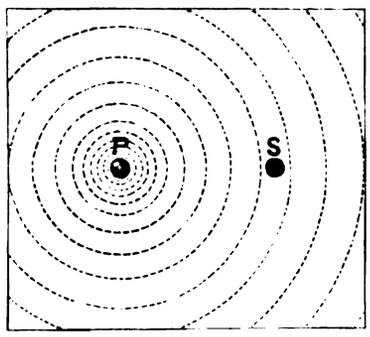

FIG. 2.

ordinary familiar experiment on induction, if a current is started flowing from A to B, it occasions a momentary inverse current from D to C in the neighbouring circuit. To neutralise, or if possible, reverse this action, I determined to introduce into intervening space portions of iron so shaped as to carry the magnetic lines of force due to the primary current out of their usual positions, and cause them to surround the secondary wire C D in the reverse sense to their usual one. To make my idea plainer, I may refer to Fig. 2, giving a section of the field in the case of ordinary induction. P is the primary wire, S the secondary. When we cause that which we call an electric current to start in P, a system of concentric lines of magnetic force is created around the wire, and these spread outwards from the centre, increasing in number until the "current" has attained its final strength. I may be pardoned if I venture, without pushing the similitude too far, to liken this action to the propagation of ripples on the surface of a pond around a central point of disturbance. As these lines of force spread outwards they meet the secondary wire S, and, to use Faraday's well-known language, are "cut" by it, this cutting of the magnetic lines by the conductor giving rise to an induced electromotive force. This action of cutting by the secondary circuit of the magnetic lines, due to the current in the primary, can be enhanced, as *was* well known, by providing iron along the path. A loop of iron wire over-wound in the manner indicated in Fig. 3 helps to

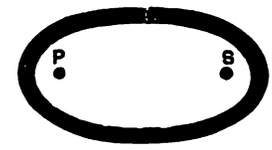

FIG. 3.

carry the magnetic lines of the primary circuit to the far side of the secondary, and greatly increases the induction. All this was known; here began my experiments. I caused a number of iron links to be made, twisted in the form of a figure of 8, but so that the two parts which cross one behind the other should not touch. These were to be threaded upon the two parallel circuits in the manner shown in Fig. 4, the object being to carry the magnetic lines across the secondary circuit in the reverse sense to the usual one, so that the cutting of the lines by the secondary wire should give rise to an inverse electromotive force. I find on refering to my note book that, using a considerable number of these and a battery of three Leclanché cells, I was completely successful, on February 26th, 1885, in obtaining not simply the diminution or annulling of the ordinary inductive action, but in producing an extraordinary induction, such that at the moment of starting a current from A to B an induced electromotive force was set up, tending to send a

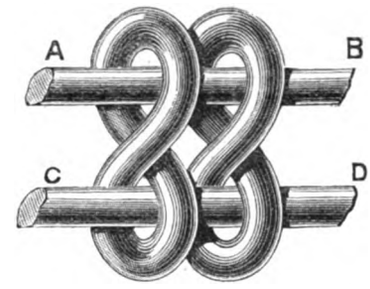

FIG. 4.

current from C to D. I showed the experiment at the time to some of the members of the Bristol Naturalists' Society at the end of one of the meetings of the Physical and Chemical Section. I also mentioned the matter to my friend, the Rev. F. J. Smith, of Oxford, who, however, when attempting to repeat the experiment with a single interwoven iron wire, instead of separate links, failed to obtain the same result. I should probably have pursued the matter further, and taken fuller means of publication at the time, had I not just then received a call to the Finsbury Technical College, and as double duties fell upon me, all my thoughts were absorbed in educational work until the summer, when I left Bristol. I discussed my experiments, however, with Dr. J. Hopkinson and with several other friends from time to time.

In the experiment above described (which was one of several made at the time) the "beknottedness"—to borrow Prof. Tait's term—of the magnetic matter occupying the active

Digitized by Google

region of the medium had been artificially imposed as a sort of structure. I tried several times without success to produce such a structure naturally by discharging powerful currents through insulated wires lying in a mass of iron filings.

Returning from the question of action at a distance to the question of tying knots on magnetic lines of force, the possibility of the latter, or rather of generating magnetic lines in knots, can readily be shown by employing a knotted ring of iron, or bundle of iron wires, such as is shown in Fig. 5, as a

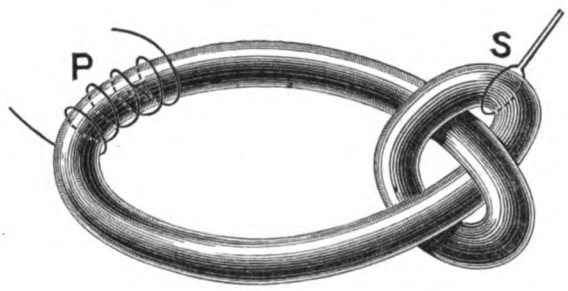

Fig. 5.

closed magnetic circuit. A magnetising coil is provided as at P, and a suitable battery and reversing key. Then an exploring coil, S, connected to a galvanometer, if slipped successively along the tortuosities of the core, will reveal the fact that the magnetic lines follow, at least for the most part, the knotted form of the core, and are themselves, therefore, knotted.

Yours, &c., SILVANUS P. THOMPSON.

20, Arundel gardens, Sept. 15, 1888.

LEA'S HAND-STARTER FOR GAS ENGINES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In reply to Sir David Salomons' letter in your last issue, my hand-starter for gas engines in its present form has no ratchet.

I abandoned ratchets because of the noise and the waste movement. There are no springs or rollers or balls, the grip is instantaneous, and when the hand bar is removed the shell is free to turn round either way on the shaft. The apparatus seems to be fairly well appreciated. In the case of a twin 8 horse-power engine, one man does easily with the starter what it certainly required two men to do previously. Fly-wheels and belts are not safe things to embrace and pull round. Serious accidents have happened with them.

No doubt Sir David Salomons' proposed double-acting arrangement would be very good; but it must of necessity be more expensive and more complicated than mine, which, exclusive of the four bolts and nuts, has only five pieces in it, counting the halves of the shell as two pieces, and including the hand bar.—Yours, &c., HENRY LEA.

LIGHTNING CONDUCTORS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: When pilots differ widely as to the position of hidden rocks and shoals, and as to the force and direction of currents, being also divided in opinion as to the best method of avoiding them, the passengers are perfectly justified in forming their own conclusions on the subject. Such was my reflection after reading the report of what was said at the British Association on the subject of lightning conductors.

No branch of electrical science has benefited more from experimental research than this one, and I believe that more experience of lightning may be gained from a well-directed experiment, no matter where made, than from a piece of wire projecting from the top of every telegraph pole, even though they may be counted by thousands.

Experimental research has done, and is still doing, much to advance our knowledge of electricity; it must not, therefore, be ignored, but accepted as one of the great means to a great end.

There is a phenomenon in Nature which we call wind, and it is divided into well-known degrees of comparison according to the locality in this world of ours over which it more or less moves to establish an equilibrium; electricity is a phenomenon in Nature which behaves in precisely the same way as the wind.

Not by the mere passive experience of observation, but by the active experience of experiment did Dr. Franklin prove that lightning and electricity are one and the same thing, and having invented and brought into his own house a lightning conductor with which he experimented, he was able to formulate simple rules which he communicated through Mr. Peter Collinson to the Royal Society in 1753. These simple rules I should have thought would be all-sufficient for the guidance of those desirous of erecting lightning conductors for the protection of their buildings, &c., at any rate in this comparatively small country where, fortunately for us, lightning is much less prevalent and devastating in its effects than in some of the larger sections of the globe. I have seen lightning "strike" a conductor, and a very beautiful but awe-inspiring sight it was.

If the bottom end of a lightning conductor be placed at one end of an insulated tank filled with water, and a wire making a good earth enters the water at the other end, there are times when, the atmosphere being sufficiently electrically disturbed, the end of the conductor will give off gas and sound in the same way as one pole of a battery will when similarly placed.

I am painfully aware from personal experience of the great ignorance prevailing among "electrical engineers," who are usually employed for this work and who profess to understand the subject. After all, the erection of a lightning conductor is as simple, when properly done, as it is efficient, its length being so short that, to my mind, what metal is used is quite immaterial. Priestley foreshadowed that there was a difference between iron and the other metals when, in one of his experiments, he sent the charge from Leyden jars through two lengths of metal, one iron and one copper; the iron melted, but the copper remained intact. From this experiment he concluded "that copper would be a much greater security as a conductor to guard a building from lightning, besides its being less likely to rust, but then it is more expensive." Alluding to iron, he says, "It is very remarkable that when iron wires are melted by the electric explosion, *bright sparks* are generally dispersed about the room in all directions, but that they are seldom or never seen when wire of other metal is used. . . . ." "It is remarkable that iron should require more heat to bring it into a state of fusion than any other metal, and yet should require but a small force of electricity to do it."

It is always surprising to me how much good work was done in past days by the inadequate means at the disposal of the experimenters, for it must be remembered that they then had only frictional machines and Leyden jars with which to experiment, and yet among their valuable results are to be found conductivity, induction, &c.

In June, 1884, I delivered a lecture at the Royal Institution of Great Britain, entitled, "Volta and Magneto-Electric Induction." I then showed in my induction experiments, that with currents of low duration copper was superior to iron, but that when the currents were increased in speed then iron became superior to copper. I verified these experiments with revolving discs in a magnetic field, with the results given in my lecture, and I at the same time said: "If, as in the case of volta-electric induction, the lines of force are generated too quickly, or, as in the case of magneto-electric induction, the diamagnetic body passes too quickly through the magnetic field, the atoms of the substance in each case have not time to polarise with sufficient rapidity to radiate in the same time or place as when influenced more slowly by this force. This would account for the apparent interruption of the lines of force by the copper plate in the volta-electric experiments, and also for the 'drag' or retardation on the disc of the same metal, whilst part of it is passing quickly through a magnetic field. That being the case, it is easy to perceive that a speed of the copper disc might be attained when the current would be *nil* through the atoms being unable

Digitized by Google

to polarise in the allotted time. Not so with magnetic metals, as iron or nickel, in each of which the atoms appear to be very susceptible to magnetic influence, and to polarise very quickly."

If these experiments are as valid as I believe them to be, it of course follows that upon the conditions and effects to be produced will depend whether iron or copper should be used as a conductor.—Yours, &c., WILLOUGHBY SMITH.

PATENT RECORD.

APPLICATIONS FOR PATENTS.

NOTE.—*The undermentioned applications are not open to public inspection until after the acceptance of the complete specification. The names within parentheses are those of communicators of inventions.*

12,918. E. G. RIVERS. Clevedon. An improved method and principle of constructing secondary batteries or accumulators. Sept. 7, 1888.

12,935. A. CALIPÉ, Jun. London. A new or improved electrical burglar alarm. Sept. 7, 1888.

12,963. J. P. ZIGANG. London. An improved telephone. Sept. 7, 1888.

12,986. R. CRESSWELL. London. An improved electric or galvanic sponge or pad for stimulating and curative purposes. Sept. 7, 1888.

13,000. T. M. SARGEANT and O. R. SWETE. London. Improvements in electric batteries. Sept. 8, 1888.

13,001. T. M. SARGEANT and O. R. SWETE. London. Improvements in the treatment of wood for rendering it impervious to acids and moisture, especially adapted for use in making electric battery boxes, but applicable also to other cases where it is desired to render wood impervious. Sept. 8, 1888.

13,008 J. W. OLDROYD. London. Improvements in electric incandescent lamps with interior reflectors. Sept. 8, 1888.

13,032. G. ALLAN and J. W. BROWN. Liverpool. Improvements in telegraphy and in apparatus therefor. Sept. 10, 1888.

13,035. C. M. DORMAN and R. A. SMITH. Manchester. Improvements in the construction of socket electric lamp holders, wall sockets, and electric lead connectors. Sept. 10, 1888.

13,038. G. QUARRIE. Birmingham. Improvements in facilitating the circulation or flow of electricity in and between animate and inanimate nature. Sept. 10, 1888.

13,061. J. CERPAUX, P. BORRE, and T. MARTENS. London. A new or improved combined telegraphic and telephonic apparatus. Sept. 10, 1888.

13,063. E. S. DEANFIELD and C GRAHAM. Croydon. Improvements in electrical indicators for use on vehicles, or for other analogous purposes. Sept. 10, 1888.

13,076. F. JACOB. London. Electrical signalling apparatus. Sept. 10, 1888.

13,078. U. E. GUÈRIN. London. An electric resistance meter and rheostat. Sept. 10, 1888.

13,122. E. J. PATERSON and C. F. COOPER. London. Improvements in the armatures of dynamo-electric machines. Sept. 11, 1888.

13,126. W. H. CUTTING. London. Improvements in electric calls. Sept. 11, 1888.

13,128. J. IRWIN. London. Improvements in electric railway signalling systems. Sept. 11, 1888.

13,145. E. BÖHM. London. Improvements in incandescent electric lamps. Sept. 11, 1888.

13,191. E. M. H. ANDREOLI. London. Electrodes for electrolytic operations. Sept. 12, 1888.

13,192. E. M. H. ANDREOLI. London. Electrodes for bleaching vegetable substances by electricity. Sept. 12, 1888.

13,193. E. M. H. ANDREOLI. London. Bleaching paper pulp by electrolysis. Sept. 12, 1888.

13,194. E. M. H. ANDREOLI. London. Bleaching China grass, rhea, &c., by electricity. Sept. 12, 1888.

13,208. C. WELLS. London. Improvements in the use of incandescent electric lights. Sept. 12, 1888.

13,215. W. CLARK. London. An improvement in electrical batteries (L. Maiche, France). Sept. 12, 1888.

13,218. E. L. BERRY and F. D'ARC. London. A method of preventing the deposition of crystals in the electrolytic fluids of electric batteries, the said method also allowing of the strength of such fluids being increased beyond their normal strength or that of ordinary saturated solutions. Sept. 12, 1888.

13,221. G. F. REDFERN. London. Improvements in mechanical telephones (G. F. Shaver, United States). Sept. 12, 1888.

13,223. G. SCARLETT. Liverpool. Improvements in or relating to electrical alarm-clocks and indicators. Sept. 12, 1888.

7,853. W. P. Thompson. Liverpool. Improvements in or relating to storage batteries (C. D. P. Gibson, United States.) May 29, 1888.

September 14, 1888.

4,533. M. R. Ward. Westminster. Improvements in electric locomotives and vehicles. March 26, 1887.

10,767. W. Lowrie, C. J. Hall and H. W. Kolle. London. Improvements in instruments for measuring electric currents, and for regulating and controlling dynamo-electric machines and prime movers. August 5, 1887.

11,751. A. E. Nicholl Streatham. Improvements in electrical signalling apparatus for railways. August 30, 1887.

11,932. C. D. Abel. London. Improved means for making and insulating the joints or connections of electrical conducting tables (Siemens and Halske, Berlin, Germany). September 2, 1887.

11,950. J. S. Ross and H. Bains. London. Improvements in electrical telephones. September 3, 1887.

12,025. E. Fitzgerald. London. Improvements in apparatus for operating or controlling type writers, type setting machines and the like by the aid of electricity. September 5, 1887.

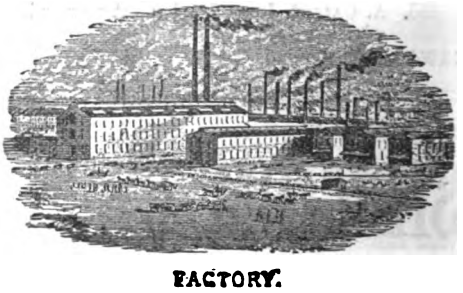
THE NON-CONDUCTOR OF ELECTRICITY.

WAREHOUSE.

VULCANISED FIBRE,
PATENTED.

This new material is supplied in two qualities, Flexible and Hard.
The FLEXIBLE is a substitute for Leather, Rubber, Gutta Percha, &c., and is extensively used by Brass Founders, Axle Makers, Hydraulic, Sanitary, and other Engineers, Pump Makers, Carriage Builders, &c.
It makes the best Hot and Cold Water Packings, and for Axle Washers of all kinds it is unequalled.
The HARD is a substitute for Metals, Hard Wood, Ivory, Vulcanite, Ebonite, &c., and is a good Insulator.
Sold in sheets, 5ft. 6in. by 3ft. 6in., varying in thickness from 1-50in. to 1in.

FLEXIBLE, 2/- per lb.; HARD, 2/3 per lb.



FACTORY.

NEW COMPANIES REGISTERED.

SHEFFIELD TELEPHONE EXCHANGE AND ELECTRIC LIGHT COMPANY (LIMITED).—This company was registered on the 11th inst., with a capital of £60,000, in £10 shares, to purchase from John Tasker, of Sheffield, the goodwill of the Sheffield Telephone Exchange and the Rotherham Telephone Exchange, and also the electrical business carried on by him. The subscribers are:—

	Shares.
*J. Tasker, Sheffield, merchant and manufacturer	1
*J. Gamble, Sheffield, merchant and manufacturer	1
*G. Senior, Sheffield, merchant and manufacturer	1
J. Burdekin Jackson, Sheffield, merchant and manufacturer	1
*G. Franklin, Sheffield, chartered accountant	1
J. Jonas, Sheffield, merchant and manufacturer	1
J. F. Smith, Sheffield, timber merchant	1

The number of directors is not to be less than 3, nor more than 6; qualification, 20 shares; the first are the subscribers denoted by an asterisk, and Mr. William Tasker; remuneration, £300 per annum, to be divided as they may determine.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended September 14, 1888, amounted to £4,406.

VICTORIAN ELECTRIC COMPANY.—At the ordinary general half-yearly meeting of the shareholders of this company, held on July 31st, at the City Bank Chambers, Melbourne, Australia, Mr. Rowan, the managing director, moved that the company be wound up voluntarily. The motion had the full consent of the shareholders in London, who had authorised him to act under the altered conditions, and thus the patent rights would be secured to the new company, to whom it was proposed to transfer the business. Negotiations with another company were still going on, and it was hoped that they would be of distinct value to this company. The motion was carried. The following resolution was subsequently agreed to:—"That Mr. J. F. Levien, Mr. F. C. Rowan, and Mr. H. Fink be appointed liquidators to sell and transfer the business, property, and goodwill of this company forthwith, or at any time hereafter, to a company registered under the Companies Statute, 1864, for the purpose of purchasing the same, and to receive in compensation for such transfer or sale shares in such new company, for the purpose of distribution amongst members of this company; or, if thought expedient, authorising the liquidator or liquidators to enter into any other arrangement whereby the members of this company may, in lieu of receiving cash, shares, or other like interests, or in addition thereto, to participate in the profits of or receive any other benefit from the purchasing company."

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended September 14th, 1888, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company (Limited), were £3,607.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The estimated receipts of this company for the half month ended September 15th, 1888, were £2,479, as compared with £2,065 in the corresponding period of 1887.

PERSONAL.—Messrs. Arthur Carey, A.M.I.C.E., and Guy C. Fricker, A.M.I.T.E. and E., inform us that they have commenced business together as consulting electricians, electrical engineers and contractors, at No. 12, Delahay-street, Westminster, London, S.W.

MICHAEL BIDDULPH, Esq., M.P.
W. P. BOUVERIE, Esq.
ARTHUR CLARKE, Esq.
Sir WILLIAM FORWOOD.
EDWARD LAWRENCE, Esq.
ERNEST NOEL, Esq.
Sir JOHN PENDER, K.C.M.G.
J. DENISON PENDER, Esq.
The Right Hon. LORD SUDELEY, P.C., F.R.S.
LEOPOLD SALOMONS, Esq.
JOHN C. SALT, Esq.
C. A. WHITMORE, Esq., M.P.

Offices—**WINCHESTER HOUSE, OLD BROAD STREET. LONDON, E.C.**

The principal objects of the Corporation are:—

1. Performing the duties of Trustee, Executor and Administrator.
2. The Insurance of Bonds, Shares and all other Securities lodged with the Corporation against risks of all kinds.
3. The Issue of Warrants and Certificates against Securities deposited, and making and procuring advances on such Warrants.

The Office of Trustee or Executor is to private persons usually a thankless post, involving much anxiety, time and money, and frequently leads to serious actual loss; whilst death, illness and change of residence necessitate frequent fresh appointments, and consequent expense to the parties interested. The Corporation undertakes all the duties of Executor, Trustee or Administrator for reasonable remuneration proportioned to the work and responsibility in each case.

The Corporation insures existing Trustees and Executors against all risks attending those positions, where the business is conducted by the Solicitors to their Trusts under the supervision of the Corporation, it not being the desire of the Corporation to interfere in any way with the duties of the family solicitor.

The Corporation acts as Trustees for the Debenture Holders in Public Companies.

For terms, &c., application should be made to the General Manager at the Company's Office.

GEORGE PEARSON, *General Manager and Secretary.*

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL SCIENCE, INDUSTRY AND ENGINEERING.

No. 541.—Vol. XXI. FRIDAY, SEPTEMBER 28, 1888. Price 4d.

NOTES.

Prof. Lodge continues this week his interesting sketch of the electrical Papers read at the Bath meeting. Prof. Hicks's Paper and the discussion to which it gave rise seem to be of considerable suggestiveness, and they deal with matters to which many physicists and mathematicians have lately been giving great attention. A *résumé* of the statements made upon each side during the recent discussion on lightning conductors is given at the end of Prof. Lodge's sketch, and will greatly diminish the reader's labour in picking out the important points of the discussion.

We are pleased to learn that Mr. Preece's advocacy of the term "joule," which was proposed by the late Sir William Siemens for the work done by a watt in a second, has prevailed with the Electrical Standards Committee, who have now definitely sanctioned its use. Mr. Preece's new term "therm" for the water-gramme-degree centigrade unit of heat has also been adopted by the committee. Mr. Preece has done an important service to practical electricians in inducing the committee to take up the subject of the redetermination of the specific resistance of pure copper, as copper can now be obtained commercially of greater purity than the so-called pure copper adopted as a standard by Matthiessen.

The influence of light on the electric discharge through air, which is referred to in Mr. de Tunzelmann's Paper on Hertz's experiments this week, and also in a note on some experiments of Dr. Borgemann, is, as we pointed out in our leader last week, a subject of great theoretical interest. We shall shortly give an account of a theory of electrical action recently developed by Prof. Lindemann, of the University of Koenigsberg, which appears to throw considerable light on the phenomenon.

The Tenth Annual Meeting of the American National Telephone Exchange Association was held at the Hotel Brunswick, in New York, on September 4 and 5. The president, Mr. Henry Metzger, of Pittsburg, in his opening address contrasted the unrest and disquiet which had so long existed in the telephone business from doubts respecting the legal standing of the patents possessed by the different companies, with the sense of security which has followed the recent decision in favour of the American Bell Telephone Company. He pointed out that the effect of this security had been in many cases to induce the directors of telephone companies to pursue a more liberal policy, and one more in accord with the necessities of the business; at the same time warning his hearers that it would not do to fold their hands and rest content with the fruits of this legal victory. Mr. Metzger further insisted on the necessity of their insuring themselves against the dangers of competition in the future by leaving no stone unturned to give the best service at the least possible cost. The warning is one which may well be laid to heart nearer home. A short account of the principal subjects discussed at the Conference will be found in our "American Notes" this week.

From a letter which appeared in the *Financial News* this week, contrasting the telephone systems of Continental cities with that which prevails in London, we learn that the German Government is rapidly substituting silicium bronze for the heavy galvanised wire which has hitherto been used by them. The writer asks, Why has not the United Telephone Company done likewise? Probably because that company is a company, and not a department of the State. With more reason it is asked, Why advantage was not taken of the last great snowstorm to reconstruct the lines on more enlightened principles? Possibly the company could reply to this by showing that they have done so as far as was in their power. We say possibly; but as the United Company never reply to criticisms, being fully occupied in earning and paying dividends, nobody can say a good word for them with any degree of confidence. We desire to give them fair play; but they take no pains to command favour, and they consequently get none.

The Streets Committee of the City have shown commendable promptitude in taking steps to consider the most effective means of lighting the City by electricity, in view of the Electric Lighting Act passed this year. We trust that the deliberations of the committee will lead to a satisfactory result, and that when they present their report it will meet with a more favourable reception from the City authorities than was accorded to the one presented last February, after the protracted negotiations with the Anglo-American Brush Corporation.

Although prices in most departments of the Stock Exchange have been advancing of late, there has been a special upward movement in the quotations of telegraph securities, which has not been been so much due to speculations for a rise as to *bonâ fide* investment purchases. Telegraph Shares have been gra-

Digitized by Google

dually absorbed by the public during the past few weeks, owing to the increased activity in trade, while a further stimulus has been given to the movement by the restoration of rates by the Atlantic companies.

THE increasing popularity of the evening classes at the Finsbury Technical College affords a welcome proof of the valuable work which it is doing, not only in imparting useful practical information to artisans and others who desire to avail themselves of the opportunity afforded them, but also in exciting a more widely diffused sense of its advantages. While we regret that the resources of the college will probably not allow of provision being made for all the applicants this year, we have little doubt that the necessity of passing a test examination before entry will have a beneficial effect in stimulating intending applicants to qualify themselves as fully as possible for obtaining the utmost benefit from the courses of instruction at the College. In order to promote this result the scheme of examination will have to be carefully considered, for one which would lead to the mere superficial "cramming" of text books would most certainly have exactly the opposite effect, but as the examination will be under the direction of Prof. THOMPSON and his able and practical colleagues we need have no fear of the kind.

THE new directors of the ill-fated Maxim-Weston Company have issued to the shareholders a statement of the position of its affairs—a statement which, if published in relation to any ordinary social affair, might be regarded as one long indictment against their predecessors in office. The present directors have the courage of their opinions, and believing that the company can be carried on prosperously "with honest and attentive management," recommend the experiment to be made. We sincerely wish they may succeed, and shall watch with interest the proposal to issue the remaining 188,000 5s. shares at 2s. 6d. It will be seen that the solicitors of Mr. HUGH WATT and the late accountants of the company call in question some of the statements contained in the document above alluded to.

MR. ROBERT ROBERTS, although no doubt a very amiable and unsuspecting person, is certainly as deficient in humour as that famous Member of Parliament who began his speech with "Sugar, Mr. Speaker," and could not understand the burst of laughter which interrupted him. Mr. and Mrs. HOWARD pouring raw sugar into the hoppers on a top floor and sugaring Mr. ROBERTS on the ground floor is such a spectacle of drollery that we can only hope the sugar came quite up to—or down to—it in refinement. Let us not be misunderstood, however. We do not deny that the sugar which Mr. ROBERTS actually saw, and the 5,000 barrels a-day which he expects to see, was and will be refined by electricity; on the contrary, we ardently hope it may be so. What astonishes us and gives us pause is his robust faith in the unseen and the unproved. Even Helen's babies wanted to see "the wheels go wound;" but Mr. ROBERTS is satisfied with the ticking—or, more correctly, the rumbling—of the machinery, which, it appears, sufficiently denotes electricity in the estimation of this gentleman "from Birmingham." BIRMINGHAM ought to know something about electrical processes, if it knows little or nothing about sugar refining. But Mr. ROBERTS has absolutely nothing to tell the people of Birmingham—who are its chief supporters in this country—about the new process except that it is a secret and is going to make their fortunes. If the sugar did not come down the spouts as rapidly as had been predicted, it was because "Mr. and Mrs. HOWARD" could not supply the hoppers with raw sugar fast enough. At present the profits of the venture appear to depend on the muscular activity of these two scions of the HOWARD family; and as regards the future, unless the number can be increased and their secrecy relied upon, electric sugar refining will apparently be conducted on a limited scale. This is disappointing, for we are burning to know what these HOWARDS are doing in the upper chambers. It may be something electrical; but at present all we can learn about it is that they are acting very much like Mr. ARTEMUS WARD'S nigger, who turned the handle of his "perpetchual moshan mashin."

Southend.—It is proposed to work the tram cars running along the new pier at Southend by electricity.

Electric Sugar.—A sample of sugar refined by the new electric process is on exhibition at the office of the *Confectioners' Union*, at 171, Queen Victoria-street.

Walsall.—A new Science and Art Institute was opened on Monday at Walsall. *Fêtes* were held to celebrate the occasion, and a football match was played at night by electric light.

The Mason Science College.—The next session of the Mason Science College, Birmingham, will commence on 1st October. Further particulars will be found in our advertisement columns.

Breaking of an Atlantic Cable.—The Anglo-American Company's Brest-St. Pierre cable broke last Monday. This is the old 1868 cable, which was only repaired on the 28th of July last.

Society of Engineers.—The next meeting of this society will be held on Monday, October 1st, at the Westminster Town Hall, when Mr. W. Lawford, M.I.C.E., will read a Paper on "Light Railways."

The United Telephone Company.—We learn that several changes have been carried out in the staff of the United Telephone Company. The reduction in numbers is small, but there has been a thorough rearrangement of duties.

The British Association.—Among the money grants submitted to the General Committee of the British Association for approval at their recent meeting was one of £100 for continuing the work of the Committee on Electrical Standards.

Cowpen.—Owing to the dispute between the local board and the gas company the town of Cowpen has been left for some time in darkness. By way of protest against this state of things, there was recently a large torchlight procession all round the town. The negotiations with regard to the electric light have come to a complete deadlock.

Portuguese Cable to the Azores.—The *Diario Popular* of September 21st says that the submarine cable which is to join Portugal with the Azores was expected to leave London on Sunday last. The cable will be laid from a point on the River Minho to be chosen by the Government, which has instructed the engineer, Senhor Benjamin Cabral, to take the necessary steps.

Electrical Communication with Lightships.—In the course of a discussion upon the defence of the country, at the autumn

Digitized by Google

meeting of the Association of Chambers of Commerce at Cardiff, Mr. Brooke, of Plymouth, said that the Plymouth Chamber were strongly of opinion that the Government should give greater attention to the question of electrical communication between lighthouses, lightships, and the coast.

Berlin.—The following is a list of the Berlin Theatres lit by electricity, and using a total of more than 13,000 incandescent lamps:—The Royal Opera, 5,000; The Comedy, 2,000; the German Theatre, 1,200; the Barnay Theatre, 1,250; the Kroll Theatre, 300; the Reichshallen, 600; the Freidrich Wilhelm Stadt Theatre, 1,200; the Lessing Theatre, 1,000; the Residenz Theatre, 1,000; and the American Theatre, 200.

Greenwich District Board.—At a meeting of the Greenwich District Board on September 19th a letter was read from the solicitors to the London Electric Supply Corporation, applying for a license, under the Electric Lighting Act, authorising that corporation to erect and maintain electric lines and works and to supply electricity within the district of the Board. The matter was referred to the District Committee, but was not to be considered until certain information was obtained.

The Telephone at Aldershot—During the recent experiments with the new rifle at Aldershot communication was maintained between the markers and the firing party by means of the telephone, and direction and elevation were corrected according to the intimations received from the targets. Some idea of the assistance afforded by the use of the telephone at these important experiments may be gathered from the fact that the firing took place at ranges varying from 2,000 to 2,800 yards.

Electrical Engineering Courses.—Prof. W. Grylls Adams, F.R.S., of King's College, London, will deliver a course of lectures on "Electricity and Magnetism" during the forthcoming Academical year. The lectures will be given once a week, and two days every week will be devoted to practical work. Courses of instruction in electrical engineering have also been arranged for the 1888-89 Session of the Glasgow and West of Scotland Technical College. Further particulars with regard to both of these courses will be found in our advertisement columns.

Manchester Electric Works Company.—We hear that Mr. Binswanger and some of his friends have purchased the works and patents of the defunct Electrical Portable Battery and Gas Igniting Company, with the intention of carrying on the manufacture of electric light fittings and other electrical apparatus. These large works, which are at Manchester, will be carried on under the title of the Manchester Electric Works Company. To meet the requirements of London customers, however, Messrs. Binswanger and Co. will still continue to manufacture in town.

A New Torpedo Boat.—A new submarine torpedo boat, called the "Gymnote," laid down at Toulon on the 30th of April last year, and built on the plans of M. Zede, a retired French Navy constructor, was launched on Tuesday last, the operation being carried out in the strictest privacy. The new boat is nearly 60ft. in length between perpendiculars, and about 6ft. beam. She is provided with a 50 horse-power Krebs electric motor and other machinery, the latter to be worked by means of compressed air. Accommodation is provided for one officer, two engineers, and a seaman.

An Electric Actinometer.—Messrs. Gony and Rigollet have devised a small battery of peculiar construction that may, according to the *British Journal of Photography*, be used as an actinometer. It is made by heating a clean plate of copper over a Bunsen burner till a layer of cuprous oxide forms; this plate, with one of unaltered copper, forms the battery. A galvanometer is introduced into the circuit and the battery then exposed. The effect is instantaneous, and disappears when the light is cut off. Diffused daylight produces an alteration of several hundredths of a volt, direct sunlight an alteration of at least a tenth of a volt. It is stated that with a Thomson galvanometer it is possible to recognise the effect of a candle flame at a distance of several yards.

The Krebs Telephone.—M. Krebs has recently designed a form of telephone the magnetic circuit of which is closed, save for the small air space between the core and the diaphragm, and at the same time is of constant magnetic resistance. Both the core and diaphragm are of soft iron, the magnetic field being produced by one or more magnets, which on the one hand have magnetic connection with the diaphragm, and on the other with the core carrying the bobbin. The diaphragm is of somewhat curious construction, not being of uniform thickness, but designed so that in no part of its section is the iron saturated. By this arrangement the variations in the magnetic field due to the vibrations of the plate are much intensified, with a corresponding increase in the efficiency of the telephone.

Strand District Board of Works.—Dr. Sandwell brought up the report of the Lighting Committee with regard to an application by the London Electric Supply Corporation (Limited) for permission to run a cable through Carey-street and across Portugal-street to the rear of the Royal College of Surgeons. The committee advised that the Board do not refuse the application, subject to certain conditions being complied with. The committee had considered the various applications before them in respect both to licenses and provisional orders for supplying the district with electricity. They were of opinion that the Metropolitan Electric Supply Company (Limited) presented the greatest advantages for the supply within the district, and therefore recommended the Board to approve the granting of a license by the Board of Trade to that company. The report was adopted.

Douse's Fire Check.—Among the appliances which were shown at the recent Fire Rescue Exhibition was Douse's electrical and automatic fire check. Briefly described, this is a chemical sprinkler which is fixed to the ceiling of the building to be protected. By pressing an electric button an alarm is sounded in every room, and the chemical sprinklers are set in action; it also acts automatically. The apparatus consists of a cylinder filled with chemicals, which, on being released, generate a gas in which fire cannot live. The setting in action by electricity is accomplished in two ways. First of all, there is a connection with the outside of the building, on the principle of the fire-alarms in the streets. If a passer by observed that a fire had broken out he could at once press the electric button, which sets the fire check in action. Secondly, immediately the temperature rises to 150° F. an electro-magnet is brought into play, and the sprinklers act automatically.

The Electric Lighting of the City.—At the fortnightly meeting of the Commission of Sewers, held on Tuesday at the Guildhall, Mr. J. V. Moore asked the Chairman of the Streets Committee whether he could give the Court any information on the subject of the electric lighting of the City.—Mr. Bridgman said although the new Act with reference to electric lighting dated only from this year, the committee had very effectually commenced to grapple with the question, and had come to a resolution to refer the matter to the engineer and solicitor to take the opinion of Mr. Preece, and to report on the matter generally, in order that the committee might have drawn up certain conditions on which the electric lighting companies might be asked to send in tenders for lighting the City,

Digitized by Google

Several communications had been received from these companies, and their consideration had been adjourned in order that the committee might deal effectually with them when they got the report.

Leamington.—At the close of the meeting of the Leamington Town Council on Monday, the 17th inst., an animated discussion took place in committee on the question of the electric lighting of the town. After a letter of Messrs. Shippey Brothers, setting forth the advantages of the Waterhouse system, had been discussed, Alderman Gilbert moved a resolution to the effect that Messrs. Chamberlain and Hookham be requested to meet the Council in fourteen days from that date to explain fully what course they intended to take to improve the insufficient lighting of the main thoroughfare of the borough. This resolution was not seconded until after considerable discussion; and then Dr. Thursfield moved an amendment that an expert be called in to determine the quality of the light now being supplied, and whether it is of the illuminating power specified in the contract. A second amendment was moved, to the effect that an estimate be invited from Messrs. Chamberlain and Hookham for the erection of eight arc lamps to be fixed on the Parade as an experiment. This was carried after two hours' discussion.

The Paris Telegraphists.—About 1,500 post office and telegraph clerks met on Monday evening last at the Salle Wagram to protest against the disciplinary measure taken against their comrades of the central office by the Director-General. A number of female telegraphists were present at the meeting. A resolution was passed protesting against the punishment inflicted on the delegates who had signed a circular in the name of the whole body of clerks, and approving every word in that circular. A subscription on behalf of the clerks banished from Paris, started at the meeting, produced about six hundred francs. An official note has contradicted the statement that telegrams have been delayed in consequence of acts of the telegraph clerks. The note attributed the delay to the stormy state of the atmosphere. It appears, however, that there really was delay in the transmission of telegrams not explained by the state of the weather. At the Bourse the Morse apparatus was broken, and parts of the Hughes apparatus were removed. Communication with Amsterdam was interrupted, and telegrams to Brussels, Havre, Lyons, and Marseilles were delayed. A strict inquiry has been ordered into what has occurred, and several of the clerks have been temporarily suspended.

Telephone Extension.—In 1886 the Minister of Posts and Telegraphs granted to the Société des Téléphones, for thirty-five years to come, the concession of all the telephone lines then in existence or to be afterwards constructed. This concession placed a serious obstacle in the way of the development of the telephonic system, and the Government authorities have lately been pressed to seek some means for remedying the evil. An effective step in this direction, says *Industries*, has just been taken. M. Coulon, the Director-General of Posts and Telegraphs, has addressed to the departmental directors of his administration a circular relative to the construction of new telephone systems in towns. After setting out the actual situation of the urban State telephone systems, in which the subscribers pay the annual rent of 200fr., plus the cost of the apparatus and erection, charged for at the rate of 150fr. per kilometre of wire, the circular points out the method of procedure in the case of new urban systems. For all towns which shall apply for it, the Government authorities will draw up plans and estimates of the cost of erection and maintenance till the year 1890, and if the municipal authorities are willing to advance the money, the State will execute the work. The town will then be allowed to repay itself this advance by collecting the subscriptions till the sum is made up; in short, each town controls its own telephone system, the municipal budget provides the necessary funds, and these are repaid by the subscribers' rents.

Evening Classes at Finsbury Technical College.—The evening classes at the Finsbury Technical College open for the Winter Session on October 1. The numbers of students who attended during the past session at the courses in electrical engineering were so great that the authorities talk of instituting an entrance examination to keep out the less competent applicants if, as is expected, there is as great a rush as last year. The Wednesday evening elementary course, devoted chiefly to electric instruments and more general applications of electricity, remains almost unchanged from last year; but the laboratory work for this course has been revised, and the electric lighting of the beginners' laboratory and of the magnetic laboratory has been refitted. The Monday evening advanced course begins this year with the topic of Accumulators and Electro-plating, Professor Thompson having placed these early in the course in order that they may not be crowded out by the lectures on dynamo machines, arc lamps and glow lamps. The laboratory work for this course has been enlarged, and the dynamo room re-arranged so as to admit of more machinery being placed at the disposal of students. Mr. Robinson lectures on "Practical Physics," and Mr. Rousseau again takes a special laboratory class for instruction in electro plating and typing. There are no "special short courses" on electrical subjects this year, but Prof. Perry is to give one on "Spiral Springs" in the autumn, and another short course after Christmas on the "Differential Calculus as applied to Mechanical and Electrical Engineering." There is also a special class in pattern making for engineers. Prof. Thompson is to give a short course of lectures in the new year on "Optical Principles and Practice."

The Electric Light at Barnet.—The following is taken from the *Barnet Press*:—"We regret to say the electric lighting at Barnet has not improved since our notice of last week; there are still about one-third of the lamps unlighted, and although an attempt has been made to assist the electric rays by the feeble flicker of a few oil lamps, the present position is anything but satisfactory, a considerable part of the district being in darkness. On the 6th inst., at about ten o'clock, the whole of the lights went out for some minutes. Again, on the 12th inst., the lights were not started till a quarter-past seven, and after burning unsatisfactorily for an hour they all went out; they were, however, re-lighted, but finally collapsed at half-past eight, and were not lighted again till after midnight. As an illuminant of our public streets the new light has nothing to recommend it in point of cost, for it is indubitably more expensive than the gas which it has for the time replaced, and it is, to say the least, disappointing to find that, as a whole, our town is less effectively lighted than formerly. Matters of opinion apart, it is generally recognised that there has been failure on the part of the contractor to fulfil the contract which he voluntarily entered into after months of deliberation and arrangement; the agreed number of lamps have never been lighted, many of the lamps are admitedly below the contract standard, and when the light has failed, the reserve store of oil lamps (which we were told would be held in readiness in case of emergency) were conspicuous by their absence. The contractor is either doing his level best or he is not, and a judgment based upon either alternative is unsatisfactory: if doing his best, the result is poor; if he is not doing his best—well, he ought to be. Promises are held out of more powerful machinery

Digitized by Google

and a better light presently. We should be sorry to discourage any reasonable hope of improvement; but we confess that the patience of the public is very severely tried."

Long-Distance Telephony.—Dr. Wietlisbach has investigated the best conditions for telephone lines, and has arrived at the following laws for the effect of the disturbing causes: 1. The greater the resistance and leakage, the smaller is the strength of the current received; 2. High self-induction increases the distinctness of high notes; 3. Large capacity increases the distinctness; 4. High resistance diminishes the effect of self-induction, and increases the effect of capacity; 5. Leakage diminishes the effect of capacity, and increases that of self-induction; 6. In a conductor having high self-induction and large capacity, the relative intensity of the undulations increases and decreases periodically with the rise in the height of the note; 7. The magnetic permeability and the polarisation of the conductor destroy the clearness of the transmission. If all of the factors remained constant, it would be possible to design a line in which the relations between capacity, self-induction, resistance, &c., were such that all notes would be transmitted with equal clearness. For example, in a submarine cable where the capacity is great, a man's voice is heard further and more distinctly than a woman's, since capacity increases the distinctness of low notes as compared with high notes; but it would be possible to so increase the self-induction of the line that both would be heard with equal distinctness, and at the same time both would be more perfectly reproduced, since all the tones would be given their proper relative values. Unfortunately this cannot be readily done in practice, since the leakage, which diminishes the effect of capacity, and increases that of self-induction, is in most lines a quantity which varies with the state of the weather. Dr. Wietlisbach thinks, therefore, that the best way to build a line is to make all of the effects as small as possible, using a looped circuit of copper wire of low resistance and capacity. The empirical rule used in practice is to make the product of the resistance and capacity of any line less than a certain constant which has been determined by experiment. One would suppose, however, that by roughly adjusting the capacity and self-induction of the line much clearer speech would result.

Influence of Light on the Electric Discharge.—The current number of the *Philosophical Magazine* contains an interesting letter on this subject from Dr. J. Borgmann, of St. Petersburg. Some time ago the author communicated to the Russian Physico-Chemical Society some experiments on the transmission of the electric current through air, in which flames or points were used as electrodes. In the case of flame electrodes the author arrived at the conclusion that the transition resistance at the surface of the cathode flame was less than that at the surface of the anode flame. He considers that there is a connection between these results and the experiments of Hertz, Hallwachs, Wiedemann, Ebert, and Arrhenius, according to which the effect of light is to diminish the potential, especially if negative. According to the results obtained by some of these physicists, a current can be produced through the air between a negatively charged body and any insulated body separated from it by air; while, according to the author's experiments, such a current is produced directly between the flames or points. The similarity of the effect of points and flames he attributes to the electric glow from the point. On repeating Hallwachs's experiments, the author found that in the case of a negatively charged zinc disc the loss of charge takes place at an increasing rate as the illumination continues. Some experiments seemed to show an after effect of the light. Another experiment described in the letter was the following:—An electric regulator was removed to a considerable distance from the zinc disc, and the electric light was weak. When the disc was illuminated no diminution of the potential on it was visible, even when a zinc screen, perforated for the passage of the light, was placed very near the disc. The screen was removed, and in its stead a Bunsen flame in contact with the earth was placed before the disc at such a distance that it could have no influence on its charge. As soon as the regulator was opened and the light thrown upon the disc, the diminution of the potential of the disc immediately began, *i.e.*, *a current was established between the disc and the flame.* Thus the use of a flame as one electrode favours the creation of a current through the air when a charged zinc disc forming the opposite electrode is illuminated.

The Discovery of the Conducting Power of the Earth.—Historical Note.—The discovery of the conducting power of the earth, one of the most important discoveries affecting telegraphy, was due to Prof. August von Steinheil, astronomer and physicist, who was born at Kappoltsweiler on the 12th October, 1801, and who died at Munich on the 14th September, 1870. In the year 1835, whilst studying at Göttingen, Steinheil was earnestly invited by Gauss to reduce the Gauss-Weber system of telegraphy to a practical shape. This was the commencement of Steinheil's work in the domain of telegraphy, and his investigations soon led him to transform his laboratory at the Munich Academy into a veritable telegraph office. The *Electrotechnische Zeitschrift*, in a notice of a recently issued pamphlet containing an account of his life and work, points out than this great discovery of Steinheil's was by no means his only one. We owe to him the first telegraphic apparatus for the visible or audible reproduction of electric signals, not to mention the principle of the lightning arrester now so universally employed. In 1837 Steinheil established telegraphic communication between the Munich Academy and the Observatory, a distance of over three miles, and between his private observatory and his laboratory. The conducting power of the soil in the case of frictional electricity had been shown in 1746 by Winkler; and in 1803 Basse, of Hameln, had shown that the same held for galvanic currents; but it is evident that neither Winkler nor Basse clearly understood the phenomenon they had observed. Profs. Ermann, of Potsdam (1803); Aldine, of Calais (1803), von Sömmering and Schilling (1811) repeated Basse's experiments, but none of them thought of this fact in connection with telegraphy. Gauss being imbued with the idea of utilising the rails of a railway line as conductors, Steinheil set to work to investigate the matter, and obtained permission to carry out his experiments on the Nuremberg-Fürth line, the first constructed in Germany. Steinheil joined the rails at either end by copper wires, and in this closed circuit he placed his telegraph instruments; but the rails not being insulated he was unable to transmit signals through more than about 30 lengths of rail. He then insulated the rails as much as possible, and again tried to transmit signals, but without success. It was evident that the current was short-circuited, and this could only be through the earth. Steinheil then replaced one of the rails by an overhead wire, the two ends of which were connected to the remaining rail. Signals were now easily sent through the circuit, and the same took place even when several lengths of rail were taken up. Thus, in 1838, exactly 50 years ago, Steinheil discovered the fact that the earth was a conductor, and could be used in lieu of a return wire. He immediately applied his discovery to his Munich lines with perfect success. When Steinheil first announced his discovery it was regarded as a piece of trickery, but before long its value was realised and its truth tested.

SKETCH OF THE ELECTRICAL PAPERS IN SECTION A AT THE RECENT BATH MEETING OF THE BRITISH ASSOCIATION.

BY PROF. OLIVER J. LODGE, F.R.S.

(Concluded from page 625.)

On Saturday the principal communication was one from Prof. Hicks on "A Vortex Analogue of Static Electricity," wherein an idea concerning the ultimate nature of electrostatic attraction is promulgated, which promises to have the most vital influence not only in electrostatics, but in electro-chemistry and theories of valency in general. These points came out most strikingly, not on Saturday when the Paper was read, but at a later stage on the Wednesday following. It so happened that, by reason of the section meeting on this Wednesday an hour earlier than usual, several of the authors failed to turn up, and the sitting threatened to collapse. The section, however, promptly requested its President to fill up the time by telling them the present state of the controversy concerning the elimination of Ψ from the general equations of the electromagnetic field—the equations concerned with electromagnetic wave propagation. Prof. Fitzgerald at once responded by telling us, not about Ψ, but about Hicks; calling attention to a few ideas which the vortex analogue of static electricity had suggested to him. Prof. Hicks joined in with fresh suggestions, and in about ten minutes of to and fro conversation the most splendid possibilities of future theory, avenues of light permeating the ultimate facts of chemistry as the ramifications of a lightning flash permeate the atmosphere, were opened up. One may attend many British Association meetings without hearing a "desultory conversation" such as this; one may organise discussions and endeavour to secure them, but they are by no means certainly so procurable. Like genius they must arise spontaneously, or not at all, and woe be to the President who nips them in the bud.

The main point in Prof. Hicks' communication was a statement of the way in which, under certain circumstances, a hollow vortex may arise between two bodies which are being separated in a perfect fluid. These hollow vortices, or whirls, or cyclones, differ from ordinary vortices in having as their core a stagnant portion of fluid, or an empty space, and their motion is what is known as irrotational—that is, there is no spin at every point of the liquid. The consequence of the centrifugal force of the whirl is a reduction of pressure at the centre, as meteorologists well know is the case with atmospheric cyclones, and as anyone may see in an ordinary plug washhand basin. The effect of this reduced pressure at the axis of the whirl is to enable the circumambient fluid to press the two bodies towards each other, and thus to give rise to a measurable attraction. The mathematical laws of hollow vortices are found by Hicks to be such that they distribute themselves over the surfaces of bodies precisely like lines of electrostatic force, and they urge the two bodies together with a force varying inversely with the square of the distance. Thus they obey the laws of electrostatic attraction, and every hollow vortex may be called a line of force. Their ends abutting on the surfaces of the bodies will be analogous to, and will represent, the phenomenon called "electrostatic charge;" and however far the bodies are separated these "charges" remain constant. The aspect of the whirls being opposite, as seen from either body, their ends may be styled positive and negative respectively.

If a third body is introduced between the original pair, some of the whirls separate into two, with their ends abutting on the intermediate body, which thus acquires equal positive and negative charges: it is subject to induction. And so on. All the main phenomena of static electricity may be imitated by the behaviour of these hollow vortices in a perfect fluid, and they take the place of lines of force.

Now comes the chemical application. The circumstance which is essential for the generation of these hollow vortices, when two bodies are separated from contact, is that during contact they shall be connected by an ordinary vortex filament with its ends abutting one on each body. Such a filament causes throughout the medium a state of rotation which results in the generation of a hollow vortex at the point of contact as soon as that contact is broken. When the distance between the bodies (which may now be called atoms) becomes considerable, the original vortex filament is so pulled out as to exert very little effect, and it may be neglected; but the hollow vortex generated by it increases in energy as the bodies are separated against its attractive influence, and retains its cross-section unimpaired.

The original vortex filament joining the atoms in contact thus corresponds to what chemists call a "bond" or unit of chemical affinity. There may easily be more than one such bond, perhaps as many as six, joining two bodies; it is a question of stability, and the limit of number can be worked out by vortex mathematics. The hollow vortex which makes its appearance when the atoms are separated corresponds to the electrostatic charges and lines of force existing between the monad constituents of a dissociated molecule.

If there are two bonds with the same sense joining two atoms in contact, then when they are separated two hollow vortices will be found between them, corresponding to the two units of electrostatic charge which are found on a dissociated dyad atom. Any one hollow vortex may easily split up so as to distribute its ends properly over the surfaces of the bodies as they are further separated, but its essential properties are unaltered by fission; and the exact dependence of the electrostatic charge on the original number of dissociated bonds is an evident restatement of Faraday's law of electrolysis.

But there is the possibility that two original bonds should whirl in opposite directions, and in that case they would neutralise each other's effect at the point of contact and generate no electrostatic charge at all when the bodies are separated. Such a mode of combination may correspond to what chemists style "molecular," and atoms dissociated from such molecules would be intractable to electrical influence—the compound would not be an electrolyte.

There is no need for the original vortex filament to reach across from one body to another; its ends may quite well abut both against the same body, and in that case we shall have a self-satisfied pair of units of chemical affinity. Another body coming into the neighbourhood of such a looped bond may open it out; and it may do so in either of two ways; it may break it in two in the middle, thus linking itself to the first body by two bonds of opposite sign; or it may let one end slide from the original body on to itself, thus effecting a monad style of combination, giving rise to electrified atoms when dissociated.

Furthermore, of the self satisfied or looped bonds possessed by a body there may be a considerable number—possibly a very great number; it is again a question of stability to be worked out, but not yet worked out, by hydrodynamics; and the loops may some of them be long, so as to project a good distance from the body, while some may be quite short and close to its surface.

The long loops will correspond to the important bonds able to intersect and combine with another atom at a considerable distance—that is, at a high temperature; while the shorter and closer loops can only be expected to act at close quarters, *i.e.*, when the temperature of the substance is low. Thus it may turn out that at very low temperatures all manner of complex aggregations are possible.

At first sight it might seem as if high temperature favoured chemical combination, but that is a mistake. High temperature is often necessary to break up existing molecules, and so to enable fresh and often more powerful combinations to form; but high temperature is a dissociating and expanding influence *per se*, and it is at low temperatures that the most unwieldy complexes are formed.

So far nothing has been said concerning the nature of the atoms themselves; but assuming that they can be formed of groupings of circular vortices, it becomes of interest to see what combinations are stable, and therefore possible. It has been shown that the greatest number of columnar or cylindric vortices which can waltz round one another in stable equilibrium is six;

Digitized by Google

but Mr. Hicks surmises that, the circular form being a little more stable, a combination of as many as seven *rings* may be able to group together, threading each other in regular succession, and forming a single atom of a definite kind, up to which there are six grades, constituting other and simpler kinds of atoms. To form a more complex atom than this, these seven rings must be treated as a single atom, which can begin to link itself with from one up to seven others; and then the grouping will begin again; so that the properties of the elements and their atomic weights will fall into octaves. Should this view be borne out by hydrodynamical calculation the meaning underlying Mendelejeff's law will have a good chance of displaying itself; or rather, it will have been completely displayed.

So busy was Section A, that on Saturday, when many of the sections took a holiday, it split itself into two in order to get through its work; and even so, one of the sub-sections continued sitting till three p.m.

Towards the end of the day the report of the Electrolysis Committee was read. It was a short statement of the work that had been done by the members during the past year, and was followed by a few Papers. The communication of Lord Rayleigh concerning the velocity of light in electrolytes should have formed part of this report, and would have done so had the secretary of the Electrolysis Committee (O. J. L.) looked after its interests as he ought.

Prof. Fitzgerald and Mr. Trouton have continued their investigations into the accuracy with which electrolytes obey Ohm's law, and are now able to state that if there is any discrepancy for sulphate of copper it is less than three parts in a million. This is a very satisfactory result, the obtaining of which means a good deal of careful work as well as an ingenious method.

An account of Dr. Gladstone and Mr. Hibbert's experiments on the conduction of alloys and solid sulphides followed, wherein it was shown that the conductivity of fusible alloy was mainly and probably wholly non electrolytic, while sulphides of the form M_2S were most of them electrolytically decomposed by a current.

Prof. Armstrong and Dr. Arrhenius contributed some critical remarks on the general theory of electrolysis, which, however, in their absence, were taken as read, and will be printed with the report.

Mr. Shaw communicated a Paper sent by Dr. Richarz, from Berlin, containing an account of some experiments on the polarisation E.M.F. of a voltameter with very small electrodes, wherein he switched the voltameter cell quickly from a charging battery to a galvanometer by means of a Helmholtz pendulum, and thus obtained values of the polarisation decidedly lower than had been previously obtained with point electrodes by Buff. Richarz seeks to explain the difference by neglected heat effects.

The time of Tuesday was so largely taken up with a discussion on lightning conductors that Dr. Fleming's two Papers "On a Form of Standard Resistance Coil," and "On a Commutator for Charging and Discharging a Condenser at a known Rate," had to be taken as read.

Mr. Glazebrook stated the results of his continued most careful investigation into the state of the old B. A. Standards of resistance. Examining them with the most minute accuracy and plotting their results over a certain range of temperature, their curves all nearly intersect at a temperature where they are supposed to be correct. They do not, of course, exactly intersect at a point, but they agree very well; and, what is of most interest, they have preserved their relative values among themselves ever since they were first exactly compared by Dr. Fleming in 1875 (?). All except one, which has recently begun to show distinct signs of aberration, probably by reason of some slight defect in insulation. Since these coils are the world's material standard of resistance at the present time, it is most desirable to know that they are constant; and, inasmuch as they are made of different materials and have preserved their relative values, it is practically quite certain that their absolute values have remained unchanged.

The Committee on Electrical Standards are undertaking experiments with a view to construct a reliable standard of electrostatic capacity, and are examining some air condensers constructed and measured some time ago by Dr. Muirhead.

Mr. Preece's Paper on C.-G.-S. units is really a communication to the Electrical Standards Committee, asking them to sanction the use of the term "joule" for the work done by a watt in a second, as proposed by the late Sir W. Siemens. The committee have acquiesced in the suggestion, and the Joule is therefore now 10 million ergs, or a coulomb-volt. They have also, at Mr. Preece's instigation, sanctioned the name "therm" for the water-gramme-degree-centigrade unit of heat, the absolute unit of heat being either the erg or the joule, according to taste. The joule will make a unit of heat of very convenient size, because 4·2 such units will equal 1 therm. In other words, the absolute specific heat of water will be henceforward 4·2, and the specific heat of other things in proper proportion.

Mr. Preece further proceeds to lament the unfortunate circumstance which has caused the ampere to be one-tenth of the C.-G.-S. unit of current instead of one unit. He is sanguine enough to hope even yet for a change in this matter, but the feeling of the committee was not with him, though they all felt the inconvenience of the present state of things.

Another matter which he has succeeded in inducing the committee to take up is a redetermination of the specific resistance of pure copper. It appears that copper is now supplied commercially by manufacturers which eclipses the standard as tested by Matthiessen, and which was known in his day as pure copper.

Sir William Thomson described a determination of the product μK for air, commonly called a determination of the velocity of electromagnetic waves "v". A certain condenser had its capacity measured electromagnetically at Glasgow with the use of one of Sir William's new standard current weighing instruments, and it was then measured electrostatically in London by Professors Ayrton and Perry. The resulting value of "v" comes out from the experiments so far made distinctly too low, something like 293 thousand kilometres per second, with a possible total error of $1\frac{3}{4}$ per cent.; as compared with the 299·5 thousand kilometres per second determined by Professor Rowland, with very perfect condenser, absolute electrometer and ballistic galvanometer. Most of the German determinations of "v" slightly exceed 300; most of the British determinations slightly fall below it. If the method now described is to give a reliable value, it will doubtless be repeated many times, and the somewhat large margin of error reduced.

In connection with absolute determinations of great accuracy, it is surprising how many difficulties come in, such as seldom have to be thought of in ordinary laboratory observations. Considering all the care that has been taken in the construction of standards of length, it is rather depressing to be told by Prof. Rowland that the standard metre is an uncertain quantity, and that the various metre standards in use differ by so much as one-tenth of a millimetre, or a hundredth per cent. People accustomed to speak glibly about obtaining an accuracy of a tenth or a hundredth per cent. in their measurements little know what they are talking about. Probable errors of as much as 1 per cent. in an absolute measurement are much more frequent than is by many persons suspected.

Mr. Glazebrook has been most carefully and for a long time examining the specific resistance of mercury in glass tubes, a measurement which has revealed unexpected difficulties and distinct though minute discrepancies from previous determinations. There can be little doubt that Mr. Glazebrook's results are the most accurate yet obtained, and he states that the true ohm is equal to the resistance of a square millimetre column of mercury 106·29 centimetres long.

We are here getting down to the limit of accuracy with which the standard metre itself is known.

Sundry minor communications may be hastily glanced through. A method of utilising an electric current for calorimetry by Prof. Stroud and Mr. Gee really belongs to the subject of Heat. Mr. W. N. Shaw exhibited an arrangement for measuring the average temperature of an ex-

Digitized by Google

tended body, consisting of wires imbedded in a long ribbon of india-rubber which could be wrapped about the body, and the resistance of the wire measured. The wire is made in two branches, each of a different metal, so that a differential galvanometer balance can only be exactly obtained at one particular temperature, and the compensation needed to correct any outstanding error is used to obtain the temperature. It is said to give it to about $\frac{1}{500}$th of a degree. Mr. J. Brown, of Belfast, exhibited some pretty and curious branching figures made by an electric spark on an ordinary photographic dry plate. Mr. Lant Carpenter stated some particulars concerning the E.M.F. and internal resistance of Gassner's jelly-filled battery cells, as measured by Mr. Rimington; and last, though not least, Sir William Thomson described some experiments made in his laboratory by Mr. Tanakadaté on the magnetisation of soft iron bars of different lengths in a uniform field. This Paper the writer regrets not having heard.

And now we have cleared the course for the Lightning Rod Discussion, which excited a good deal of interest, and which really was a discussion, in which many prominent members of the section took part, and on which much more might have been said had there been time.

The discussion is being reported in this journal pretty nearly verbatim; but out of such a mass of matter it will be difficult for anyone to pick out the salient points of difference between the opposite camps, and it may be useful to bring them into more marked relief.

The opposite camps may be styled the Practical *versus* the Theoretical. On the one side we find Constructors of lightning rods, Members of the Lightning Rod Conference, Meteorologists, and Engineers: a miscellaneous body of great experience headed for the time being with efficiency and good humour by the President of Section G, who has necessarily in his official position an enormous number of lightning protectors under his supervision.

On the other side we find some laboratory experiments, and a theory of the alternating character of a discharge, combined with a mania for talking about self-induction or electromagnetic inertia, and for poking this idea into a lot of places where it does not naturally seem to fit; excluding its influence, however, from other places where one would expect to find it, such as the interior of an iron rod.*

If views and statements so founded are to make headway against the experience of practical men, and to gradually introduce reform into existing procedure, it must be by reiterated statement and discussion, and after gradually acquired further experience, under circumstances and conditions arranged to test the new views on a large scale. On the other hand, if the self-induction mania has no sound basis in fact, the surest way of destroying it is to bring it into the arena and expose it to conflict. Hence it is that the organising committee of Section A arranged for the opposite camps to meet and skirmish at Bath.

The combat was not waged to the death, the lists being cleared before the combatants were half exhausted, so that it is quite possible they may meet again on some other arena. Meanwhile, the points at issue may be summarised thus: selecting those statements of Mr. Preece and his supporters which seem most generally accepted, or likely to be accepted, on that side; and numbering the opposing statements so as to correspond with them. No statement is here quoted or suggested which to the writer seems entirely absurd; because absurd statements may easily be made in debate without sufficient thought, and because such statements are not likely to be generally or weightily accepted, even if pressed by their propounder.

Statements made in the Practical Camp.

1. Properly constructed lightning rods never fail. When existing rods fail it is because there is something the matter with them—usually an insufficient earth.

2. Leyden jar discharges have nothing oscillatory or alternating about them, or at least the existence of such alternations is an unproved assumption.

3. Even if Leyden jar discharges should turn out to be oscillatory, there is no reason why lightning flashes should be of the same character. Lightning flashes have an apparent duration, and transmit telegraph signals, deflect compass needles, and do other things which alternating currents could not do.

4. The one thing needful for an efficient lightning protector is conductivity, sufficient conducting power to convey the whole charge quickly and harmlessly down to the earth, with which the conductor must make elaborate contact.

5. No danger is to be feared from a lightning conductor if only it be well earthed and be sufficiently massive not to be melted by a discharge. All masses of metal should be connected to it, that they may be electrically drained to earth.

6. The shape of the sectional area of a conductor is quite immaterial; its carrying power has nothing to do with extent of surface; nothing matters in the rod itself but sectional area or weight per foot run, and conductivity.

7. Points, if sharp, should constitute so great a protection that violent flashes to them ought never to occur.

8. Lightning conductors, if frequently tested for continuity and low resistance by ordinary galvanic currents, are bound to carry off any charge likely to strike them, and are absolutely to be depended upon. The *easiest* path protects all other possible paths.

9. A certain space contiguous to a lightning rod is completely protected by it, so that if the rod be raised high enough a building in this protected region is perfectly safe.

Statements made in the Theoretical Camp.

1. Rods as at present constructed, though frequently successful, may and do sometimes fail, even though their earth is thoroughly good; the reason being that they offer to a flash a much greater obstruction—a much worse path—than is usually supposed: an obstruction to be reckoned in hundreds or thousands of ohms, even for a very thick copper rod.

2. When a Leyden jar is charged it corresponds to a bent spring, and its discharge corresponds to the release of the spring. Its discharge current alternates, therefore, in the same way and for much the same reason as a twitched reed or tuning fork vibrates. The vibrations decay in either case because of frictional heat production, and because of the emission of waves into the surrounding medium. A single spark of a Leyden jar, examined in an exceedingly fast revolving mirror, is visibly drawn out into a close succession of oppositely-directed discharges, although its whole duration is so excessively minute.

3. A lightning flash is a spark between cloud and earth, which are two oppositely electrified flat surfaces, and the flash corresponds therefore to the internal sparking between the two plates of a great air condenser. All the conditions which apply to a Leyden jar under these circumstances are liable to be true for lightning. Sometimes the resistance met with, either in the cloud itself or in the discharger, may be so great that the spark ceases to be oscillatory, and degenerates into a fizz or rapid leak; but there can be no guarantee that it shall always take this easily manageable form; and it is necessary in erecting protectors to be prepared for the worst and most dangerous form of sudden discharge. The apparent duration of a lightning flash is due to its frequently multiple character, and indicates successive discharges, not one long-drawn out one. Nothing that lightning has been found to do disproves its oscillatory character; because Leyden jar discharges, which are certainly oscillatory, can do precisely the same.

4. Although some conductivity is necessary for a lightning conductor, its amount is of far less consequence than might be expected. The obstruction met with by an alternating or rapidly varying discharge depends much more on electromagnetic inertia or self-induction than upon common resistance. So much obstruction is due to this inertia that a trifle more or less of frictional resistance in addition matters practically not at all.

It is very desirable to have a good and deep earth in order to protect foundations and gas and water mains from damage, and in order to keep total impedance as low as possible.

5. The obstruction offered by a lightning rod to a discharge being so great, and the current passing through it at the instant

* Prof. Lodge's original lectures "On the Protection of Buildings from Lightning," were reprinted in *The Electrician*, June 22 and 29, July 6 and 13, 1888.

Digitized by Google

of a flash being enormous, a very high difference of potential exists between every point of the conductor and the earth, however well the two are connected; hence the neighbourhood of a lightning conductor is always dangerous during a storm, and great circumspection must be exercised as to what metallic conductors are wittingly or unwittingly brought near or into contact with it. When a building is struck the oscillations and surgings all through its neighbourhood are so violent that every piece of metal is liable to give off sparks, and gas may be lighted even in neighbouring houses. If one end of a rain-water gutter is attached to a struck lightning conductor the other end is almost certain to spit off a long spark, unless it also is metallically connected. Electric charges splash about in a struck mass of metal, as does the sea during an earthquake or when a mountain top drops into it.* Even a small spark near combustible substances is to be dreaded.

6. The electrical disturbance is conveyed to a conductor through the ether or space surrounding it, and so the more surface it exposes the better. Better than a single rod or tape is a number of separate lengths of wire, each thick enough not to be easily melted, and well separated so as not to interfere with each other by mutual induction.

The liability of rods to be melted by a flash can be easily over-estimated. A rod usually fails by reason of its inertia-like obstruction, and consequent inability to carry off the charge without spittings and side flashes; it very seldom fails by reason of being melted. In cases where a thin wire has got melted, the energy has been largely dissipated in the effort, and it has acted as an efficient protector; though, of course, for that time only. Large sectional area offers very little advantage over moderately small sectional area, such as No. 5 B.W.G.

7. Points, if numerous enough, serve a very useful purpose in neutralising the charge of a thunder-cloud hovering over them, and thus often prevent a flash; but there are occasions, easily imitated in the laboratory, when they are of no avail; for instance, when one upper cloud sparks into a lower one, which then suddenly overflows to earth. In the case of these sudden rushes, there is no time for a path to be prepared by induction, no time for points to exert any protective influence, and points then get struck by a violent flash just as if they were knobs. Discharges of this kind are the only ones likely to occur during a violent shower; because all leisurely effects would be neutralised by the raindrops better than by an infinitude of points.

8. The path chosen by a galvanic current is no secure indication of the course which will be taken by a lightning flash. The course of a trickle down a hill-side does not determine the path of an avalanche. Lightning will not select the easiest path alone; it can distribute itself among any number of possible paths, and can make paths for itself. Ordinary testing of conductors is therefore no guarantee of safety, and may be misleading. At the same time it is quite right to have some system of testing and of inspection, else rust and building alterations may render any protector useless.

9. There is no space near a rod which can be definitely styled an area of protection, for it is possible to receive violent sparks or shocks from the conductor itself. Not to speak of the innumerable secondary discharges which, by reason of electro kinetic momentum and of induction and of the curious recently discovered effect of the ultra-violet light of a spark, are liable to occur as secondary effects in the wake of the main flash.

Just one word on the subject of iron *versus* copper. The writer last year thought and stated that, in so far as the substance of the conductor was magnetised by a discharge, iron would obstruct a lightning flash or any other rapidly-varying current enormously more than copper does. But the fact is, that the substance of a conductor is, by sufficiently rapidly alternating currents, not magnetised at all. The current is tubular, keeps wholly to the outer surface, and magnetises nothing inside. Hence the magnetisability of the substance of the conductor is of no moment at all; and iron, therefore, will do every bit as well as copper. Mr. Preece's experience with half a mill on iron-wire telegraph-post protectors leads him to uphold iron as entirely satisfactory. So, on this one point, as well as on the necessity existing for a good earth, a portion of the practical and of the theoretical camps have been able to agree.

Immediately after the discussion Dr. Janssen exhibited some preliminary attempts at photographs of lightning taken with a double-nozzled camera, having two sensitive plates, one fixed, the other revolving 30 times a second.* The same flash was depicted on both plates, but on the moving plate it was separated into two or three distinct streaks, showing its multiple character. Each constituent, however, was as clear and distinct on the rotating as on the fixed plate, and had, in fact, exactly the same shape and appearance, so that one could be superposed on the other exactly; thus proving its instantaneous character. The rate of spin was naturally nothing like sufficient to exhibit the alternating character of each constituent.

It is to be hoped that many more photographs of lightning will be taken on this plan, because there are evidently many kinds of composite flashes, and it is an excellent way of analysing them and correcting the impressions, often erroneous, formed by the eye.

On the whole, the Bath meeting, though not largely attended by the temporary class of members and associates, may be considered, so far as Section A is concerned, as one of the most interesting and important that have ever been held—thanks largely to the excellent arrangements made by the Secretaries; and the discoveries of Hertz, referred to by the President in his address, mark a distinct epoch in our acquaintance with electromagnetic phenomena.

* *See* "The Eruption of Krakatoa," a pamphlet by E. Douglas Archibald, Tunbridge Wells; or the Report of the Krakatoa Committee.

HERTZ'S RESEARCHES ON ELECTRICAL OSCILLATIONS.

BY G. W. DE TUNZELMANN, B.SC.

(*Continued from page 627.*)

Nodes.—The vibrations in the micrometer circuit which have been considered are the simplest ones possible, but not the only ones. While the potential at the ends alternates between two fixed limits, that at the central portion of the circuit retains a constant mean value. The electrical vibration, therefore, has a node at the centre, and this will be the only nodal point. Its existence may be proved by placing a small insulated sphere close to various portions of the micrometer circuit while sparks are passing at the discharger of the coil, when it will be found that if the sphere is placed close to the centre of the circuit the sparking will be very slight, increasing as the sphere is moved further away. The sparking cannot, however, be entirely got rid of, and there is a better way of determining the existence and position of the node. After adjusting the two circuits to unison, and drawing the micrometer terminals so far apart that sparks can only be made to pass by means of resonant action, let different parts of the circuit be touched by a conductor of some capacity, when it will be found that the sparks disappear, owing to interference with the resonant action, except when the point of contact is at the centre of the circuit. The author then endeavoured to produce a vibration with two nodes, and for this purpose he modified the apparatus previously used by adding to the micrometer circuit a second rectangle *e f g h* exactly similar to the first (as shown in Fig. 7), and joining the points of the circuit near the terminals by wires 13 and 24, as shown in the diagram.

The whole system then formed a closed metallic circuit, the fundamental vibration of which would have two nodes. Since the period of this vibration would necessarily agree closely with that of each half of the circuit, and, therefore, with that of the circuit C C', it was to be expected that the vibration would have a pair of loops at the junctions 13 and 24,

* *See* a letter in *Nature*, July 12, 1888.

Digitized by Google

and a pair of nodes at the middle points of cd and gh. The vibrations were determined by measuring the sparking distance between the micrometer terminals 1 and 2. It was found that, contrary to what was expected, the addition of the second rectangle diminished this sparking distance from about 3 millimetres to about 1 millimetre. The existence of resonant action between the circuit C C′ and the micrometer circuit was, however, fully demonstrated, for any alteration in the circuit $efgh$, whether it consisted in increasing or in decreasing its length, diminished the sparking distance. It was also found that much weaker sparking took place between cd or gh and an insulated sphere, than between ae or bf and the same sphere, showing that the nodes were in cd and gh, as expected. Further, when the sphere was made to touch cd or gh it had no effect on the sparking distance of 1 and 2; but when the point of contact was at any other portion of the circuit the sparking distance was diminished, showing that these nodes did really belong to the vibration, the resonant action of which increased this sparking distance.

The wire joining the points 2 and 4 was then removed. As the strength of the induced oscillatory current should be zero at these points, the removal ought not to disturb the vibrations, and this was shown experimentally to be the case, the resonant effects and the position of the nodes remaining unchanged. The vibration with two nodal points was, of course, not the fundamental vibration of the circuit, which consisted of a vibration with a node between a and e, and for which the highest values of the potential were at the points 2 and 4.

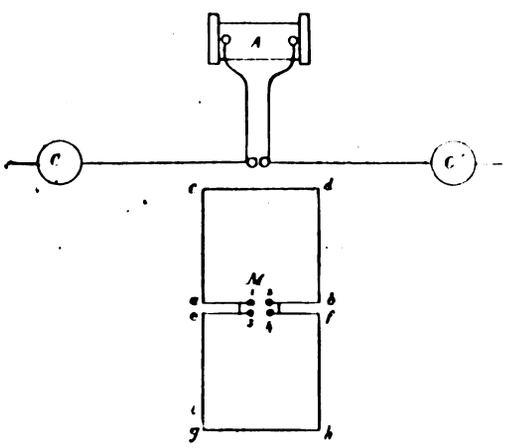

FIG. 7.

When the spheres forming the terminals at these points were brought close together slight sparking was found to take place between them, which was attributed to the excitation, though only to a small extent, of the fundamental vibration. This explanation was confirmed in the following manner:—The sparks between 1 and 2 were broken off, leaving only the sparks between 2 and 4, which measured the intensity of the fundamental vibration. The period of vibration of the circuit C C′ was then increased by drawing it out to its full length, and thereby increasing its capacity, when it was observed that the sparking gradually increased to a maximum, and then began to diminish again. The maximum value must evidently occur when the period of vibration of the circuit C C′ is the same as that of the fundamental vibration of the micrometer circuit, and it was shown that when the sparking distance between 2 and 4 had its maximum value, the sparks corresponded to a vibration with only one nodal point, for the sparks ceased when the previously existing nodes were touched by a conductor, and the only point where contact could take place without effect on the sparking was between a and e. These results show that it is possible to excite at will in the same conductor, either the fundamental vibration or its first overtone, to use the language of acoustics.

Hertz appears to consider it very doubtful whether it will be possible to get higher overtones of electrical vibration, the difficulty of obtaining such lying not only in the method of observation, but also in the nature of the oscillations themselves. The intensity of these is found to vary considerably during a series of discharges from the coil even when all the circumstances are maintained as constant as possible, and the comparative feebleness of the resonant effects shows that there must be a considerable amount of damping. There are, moreover, many secondary phenomena which seem to indicate that irregular vibrations are superposed upon the regular ones, as would be expected in complex systems of conductors. If, therefore, we wish to compare electrical oscillations, from a mathematical point of view, with those of acoustics, we must seek our analogy in the high notes intermixed with irregular vibrations, obtained say, by striking a wooden rod with a hammer, rather than in the comparatively slow harmonic vibration of tuning forks, or strings; and in the case of vibrations of the former class we have to be contented, even in the study of acoustics, with little more than indications of such phenomena as resonance and nodal points.

Referring to the conditions to be fulfilled in order to obtain the best results, should other physicists desire to repeat the experiments, Dr. Hertz notes a fact of very considerable interest and novelty, namely, that the spark from the discharger should always be visible from the micrometer, as when this was not the case, though the phenomena observed were of the same character, the sparking distance was invariably diminished. This effect of the light from the spark of an induction coil in increasing the sparking distance in the secondary circuit of another coil excited great interest when referred to by Prof. Lodge in the course of the recent discussion on Lightning Conductors at the British Association, and he pointed out that the same effect was produced by light from burning magnesium wire, or other sources rich in the ultra violet rays.

Theory of the Experiments.—The theories of electrical oscillations which have been developed by Sir William Thomson, von Helmholtz and Kirchhoff have been shown* to hold good for the open circuit oscillations of induction apparatus, as well as for the oscillatory Leyden jar discharge, and, although Dr. Hertz has not succeeded in obtaining definite quantitative results to compare with theory, it is of interest to inquire whether the observed results are of the same order as those indicated by theory.

Hertz considers, in the first place, the vibration period. Let T be the period of a single or half vibration proper to the conductor exciting the micrometer circuit; P its coefficient of self-induction in absolute electromagnetic measure, expressed, therefore, in centimetres; C the capacity of one of its terminals in electrostatic measure, and, therefore, also expressed in centimetres; and v the velocity of light in centimetre-seconds.

Then, if the resistance of the conductor is small,

$$T = \frac{\pi \sqrt{P C}}{v}$$

In the case of the resonance experiments, the capacity C was approximately the radius of the sphere forming the terminal, so that C = 15 centimetres. The coefficient of self-induction was that of a wire of length $l = 150$ centimetres, and diameter $d = 1/2$ centimetre.

According to Neumann's formula,

$$P = \int\int \frac{\cos \epsilon}{r} d s \, d s',$$

which gives in the case considered

$$P = 2 l \left(\log \frac{4 l}{d} - 0{\cdot}75 \right) = 1902 \text{cm}.$$

As, however, it is not quite certain that Neumann's formula is applicable to an open circuit, it is better to use von Helmholtz's more general formula, containing an undetermined constant k, according to which

$$P = 2 l \left(\log \frac{4 l}{d} - 0{\cdot}75 + \frac{1 - k}{2} \right).$$

Putting $k = 1$ this reduces to Neumann's formula, for $k = 0$ it reduces to that of Maxwell, and for $k = -1$ to Weber's. The greatest difference in the values of P obtained by giving these different values to k would not exceed a sixth of its mean value, and, therefore, for the purposes of the present approxi-

* Lorentz, Wiedemann's *Annalen*, Vol. VII., p. 161, 1879.

mation it is enough to assume that k is not a large positive or negative number; for if the number 1902 does not give the correct value of the coefficient for the wire 150cm. in length, it will give the value corresponding to a conductor not differing greatly from it in length.

Taking P = 1902cm. we have $\pi\sqrt{CP} = 531$cm., which represents the distance traversed by light during the oscillation, or, according to Maxwell's theory, the length of an electro-magnetic ether wave. The value of T is then found to be 1·77 hundred millionths of a second, which is of the same order as the observed results.

The ratio of damping is then considered. In order that oscillations may be possible the resistance of the open circuit must be less than $2v\sqrt{P/C}$. For the exciting circuit used this gives 676 ohms as the upper limit of resistance. If the actual resistance r is sensibly below this limit, the ratio of damping will be $e^{\frac{rT}{2P}}$. The amplitude will therefore be reduced in the ratio 1 : 2·71 in

$$\frac{2P}{rT} = \frac{2v}{\pi r}\sqrt{\frac{P}{C}} = \frac{676}{\pi r} = \frac{215}{r}$$

oscillations. We have, unfortunately, no means of determining the resistance of the air space traversed by the spark, but as the resistance of a strong electric arc is never less than a few ohms we shall be justified in assuming this as the minimum limit. From this it would follow that the number of oscillations due to a single impulse must be reckoned in tens, and not in hundreds or thousands, which is in accordance with the character of the experimental results, and agrees with the results observed in the case of the oscillatory Leyden jar discharge. In the case of closed metallic circuits, on the other hand, theory indicates that the number of oscillations before equilibrium is attained must be reckoned by thousands.

Hertz compares, lastly, the order of the inductive actions of these oscillations, according to theory, with that of the effects actually observed. To do this it must be noted that the maximum E.M.F. induced by the oscillation in its own circuit is approximately equal to the maximum potential difference at its extremities; for if there were no damping these quantities would be identical, since at any moment the potential difference at the extremities and the E.M.F. of induction would be in equilibrium. In the experiments under consideration the potential difference at the extremities was such as to give a spark 7 to 8mm. in length, which must therefore represent the maximum inductive action excited in its own circuit by the oscillation. Again, at any instant the induced E.M.F. in the micrometer circuit must be to that in the exciting conductor in the same ratio as that of the coefficient of mutual induction p of the two circuits to the coefficient of self-induction P of the exciting circuit. The value of p for the case considered is easily calculated from the ordinary formulæ, and it is found to lie between one-ninth and one-twelfth of P. This would only give sparks of from $\frac{1}{2}$ to $\frac{3}{4}$mm. in length, so that according to theory visible sparks ought in any case to be obtained; but, on the other hand, sparks several millimetres in length, as were obtained in the experiments previously described, can only be explained on the assumption that the successive inductive actions produce an accumulative effect; so that theory indicates the necessity of the existence of the resonant effects actually observed.

(To be continued.)

ON THE APPLICATION OF ELECTRICITY TO THE WORKING OF A 20-TON TRAVELLING CRANE.*

BY W. ANDERSON, M. INST. C.E.

One of the travelling cranes in the foundry of the Erith Ironworks was originally constructed to be worked by hand, but preparations had been made for the application of wire-rope driving at some future time.

The crane is 39ft. 6in. span, and consists of a pair of wrought-iron girders resting on end carriages, each running on two wheels on an elevated line of rails. The gearing for hoisting for longitudinal and for cross traverse is secured on to the tops of the main girders; the hoisting chain passes from the barrel, which is at one end of the crane, over a pulley at the other, then back to pulleys in the cross traversing carriage which runs between the main girders, thence through a falling block, and finally to an anchorage under the barrel at the extreme end of the main girders. By this arrangement the crane occupies a moderate height, and the hook can come within 3ft. of each wall.

The inconveniences and wear attending the use of rope driving gear or of a long main driving shaft, and the dirt and special attention required by a steam crane, induced the writer to try whether electricity might not be used with advantage. Messrs. Elwell-Parker, of Wolverhampton, were communicated with, and these gentlemen undertook to supply the dynamo and a motor suitable for the peculiar requirements of a heavy crane.

The dynamo, which is considerably larger than is needed for the crane in question, is arranged to give up to 80 amperes at 120 volts, with 1,200 revolutions per minute. The armature is of the cylinder type, field-magnets shunt wound, resistance of armature ·07 ohm, and of the magnets 75 ohms. It is fixed in the main boiler house of the works, and is driven by a horizontal engine, having a cylinder 9½in. diameter, 12in. stroke, running at 180 revolutions with 50lbs. steam, by means of a link belt. The leads from the boiler house up to the conductor in the foundry, for a distance of 60 feet, are of 6 B.W.G. copper wire, while the conductor in the foundry is formed of an angle iron bar, 2in. × 2in. × ¼in., extending the whole 350 feet length of the shop; it has one face, roughly ground, and protected from rust by vaseline, and is secured to the iron pillars supporting the roof, being insulated by wood blocks. The return current travels along one of the rails on which the crane runs, the joints of the rails being united electrically by copper staples. The motor is one of Messrs Elwell-Parker's latest types, with single vertical magnet and a drum armature; it is shunt wound and constructed for 100 volts and 50 amperes, the armature resistance is ·056 ohm, that of the shunt 49·2 ohms. It is fixed on the working platform of the crane, beside one of the main girders. Its driving spindle carries a steel pinion, which gears into a double helical spur wheel, keyed on to a shaft which runs longitudinally on the top of the girder, and is connected by nests of three-bevel wheels, with friction clutch connections to the three shafts which command the several movements of the crane, the means of using the hand-power being still retained. Two sets of speed are arranged for each of the movements, namely :—

	Slow per min.	Fast per min.
Hoisting	3·4ft.	10ft.
Cross traverse	25 „	105 „
Longitudinal traverse	78 „	213 „

To provide against an undue current passing through the motor an automatic magnetic cut-out is fixed on the crane, and as an additional security a fusible wire is placed close to the dynamo to provide for the contingency of a short circuit. For the purpose of varying the power and speed to meet the requirements of the foundry, a set of resistance coils is provided governed by a special switch, by means of which different resistances can be introduced into the armature circuit of the motor, and the current can be cut off altogether; but so that it must be done by steps, and not suddenly. In starting the motor the reverse action takes place. The shunt coils of the magnets are connected to the two collectors so that the fields are always excited when the dynamo is running, whether the motor is working or not, the switch controlling only the armature circuit. The collector for the angle-iron conductor consists of a pair of insulated brass blocks pressed against it by means of a flat spring having a considerable range. An ordinary wire brush serves to collect the current from the rail; but the axle of one of the wheels is also connected to this brush to provide for the contact being in any way interrupted.

The handles for operating the several movements, the brake lever, the switch, and the automatic cut-out are all collected

together, so that a single attendant can readily work the crane from one spot.

The crane was set to work in June last, and has continued to act satisfactorily ever since. The advantages of working by electricity are very great, especially in comparison to steam cranes. In large works a powerful dynamo would be established, and be driven by engines of an economical type. The steam from the main boilers is necessarily always available when the factory is at work, and the current can be easily carried into any part of the establishment. Steam cranes require the attendant to be at his post an hour or more before the works open, water and fuel have to be hoisted on to the crane, and the working is accompanied by dirt, steam, and smoke, the latter especially objectionable with overhead lights, or in shops where bright work is prepared or erected.

The duty realised is about 65 per cent. of the power developed in the driving steam engine. As far as can be judged at present, there is no special wear to apprehend. The conductors act satisfactorily though a considerable length is in the open air, and the dust, heat, and smoke of the foundry do not appear to affect the working.

The above table gives the electrical measurements made by Mr. E. W. Anderson, to whom the author is indebted for carrying out this comparatively novel application of electricity.

When first proposed the writer was not aware of the existence of any other electric crane, but he has since learned that Messrs. Mather and Platt, of Manchester, have had one working satisfactorily for some time, and that there is one also in France

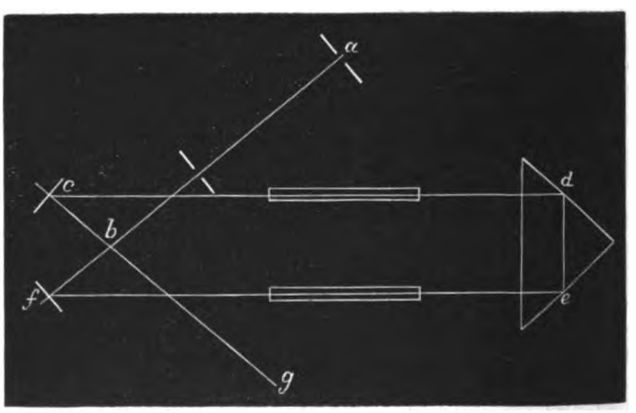
IS THE VELOCITY OF LIGHT IN AN ELECTROLYTIC LIQUID INFLUENCED BY AN ELECTRIC CURRENT IN THE DIRECTION OF PROPAGATION?*

BY LORD RAYLEIGH, SEC. R.S.

The question here proposed has been considered by Roiti (Poggendorff's *Annalen*, Vol. CL., p. 164, 1873) and by Lecher (*Rep. de Phys.*, Vol. XX., p. 151, 1884).† My experiments were made in ignorance of the work of these observers, and the results would scarcely be worth recording were it not that the examination seems to have been pushed further than hitherto. It may be well to say at once that the result is negative.

The interference fringes were produced by the method of Michelson, as used in his important investigation respecting "The Influence of Motion of the Medium upon the Velocity of Light."‡ The incident ray $a\,b$ meets a half-silvered surface at b, by which part of the light is reflected, and part is transmitted. The reflected ray follows the course $a\,b\,c\,d\,e\,f\,b\,g$, being in all twice reflected at b. The transmitted ray takes the course $a\,b\,f\,e\,d\,c\,b\,g$, being twice transmitted at b. These rays, having pursued identical paths, are in a condition to form the centre of a system of fringes, however long and far apart may be the courses $c\,d$, $e\,f$.

There is here nothing to distinguish the ray $a\,b$ from a neighbouring parallel ray. The incident plane *wave front* perpendicular to $a\,b$ gives rise eventually to two coincident wave fronts perpendicular to $b\,g$. With a wave incident in another direction the case is different. The two emergent wave fronts remain indeed necessarily parallel, both having experienced an even number of reflections (4 and 6). But there will exist in general a relative retardation of amount (for wave fronts perpendicular to the plane of the diagram) proportional to the deviation from the principal wave front. Hence, if the incident light comes in all directions, a telescope at g, focussed for infinitely distant objects, reveals a system of interference bands, whose direction should be vertical if the adjustments could be perfectly carried out in the manner intended.



The success of the method does not require the complete symmetry of the diagram. If the reflections at $d\,e$ are effected by a right-angled prism, it is necessary that $c\,d$, $f\,e$ be parallel to one another, but not that they be parallel to the surface b. Supposing all the surfaces to remain vertical in any case, the positions of b, f, and the incident ray $a\,b$, may be chosen arbitrarily. If the distance $d\,e$ between the parallel courses is not closely prescribed, *one* adjustment by rotation of the mirror C will suffice. In my experiments the optical parts were mounted upon a large iron plate, so that the movable pieces c, d, e could be shifted without loss of level. The incident ray $a\,b$ was defined by a small hole near the paraffin lamp, which served as a source of light, and by the centre of moderately large circular aperture perforated in a screen and illuminated, when necessary, with a candle. The mirror c was then rotated, until the rays $c\,d$, $f\,e$, were parallel. This was tested by observing the equality of their mutual distances near the extremities of their course.

If the distance between the parallel rays is prescribed, the

Digitized by Google

adjustment is more troublesome. The line *f e*, being fixed, sights are laid down defining the desired position of *c d*. These sights, as well as those before referred to defining the incident ray, have now to be brought to apparent super-position as seen by an eye looking along *d c*. For this purpose *two* conditions have to be satisfied by, and two motions must be provided for, the mirror c. One of these should be a movement of rotation, and the other of translation in a direction nearly perpendicular to the plane of the mirror. Thus the mounting may consist of a circular turntable resting upon the iron plate, the curved edge of which is guided by the sides of a V cut out of a flat piece of metal and clamped to the plate. In each position of the V the angular motions are easily swept over, and the double adjustment is effected without much diffitulty. Where the parallelism of the rays is secured, the insertion of the reflecting prism is all that remains. The adjustment of this is here effected with the eye at the observing telescope, which at this stage should be focussed upon the small aperture in the neighbourhood of the flame. By a motion of the prism parallel to its hypothenuse the two images are brought to coincidence,* and then the bands appear, if not at once, when the telescope is accommodated for infinitely distant objects.

The half-silvered central plate would be at its best if it reflected light of the same intensity as it transmits. I have generally found the reflection on the side next the air more powerful than upon the side next the glass, so that the ideal would require the geometric mean of the two reflections to be equal to that of the two transmissions. A very slight silvering is all that is wanted, such as from its want of coherence and brilliancy would be useless for other purposes; and the bands appear tolerably black, even though the interfering lights are of decidedly unequal intensities. There is, of course, also a reflection from the unsilvered surface of the plate. Owing to a want of parallelism in my apparatus this image was distinctly separated from the other. The two back reflectors were of flat glass, silvered by the milk-sugar process, and used as specula.

The imperfections of the surfaces disturbed the formation of the bands from full accordance with theory. The definition was usually better when the pencils were limited, as by the screens employed to define the incident ray, than when all obstruction was removed. The final adjustments for the distinctness and desired width of bands were made with the eye at the telescope by shifting the reflecting prism, and occasionally by slight displacements of one of the other reflectors. The tubes enclosing parts of *c d*, *f e*, and containing the electrotype (diluted sulphuric acid of nearly maximum conductivity), were closed at the ends by plates of parallel glass. The current entered by lateral attachments, so arranged that liquid (or gas) rising or falling from the platinum electrodes would not at first enter the operative part of the tubes. The diameter of tubes was about $\frac{3}{4}$in., and effective length about 11in.

It will be sufficient to give the details of one experiment. The two tubes were connected in multiple arc, and of course in such a manner that the current travelled in opposite directions. The magnitude of the whole current (say, from eight Grove cells) was of 1·5 ampere; so that the current density in amperes per square centimetre was

$$\frac{\cdot 75}{\pi \times \cdot 38^2 \times 2 \cdot 54^2} = \cdot 26.$$

Now, one of the interfering rays travelled 22in. or 56 centimetres with the current, and the other ray the same distance against the current. On *reversal* of the current no shift of the bands could be perceived under conditions where a shift of $\frac{1}{10}$† of a band must have been evident. Hence we may conclude that a current of the above-mentioned density does not accelerate (or retard) the propagation of light in the ratio of $\frac{1}{10}\lambda$ to 224 centimetres. In the liquid we may take $\lambda = 4 \times 10^{-5}$ centimetre; and if we reduce the result so as to correspond to density unity, we may say that in dilute sulphuric acid a current of one ampere per square centimetre does not alter the velocity of light by one part in 13 millions, or by 15 metres per second.

It would probably be possible to carry the test 10 or 15 times further by the use of much longer tubes and a more powerful battery; but there seems to be no sufficient encouragement at present to make the attempt. The case would, of course, be very different were anyone to show by *à priori* argument a reason for expecting an effect of this order of magnitude.

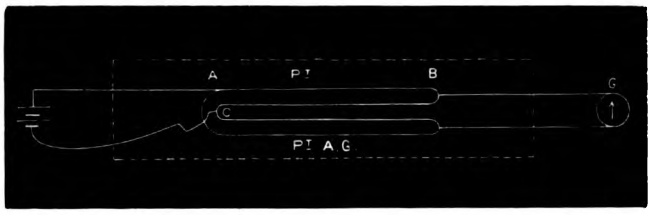
* It should be noticed that if the objects were at infinity, or if with the aid of a collimating lens an image of it were thrown to infinity, the two images as seen focussed through the telescope would overlap in any case; for it may be proved that whatever may be the position of the five reflecting surfaces the two emergent rays corresponding to any incident ray are necessarily parallel.

† Probably I might say $\frac{1}{20}$, but it is best to be upon the safe side. When the contact was maintained a slight shift was observed, but in a direction independent of that of the current.

ON AN APPARATUS FOR DETERMINING TEMPERATURE BY THE VARIATION OF ELECTRICAL RESISTANCE.*

BY WM. SHAW, M.A.

This apparatus is designed to measure to a high degree of accuracy the mean temperature of a large burette immersed in a water bath. A Wheatstone quadrilateral is formed by joining the ends of a platinum wire about 30in. long (resistance about 11 ohms) to those of a platinum silver wire, B, C, D, A. The platinum wire is base, and the alloy is silk-covered ·007in. in diameter. Its resistance is 13·5 ohms per metre. At A C and B D respectively, battery and galvanometer wires are soldered. The lengths of the wires are so arranged that for some temperature near 15°C. there is a perfect balance indicated in the bridge. The wires are laid in parallel lengths, and disposed upon a strip of pure India-rubber about $\frac{3}{4}$in. wide in the manner indicated in the figure. The India-rubber is painted with a solution of India-rubber in benzene, and a second strip, similarly painted, is laid down upon it, and the wires are thus completely enclosed; the strip continues 18 metres at each end beyond the junctions of leading wires, so that the whole length of strip is about 5$\frac{1}{2}$ft, and from the two ends the galvanometer and battery leads respectively project.



A very flexible quadrilateral is thus obtained in the form of a ribbon, which can be wrapped round any apparatus whose temperature is required. Since the two wires, which together form the quadrilateral, have different temperature coefficients, there is no balance except for one particular temperature, but the balance can be restored by shunting either the wire A B or the arm B C, by connecting a resistance box in a suitable manner with the projecting leads. The resistance of the shunt required to produce a balance can be employed to indicate the temperature when the instrument has once been graduated. The graduation of the apparatus exhibited was made for the author at the Cavendish Laboratory by Mr. J. W. Capstick, Demonstrator at University College, Dundee. The ribbon was wound round a metal cylinder, and the whole immersed in ice or water, and a number of readings of the shunt taken at different temperatures between 0deg. and 28°C. The conductivity of the shunt at different temperatures is very nearly represented by a straight line cutting the zero line at the neutral point 15·16°C. The maximum divergence from the straight line corresponds to the temperature difference of a fifth of a degree between 0deg. and 15·16deg., and to about a tenth of a degree between 15·16deg. and 28deg. In the graduation the temperatures are referred to the Kew standard by means of mercury thermometers previously compared at Kew. The temperature can be read with a suitable galvanometer to about the 500th of a degree.

„ Aden, Borneo, Ceylon, China, India, Japan, Java, Labuan, Mozambique, New Caledonia, Persia, Philippine Islands, Siam, Transvaal, and Zanzibar	7 6	... 14 6	... 28 0
The rates for the United Kingdom remain as follows:—	5 0	... 10 0	... 19 6

TO ADVERTISERS.

"The Electrician" offers exceptional advantages to Advertisers. **It has the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application to this office.

Trade Advertisements *intended for the current issue must be handed in not later than First Post on Thursday morning.*

Small Prepaid Advertisements *(for Rates see page XI.) are accepted up to 4 p.m. on Thursday.*

TECHNICAL PRINTING.

"The Electrician" Printing and Publishing Company (Limited) *beg to inform Electricians and Electric Light Engineers that they make a specialty of Technical Printing, and have a Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electrical Catalogues and Electro-Technical Literature generally.*

The Electricians' Directory.

Royal 8vo. Cloth Boards, 3s. 6d. Boards, 3s.

At the end of December in each year is issued The Electricians' Directory and Handbook. *The Directory was established in 1883, and has now attained considerable proportions. Every care is taken to make the names and addresses of all persons engaged in the Electrical Industries absolutely accurate. Useful Tables and Electrical Formulæ are given, together with popularly-written Biographical Notices of the leading Electricians, accompanied in many cases by Portraits.*

THE DIRECTORY FOR 1889 IS IN PREPARATION.

UNDERGROUND WIRES IN AMERICA.

Apart from their technical and scientific importance, the Papers which were read before the National Electric Light Association of New York, at its last half-yearly meeting, and which are being reprinted in this journal, possess a special interest for British Electrical Engineers, who are only just beginning to experience some of those difficulties which their comrades in America have been battling with for several years past. The Americans are so far ahead of us in electric lighting business that the overhead wire system has long been voted a public nuisance, and bidden to take itself underground. Electric Light undertakers in this country will naturally wish that they may have a touch of the same complaint. Meanwhile, they will learn a great deal from what is going on in the States both as to evils to be avoided and the way to mitigate those which are inevitable. Experience in America is on a very active and very extended scale; and by the time we need it, the solution of the problems of underground wiring and street distribution will have reached us, probably, from that part of the world. The statistics furnished by the President of the Association show the rapidity with which the electric light is being extended there; and as it is generally under an interdict in respect to overhead conductors, we may confidently expect that a safe and economical method of placing them underground will soon be discovered.

Conduit or subway systems have been largely adopted for telegraph and telephone wires, New York alone boasting of

Digitized by Google

nearly 4,000 miles of these conductors so treated; but as regards electric light cables hardly any practical progress has been made in getting them underground, some solitary experiments on the part of the Brush Company being spoken of as affording encouragement to the other undertakers to do likewise. Broadly speaking, it may be said that the law has been obeyed in respect to telegraph and telephone wires, because obedience was easy, but that as regards electric lighting wires the law has not been obeyed simply because its enforcement would have been equivalent to a general confiscation, besides the considerable extinction of a popular illuminant. The appointment of Mr. WHEELER as inspector of the systems will conduce to a settlement of this vexed question between the municipal authorities and the electrical companies. Mr. WHEELER takes the sensible view that if the wires had been maintained in anything like decent efficiency and safety they would not have been interfered with. Certainly, from Mr. WHEELER's own report it is clear that the New York guardians of public safety and good taste are not excessively exacting. An enormous quantity of wires and poles, amounting, it is said, to nearly half the whole number, are dead and abandoned to their fate; and as the workmanship expended in their erection was generally as bad as it could be their present condition may easily be imagined. Where the owners are known they are served with a notice; and at the end of a week with another notice; and then the Bureau of Encumbrances is asked to interfere. This dreadful punishment is no doubt borne with resignation by the owners, even when it is inflicted; but as Mr. WHEELER does not tell us that the Bureau ever act on his recommendation to pull down the wires we can only repeat that the people of New York are a long suffering race.

That this is so becomes more apparent when we turn to Mr. WHEELER's remarks on the overhead electric light wires. One example will suffice. "All arc lamps that are so low as to be within the reach of pedestrians with umbrellas are reported as too low." This is a moderate demand, and, together with the inspector's remonstrances on the subject of "flagrant bad work," is gradually being attended to. Nevertheless the condition of the wires is described as still being outrageous, and the conduct of their owners hardly less so. The picture of the state of things which prevails in the chief city of the United States is so instructive that we cannot refrain from quoting Mr. WHEELER's own words for the benefit of people here who desire unlimited competition:—"The companies owning wires will not permit each other to make common use of the poles, but will chop off wires owned by others without notice. The telephone people object to the electric light wires on account of the induction. Where there is a line of electric light wires on their side of the street passing close to their poles, they do not allow them to be made fast. The result of the necessity thus made for extra poles is sometimes four lines of poles on one side of the street; hence most of the wires swing close to or against the other poles to which they are not attached, and linemen in climbing them have to crawl through all the wires which are not fastened to cross-arms."

Legal proceedings are being taken against one of the offending arc-light companies to compel it to place its wires which are proved to be dangerous in subways constructed for the purpose. Other companies are said to be on the point of doing this voluntarily; but, as we have already remarked, the experiment has yet to be tried, and we have no authentic evidence as to its probable result. Meantime, Mr. HEWITT, the Mayor of New York, let it be known to the members of the Association, whom he addressed at their recent gathering, that he did not intend to enforce the law in any precipitate or unbenevolent fashion. It is true the existing anarchical condition of the overhead wires is a scandal and a danger to society; but, says the worthy Mayor, although they are not pleasant to look at, and in places are so thick as to obscure the sky, they are for the present indispensable to our social and commercial interests, and "the man who would disturb them until something better is found out would be a barbarian" (loud applause). Still, like the Mayor himself, the wires would have to go; and he appealed to the knowledge and good citizenship of the electrical engineers present to hasten the perfecting of methods of insulation and distribution which would admit of the law being enforced without injury to their trade or inconvenience to their customers. A responsible electric light company was going to test the conduits by way of a beginning, and until the trials were completed wild horses would not compel him to order the other companies to be disturbed (louder applause).

With such a splendid accession to their debating strength, on Wednesday, no wonder the meeting came to a unanimous and highly agreeable resolution on Friday. It ran somewhat as follows:—"That the National Electric Light Association, after a full discussion of the subject, desire to express their hearty sympathy with the views expressed by his Honour, Mayor HEWITT; and take this opportunity of expressing their opinion that up to the present time no commercially practical method has been brought to their notice by which high-tension direct currents, such as are used for arc lighting, can be placed underground." What his Honour may have thought of this resolution we are only left to conjecture. His presence at the meeting does credit to the ingenuity of the Association; and the Mayor of New York has only himself to blame if they took him at his word too literally. For the present, then, overhead wiring for the electric light in New York has obtained a respite which perhaps is not wholly deserved, but which we believe will be turned to useful account. For, notwithstanding the formal resolution above referred to, several Papers were read at the meeting throwing valuable light on the subject, and tending to show that the difficulties are not so formidable as we are asked to believe. At all events, they are not regarded as insurmountable in this country. Mr. CROMPTON's method, which he described to the Society of Telegraph-Engineers and Electricians last April, seems so far to have been successful, and will no doubt be followed up, unless our American friends can supply us—as with their wider experience they probably will—with a better.

ELECTRIC LIGHT APPLIED TO NIGHT NAVIGATION UPON THE SUEZ CANAL.*

BY R. PERCY SELLON.

I.—The period embracing the concluding years of the last decade and the first years of the present one, during which a grave commercial crisis made itself felt, not only in this country but throughout industrial Europe, witnessed upon the great maritime highway which separates the Eastern and Western hemispheres a rapid increase of traffic and growth of activity.

In 1870, the year following the opening of the Suez Canal, 496 vessels of all kinds availed themselves of the facilities which this new route to the East afforded. Two years subsequently—in 1872—this number had reached over 1,000. In 1878 the number was 1,593, and by the year 1885 it had more

* Paper read before the British Association meeting at Bath, September, 1888.

Digitized by Google

than doubled itself, reaching the remarkable total of 3,624 vessels, representing a gross tonnage of 9,000,000 tons.

This active traffic, however, soon gave rise to difficulties of various kinds. Shipowners complained of delays in making the passage of the canal, delays which became more and more marked as the number of vessels using the canal increased. The channel proper being insufficiently wide (except at the "tying up" stations, which are placed every five miles apart) to admit of vessels passing one another it becomes necessary for any vessel to "tie up" in accordance with signals from the nearest station—these stations being all in telegraphic communication with one another—while any vessel coming from the opposite direction gets past.

This in a canal 87 geographical miles long, and where the speed (except in the open Bitter Lakes) is not allowed to exceed six miles an hour, meant constant delays at "tying up" stations, the delays naturally increasing directly in proportion with the traffic.

Then a further cause of delay lay in the fact that vessels could only proceed by day, anchoring at either entrance to the canal—Port Said or Suez—or "tying up" at the nearest station if in mid-channel, from sunset to sunrise. Thus we find that in 1885 the average time consumed in making the passage of the canal amounted to 43 hours, though it frequently considerably exceeded this.

II.—To meet the difficulty thus presented, the Suez Canal Company set about various improvements; the cutting away of curves in the course, deepening and widening the channel at the "tying up" stations, and finally instituted experiments to determine the practicability of navigation by night by means of the electric light.

Fig. 1.

The question of the practicability of successful navigation by night in the Suez Canal by means of electric light is not so simple as would at first sight appear. To realise this one must consider that the canal has but an average width of 22 metres (23¼ yards) upon the water line, with shelving sides providing for a depth of water of some 8m. 70 to 9 metres (27—30ft.) in the centre, and with comparatively sharp curves at various points, as may be seen from the accompanying plan of the canal, Fig. 1; and that under such conditions vessels of 400 to 500 feet length, 40 to 50 feet beam, and drawing 25 feet of water, have to navigate the channel, encountering currents of varying force, the action of the wind, and greatly diminished influence of the rudder upon the vessel owing to the slackened speed.

It will be at once seen that under these circumstances it needs but a small deflection between the axis of the vessel and that of the channel to render the vessel liable to run aground. No small amount of judgment and experience thus become necessary on the part of the pilot who accompanies each vessel through the canal.

The problem was, to reproduce by electric light the conditions requisite to enable the pilot to successfully navigate during the night.

These experiments extended over the greater part of two years, with the result that in December of 1885 it was decided to allow vessels of war and those carrying mails, if furnished with electric lights in accordance with regulations laid down by the canal company, to proceed by night between Port Said, the Mediterranean entrance to the canal, and kilometre 54, about one-third of the distance along the canal.

The first vessel to avail itself of this permission was the ss. "Carthage," of the Peninsular and Oriental Steam Navigation Company, in the month of April, 1886, followed shortly afterwards by others, the prescribed passage being made by night by means of the electric light with perfect success.

These and subsequent trials encouraged the canal company to extend its authorisation to vessels of all kinds; and, at the same time, by providing beacons and light buoys to guide the vessels in their course by night, to permit of navigation throughout the whole length of the canal.

III.—The following is the text of the regulations on this subject issued by the Suez Canal Company in February, 1887:—

"(i.) From 1st May, 1887, steamers will be allowed to pass through the canal by night, subject to the same conditions as those which hold for navigation by day, and subject to the following further restrictions:—

"(ii.) Steamers intending to pass through the canal by night must satisfy the company's agents at Port Said or Port Tewfik, that they are provided:—(1) Forward, with an electric search light throwing a beam 1,200 metres; this search light must be placed as close as possible to the waterline. (2) With an electric lamp and reflector suspended above the bridge and capable of lighting a circular area of about 200 metres diameter.

"The agents of the company will decide whether the apparatus fulfils the requirements of the regulations, so that vessels provided with them may, without inconvenience, be authorised to navigate the canal by night.

"(iii.) If a vessel proceeding by night receives the signals to 'tie up,' it must, immediately upon this being effected, extinguish its electric lamps, retaining only the regulation signal lights indicating that it is 'tied up.'"

IV.—Passing now to describe the apparatus designed to fulfil these requirements. This consists essentially of three parts:—

(1) The source of electric power—a steam engine and dynamo electro generator.

(2) A projector search light fitted upon a platform large enough to accommodate a man to manipulate the light; the whole being attached to the stem of the vessel forward and close to the water's edge.

(3) An automatic electric lamp suspended above the bridge and capable of illuminating a circular area of 200 yards diameter round the vessel.

The accompanying diagrams illustrate these various pieces of apparatus, and also a vessel so fitted traversing the canal.

The engine (Fig. 2) is of Brotherhood's 3-cylinder type, fitted direct by means of a flexible coupling to a Victoria dynamo-electro machine, manufactured, as are also the electric lamps and other electrical apparatus, by the Anglo-American Brush Electric Light Corporation (Limited), of London. The engine and dynamo are fitted upon a cast-iron bedplate common to both. To ensure reliability of operation, and minimise labour in attendance, the speed of engine and dynamo is reduced to 600 revolutions per minute, at which the latter is capable of yielding an output of 65 volts by 70 amperes or 4,550 watts.

Digitized by Google

This provides for a light in the projector search light equal to 12,000 candle-power, and at the same time supplies current for the automatic lamp of 6,000 candle-power over the bridge, when the latter is in use.

The projector search light (Fig. 3), fitted upon its platform and fixed during the passage through the canal to the stem of the vessel as near to the water's edge as possible, is used to light the course of the vessel to a distance of 1,200 metres (1,300 yards) ahead.

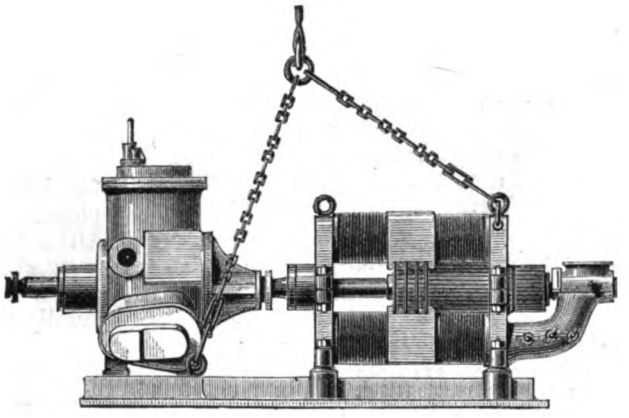

Fig. 2.

Actually, the firm of contractors above-mentioned have heard, from recent advices from the canal, that this light enables the pilot to see clearly as far as 1,600 yards ahead.

The projector proper, which is in many respects similar to the type in use for signalling and search purposes on war vessels, consists of an electric lamp of 12,000 candle-power, the light rays from which are concentrated upon a spherical

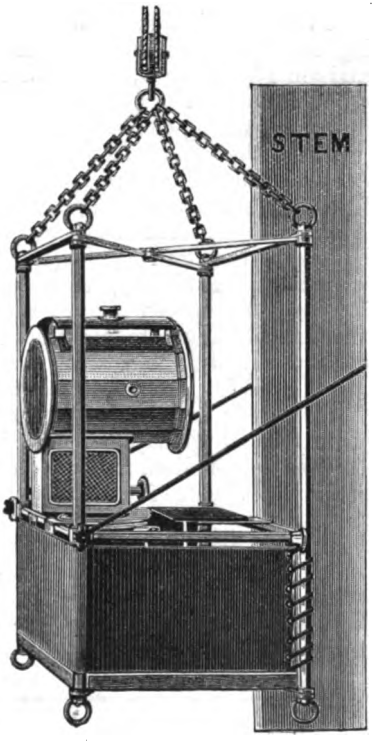

Fig. 3.

silvered mirror, made by Messrs. Chance, of Birmingham, fixed at the back of the instrument; this mirror reflects the rays, rendering them parallel, and projects them forward in a cylindrical beam; they are then made to pass through a series of plano-cylindrical lenses fitted in the front of the projector, so that the beam emerges in the shape of a fan, flattened horizontally. Fig. 4 illustrates this.

This beam, diverging to an angle of 20°, can by means of suitable adjustments provided for the purpose be directed upon any desired spot. At a distance of 1,200 metres ahead of the vessel the full width of the canal and the banks on either side, composed of the *debris* excavated from the channel, are illuminated as clearly as by day.

An attendant, seated upon the platform, attends to the manipulation of the carbons of the electric lamp, and at the same time regulates the position of the beam of light, elevating, depressing, or deflecting it on either side in accordance with the orders of the pilot upon the bridge, with whom he is generally in telephonic communication.

The placing of the projector close down to the water's edge, where the light is hidden under the bow of the ship, is a point of essential importance, since any direct rays of light intervening between the pilot and the distant object illuminated by which he steers the vessel, serves to dazzle his eye.

The automatic electric lamp is of 6,000 candle-power, enclosed within a lantern fitted with a concave reflector, and arranged to concentrate the light round a circular area of 200 yards. When slung up over the bridge of the vessel the area illuminated includes the whole deck of the vessel and the canal and its banks immediately on either side. This light is only intended for use when passing other vessels "tied up" at the stations, or to provide light around the ship when "tying up" so as to allow another vessel to pass.

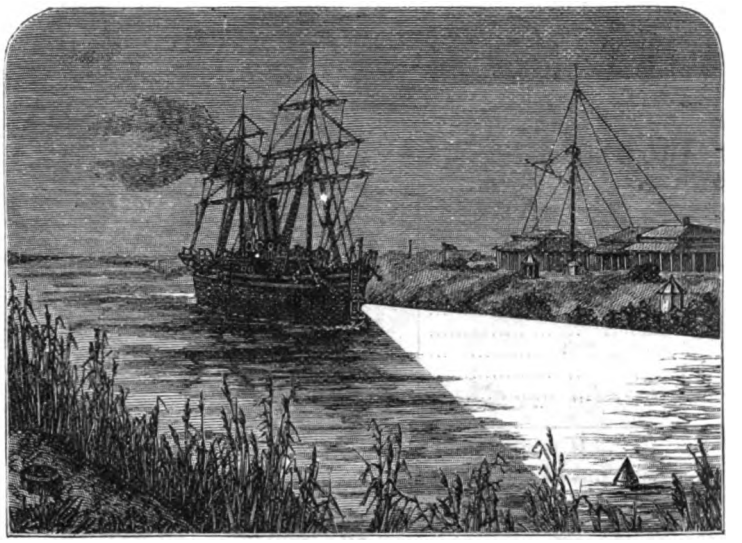

Fig. 4.

V. A large majority of mail and passenger steamers are now fitted throughout with the incandescent electric light. In fact, electric light has come to be regarded as a *sine qud non* to any first-class passenger vessel.

In such cases the steam engines and dynamo generators already in the ship are usually utilised to supply electricity for the special Suez Canal lamps, which latter may form part of the permanent equipment of the vessel. This is the case with many vessels of the P. and O., the Orient, and the North German Lloyd lines of steamers.

On the other hand, where a vessel which is not already fitted with the electric light desires to avail itself of the permission to traverse the canal by night, it can hire the necessary plant at either entrance to the canal.

The *modus operandi* is as follows:—

Several of the prominent coaling firms at Port Said have possessed themselves of a certain number of sets of portable electric lighting plant for the Suez Canal. These they hold in readiness for vessels to their consignment which may require the light, making an average charge for the use of this, which at the present time amounts to £10 per vessel for the passage through the canal.

On receiving a given signal from an incoming vessel that electric light is required, a tender is sent out to meet it, having

Digitized by Google

on board the necessary portable plant. Coming alongside, the engine and dynamo are quickly hauled up, dropped on to some convenient spot on deck, and the engine connected with the nearest steam pipe—generally a branch from the system in use for steam winches forward; the automatic lamp slung up over the bridge; the projector floated round and made fast to the stem; temporary conducting wires run from the dynamo generator to the two lamps; and in less than an hour from the time of the tender coming alongside the ship is ready to make the passage of the canal by night. On reaching the opposite end of the canal the electric light plant is disembarked, and the vessel proceeds on her way.

It is with such a portable plant as has just been described, and which the accompanying figures illustrate, that the author was engaged in trials upon the Suez Canal in the early part of last year.

VI.—To realise the development which has followed upon the introduction of electric light for the purpose of night navigation, and to appreciate how real has been the benefit flowing therefrom, we have only to examine the following figures, which illustrate the number of vessels which have passed through the canal in this way at different periods since the first authorisation to use electric light in December, 1885; and which define the percentage of vessels so using the light in comparison with the whole traffic on the canal:—

Period.	Number of vessels which passed through the canal by night by means of electric light.	Percentage which these bear to the whole traffic.
From December, 1885, to 1st March, 1887, viz., 15 months	25	·7 per cent.

March ,,	111	34½ ,,
May ,,	139	43 ,,

VII.—It remains but to inquire, "What are the advantages arising out of the use of electric light on the canal, which have led to so striking and rapid a development?"

To the Suez Canal Company, on the one hand, it means that the capacity of their canal has been rapidly, effectively, and economically increased by nearly 50 per cent., an increase attained without an army of labourers, without a host of dredgers, without a lapse of years, without interruption to traffic; that while a traffic which reaches 7,000,000 to 8,000,000 tons is now annually attained, an increased traffic, equal to 11,000,000 to 12,000,000 tons per annum can be accommodated, while offering not only equal, but greater facilities to shipowners making use of the canal; that in the meantime the canal company, relieved of the pressure put upon them from outside, can pursue their works of improvement with greater deliberation and economy.

It is only fair to say, however, that the Suez Canal Company on their side have displayed a ready initiative and far-seeing confidence in the success of the scheme, by putting down a large number of light-buoys to indicate the course by night in the Bitter Lakes, of guiding lights along the banks, and an extensive gasworks at Ismailia for supplying the above with gas, at a time when to many an extended adoption of the electric light by shipowners seemed problematical.

To shipowners, on the other hand, it means in the first place a saving of time. I pick up the *Official Gazette* of the Suez Canal Company, published at Paris, for January of this year, and read as follows:—"The 'Moskwa,' of the Russian Mercantile Marine, using the electric light, entered the Suez Canal on 12th December at 6:15 p.m., and passed out on the following morning at 8:45 a.m.; total time occupied in the passage 14½ hours."

In another portion of the same *Gazette*, for the same month, I read as follows:—

"The mean time occupied in making the passage of the canal for all vessels during the month of November last was 36 hours 10 minutes."

Taking as average periods for the passage of the canal, 18 to 20 hours for all vessels using electric light, and 35 to 40 hours for all vessels not so provided—figures which the canal company's *Official Gazettes* and the author's own experience upon the canal, prove to be in accordance with actual facts—we find that the saving of time resulting from the use of the electric light approaches the 24 hours of a whole day.

What does this saving in time represent?

For vessels carrying cargo exclusively, of an average tonnage of, say, 2,500 tons, interest on capital, demurrage, coal consumption, wages, and provision for the crew, represent a sum of £30 to £40 per diem.

For vessels of war, where rapid communication between England and her possessions in the Eastern hemisphere, or the scene of her frequent wars in the Soudan or Africa is by way of the Suez Canal, the saving of 24 hours may entail consequences not easy to calculate.

For mail and passenger boats the results are naturally more marked than in the case of cargo steamers.

An interesting example of the practical value of the electric light is afforded in connection with the transport of mails to the East during the time when the cholera in Italy led to enforced quarantine of all vessels from Italian waters communicating with the shore in Egypt. It has been customary for the mails brought by the Peninsular and Oriental Company from Brindisi to be landed at Alexandria and sent overland to Suez to save the time taken by vessels in the canal. In order to avoid the delay of quarantine, the mail boats of the Peninsular and Oriental Company proceeded, without unshipping the mails, direct through the Suez Canal by means of the electric light, reaching Suez and transhipping the mails within the same time as that occupied by the overland route in the ordinary way.

The cost per 24 hours of a first-class passenger-carrying vessel, including insurance, demurrage, interest on capital, coal, wages, provision for the crew, and provision for the passengers, cannot be put down at less than £100 to £150.

Taking as an average saving effected by each vessel traversing the canal by night the sum of £70 to £80 (a figure which, in view of the proportion of mail and first-class passenger-carrying vessels to the whole traffic on the canal is well within the mark), and taking 40 per cent. of the vessels entering the canal as making use of the electric light (a percentage which it will be borne in mind has already been exceeded), we find that for 1,200 vessels having so availed themselves of the electric light the annual saving to maritime commerce will amount at a minimum valuation to close upon £100,000.

And to this must be added the personal comfort to all concerned derived in escaping some period of the excessive heat experienced upon the canal by day, the glare from the banks of yellow white sand, the tedium and monotony of the slow passage through a wide expanse of barren desert.

Without considering to what development this use of the electric light may ultimately attain in an age in which uncasing efforts are being made to economise time and space, it has been attempted, by the foregoing few facts and figures, to illustrate the advance recently made in one adaptation of electricity to the service of man.

St. Olave District Board.—At a meeting of the St. Olave District Board on September 18th an application was received from an electric lighting company for the sanction of the Board to an application for a provisional order to enable them to supply the electric light to the district.—Mr. Lafone, in moving that the letter be referred to committee, expressed a hope that the Board would not hinder this project. He felt assured that the electric light, by dispensing with the use of gas, would do much to lessen the death-rate of London.—The letter was referred to committee.

VORTEX ANALOGUE OF STATIC ELECTRICITY.*

BY PROF W. M. HICKS, F.R.S.

Consider two bodies touching one another placed in an infinite fluid, and with a vortex filament, the ends of which are one on one surface, the other on the other. If, now, the surfaces be separated from one another there will be formed, at the point where they separate, a hollow vortex filament stretching from one to the other, with rotation equal and opposite to that of the original filament. As the bodies are moved apart these filaments will not in general take up a position of rest. If the strength of the original filament be very great, or if there be several of them, the resulting hollow vortex will, through instability, split up into a number of smaller ones. If the resulting number be very large they will ultimately take up some position of stable equilibrium. What the distribution in this will be I cannot say, but the following is one state of equilibrium, and probably, though I have not proved it, a stable one. The two sets of filaments will be mixed up with one another, and each will distribute itself according to the same law as the distribution of lines of force between the two bodies supposed equally and oppositely electrified.

In the case of the original filament, as the surfaces are further and further separated their sections become smaller and smaller. This is, however, not the case with the hollow filaments. Their section depends only on the pressure of the fluid and their circulation, and as these remain constant the areas of their sections also remain so. In such a hollow vortex the pressure inside sinks to zero. Consequently the portion of the surface on which it abuts experiences a diminution of pressure, a diminution which is the same at all distances. The two bodies are therefore attracted towards one another. Moreover, as the bodies separate further, the distribution of the filaments being the same as that of electrical lines of force, and the diminution of pressure for each line being constant, it follows that the force between the two bodies follows precisely the same laws as the force between two bodies supposed equally and oppositely electrified.

If another surface be brought into the presence of the others some of the filaments would abut on this. These would break off, rearrange themselves so that some of the filaments would end on it and an equal number start from it. Call those ends of the filaments positive at which the rotation looked at *from* the surface on which they abut is right-handed, and those ends negative at which the rotation is left-handed. The two ends of any filament will then always be of opposite name.

The analogy with electrical action is then close. Two bodies, A B, brought in contact, touch in innumerable parts, owing, possibly, to the different states of motion of the ether at their surfaces, a state of equilibrium is set up, consisting of a kind of sifting of vortex motion already subsisting, so that, on the whole, more lines go from A to B than *vice versa*. This is E.M.F. of contact. Separate the bodies, one has a number of positive ends of hollow filaments, and the other an equal number of negative ends. *The bodies are equally and oppositely electrified.* The force in its hydro-dynamical case and in its electrical analogues follows the same laws. Bring into the field another surface, C. The filaments rearrange themselves as mentioned above, the negative and positive ends abutting on C being equal. *This is induced electricity.* If the surface C consists of a large number of small unconnected surfaces, the filaments will arrange themselves in some manner depending on the sizes and distances of the unconnected parts, the field will be disturbed in a similar way to that in an electric field into which a different dielectric is placed. This is the analogue of electric strain in a dielectric. So far the ground is fully safe. The succeeding remarks must be regarded as speculative.

Returning to the case of the two separated surfaces A and B, what will happen if they be connected to a third surface—say, to fix ideas, a long, narrow cylinder or wire? It is not so easy to say certainly what the exact rearrangement will be. It would seem very probable that the hollow filaments near the wire would at once be replaced by circulation round the wire. In this case, the solid filaments must rotate as a whole round it; while at the same time, although this has not been proved, they will contract their ends, move along until they come together, form a ring, and get mixed up in the surrounding fluid.

This would correspond to the *current of discharge.* But notice that if this is so the fluid outside the wire rotates round the wire while a stationary state is being reached, and as we know that the field round a current is a magnetic field, it follows that the *analogue of a magnetic field is a flow along the magnetic lines of force.* It may, however, be further necessary that these streams must contain vortex filaments moving with the fluid, their axes at every point being perpendicular to the lines of force there.

If the field is determined by the flow of fluid independently of vortex motion, it is not easy to see the hydro-dynamical analogue of the induction of currents when, say, a wire moves across a uniform magnetic field. If, however, the vortex filaments, as above, are a necessary adjunct, it is conceivable how a movement of the wire across the lines of flow and amongst the filaments produces an instantaneous disarrangement which will travel through the vortical fluid with the velocity of propagation of transverse vibrations in a vortical fluid. That is in the ether, as Sir W. Thomson has shown, with the velocity of light.

It is difficult to see any analogue to the rotation of the plane of polarisation by a magnetic field.

* Abstract of Paper read before the British Association meeting (Section A) at Bath, September, 1888.

BRITISH ASSOCIATION.

DISCUSSION ON LIGHTNING CONDUCTORS.

(Concluded from page 648.)

The Hon. R. ABERCROMBY said he wished to be allowed to contribute to this discussion some facts which had been brought out from looking at about ninety photographs of lightning flashes in different parts of the world, which had been collected by a committee of the Royal Meterological Society of which he was secretary. A few of the most remarkable photographs he now produced for their inspection. He proposed to confine his remarks not to the whole theory of lightning flashes but only to such facts as bore on the present discussion. The first point was, is there any evidence in the photographs of a duplication of flashes—that is, of one flash rapidly following after another? He thought the answer to that must be that there is no certain evidence. He had a very remarkable photograph with him which might at first seem rather to negative that. (Fig. 3).* Here was one very bright flash, with no less than three sorts of repetitions of the bright line, in the one place. In another part of the same picture they had a thin flash, with another exactly parallel to it, only a little bit fainter. For reasons which it was difficult to give without showing the original picture, there was ground to suppose that that was due to a secondary reflection from the back of the glass (applause). One or two of the photographs were taken as paper negatives, but the bulk of them were taken on glass plates, and it was well known that if they received a bright object on the sensitive side of the plate, some of the light would go to the back and be internally reflected, and make another image a little fainter pretty close by. He thought they had often seen flashes coming very nearly after each other, but, so far, there was no photographic evidence of a flash coming exactly along the same path. But there was most decisive evidence of the tendency of flashes to be parallel to each other. He had a most magnificent photograph with him which had just been received from Massachusetts. In that, the whole air was filled with threads of lightning coming down like the roots of a tree from the sky. He thought it was very much a question where the area of protection would be when the whole air seemed to be pouring down lightning upon them. He had other photographs with him in which there were two or three flashes apparently following pretty much in the same path. Connected with this there was the inveterate tendency of a lightning flash to ramify. Sometimes they got in a photograph a comparatively smooth line; at other times it was like that which he had already shown them where the main flash seems to throw out threads in every direction. Something similar could be seen in an influence machine. Connected with that there was one thing he had not been able to find any notice of in any of the discussions or publications on lightning conductors. That is, what is the effect of rain or cloud on the passage of electricity? All laboratory experiments were taken, of course, in dry air, but every experimenter knew that the dust in a laboratory had a very considerable effect on the discharge of static electricity. His impression was that when lightning came down through rain or hail, or even through cloud, that the continuity of what are called potential surfaces, and all that sort of

* We regret that, owing to an accident, we are compelled to leave this and the two following figures over till our next issue.—ED. *E.*

† See *The Electrician*, Sept. 7, 1888, p. 556.

Digitized by Google

thing, must be very much disturbed. So much did he believe in this, that—at the next meeting of the committee of the Royal Meteorological Society, which had collected, in this year of very frequent thunderstorms, an enormous amount of material bearing on this point, including instances where much damage had been done to buildings—he was going to suggest that they should send out a circular to find out, if possible, whether the buildings were struck during rain or when it was not raining. There was another point upon which photography gave very conclusive evidence, and that was that lightning flashes were by no means as instantaneous as they are usually supposed to be. Most people had seen lightning flashes that, to their eyes, appeared to last some time, but the evidence of the eyes in a bright light is a little doubtful. There are always subjective effects on the retina. Lightning does not always jump from cloud to cloud, or from a cloud to the ground, but goes meandering about in the air something like that [illustrating on the blackboard] (Fig. 4). It meanders about in the air without very much rhyme or reason; ties itself into knots, and flies about in a very eccentric manner. He thought it was perfectly certain that when it was tying knots like that, it could not be going with anything which in ordinary parlance might be called an instantaneous speed. Of course there was no such thing really as instantaneity. Besides, the ordinary flashes of lightning, some people had seen, and everybody had read about, what had been called a globular discharge of lightning, in which a ball of light about the size of a cricket ball goes dancing slowly down the street and eventually discharges. It was perfectly certain that between that very slow discharge, and the quicker discharges ordinarily spoken of as flashes of lightning, there must be intermediate rates of discharge. There was one evidence bearing on this question of the non-instantaneity of a flash which had been adduced as evidence, but which the photographs before the committee did not confirm. In fully half of the photographs the lightning does not cover the plate as a streak, but it is more or less of a banded nature, something like a ribbon (as in Fig. 3). It had been suggested that this motion that way might have been due to the shaking of the camera, but they had evidence that this was not the case. Only yesterday Dr. Janssen made a suggestion to him which furnished additional evidence in reference to the slowness of flashes. One of their most remarkable photographs, besides showing three white flashes on the picture, has a black flash (Fig. 5). That was a very curious thing, and he very early got the idea that that must be due to the inversion of the photograph which sometimes took place from over-exposure. Photographers knew very well that in some cases, instead of white coming out as white, it came out black. This was a well-known peculiarity of plates, developers and so on; but the difficulty was to understand why so few were thus over-exposed. Mr. Janssen had made to him a very valuable suggestion, that this might be the evidence, not of a peculiarly bright flash which over-exposed the plate, but of a slow-moving flash, which gave time for the plate to be over-exposed. Of course, it was impossible to say much from one case. He thought it was a remarkably brilliant idea, and he only brought it before them as a possible confirmation of what they were certain of from other things. The only other word he would like to say was with reference to some remarks of Mr. Preece's about the height of lightning clouds. Flashes could come from a cloud only 500ft. high; but that was a very low cloud, and in the majority of cases they certainly came from very much greater heights. In the one that he had alluded to, from the scale of the picture, he was perfectly certain that the height of that cloud was considerably over 500ft. At the same time, he might mention that lightning was rare much over 7,000ft. On the side of mountains much over that height, but still at a moderate height, they would always see the lightning below. Electrical disturbance is confined certainly to the lower 10,000ft. of the atmosphere. In connection with the practical bearing of that, he might mention that in Norway they had two kinds of thunderstorms. In the summer he believed the thunder clouds were high, and very little damage was done; on the contrary, in the winter time the thunderstorm clouds were very low, and the churches frequently get struck. On practical applications he could not offer an opinion; but he was quite certain that great good would result from that discussion (applause).

Lord RAYLEIGH (who was received with great applause) said he had recovered his equanimity a little during the time that Prof. Lodge and Mr. Abercromby were speaking, because during Mr. Preece's address one felt that "mathematician" was becoming almost a term of abuse. He supposed that it was as representing the mathematicians that he had been called upon to take a part in the discussion. No doubt there is a good deal of dislike on the part of the public to mathematics, a good deal of which, he expected, was the result of sufferings undergone in early youth over Euclid and similar instruments of torture. He remembered at Cambridge it was the custom often, after the "little go" was passed, to celebrate the occasion by the burning of Euclid (laughter), and he could to a certain extent understand the feeling, for he entertained very much the same sentiments himself towards Latin and Greek. But, seriously, whatever might be the failings of individual mathematicians (and he supposed no one would deny that some mathematicians were rather unpractical in their work), it was to mathematics one must go if one wanted to foresee what would be the operation of known causes under new and unfamiliar circumstances. There was no other means of going to work. Just as the engineers would have to apply mathematical principles, even if they did not go beyond the rule of three, to the calculation of a bridge, so they required mathematics, no doubt often of a more complicated and difficult character, to foresee what the influence of electrical and other forces must be. Mr. Preece spoke of the mistakes that mathematicians had made, and no one could deny that they had made plenty of mistakes. But he did not know that they would recognise Dr. Lardner especially as a great mathematician. He it was, he thought, who made the error about the impossibility of crossing the Atlantic. The only book of Dr. Lardner's that he ever read was rather an engineering book than a mathematical one (laughter)—it was on the steam engine. His thoughts went back to a well-known book, "The Life of Stephenson," by Smiles, in which a great authority of the day is said to have offered to eat a steam engine wheel for breakfast if the locomotive ever attained a speed of twelve miles an hour. That, he believed, was a great engineer, and not a mathematician (laughter). But enough of recriminations. They all knew that engineers had very important work to do, and most of them would admit, he thought, that there was work also for mathematicians to do which engineers were not so competent to perform. As to the more particular question, he had no special experience of lightning conductors, and could only speak from a general knowledge of electricity, no doubt to be applied in this case to very peculiar circumstances, so that everything that stood upon a merely *à priori* foundation should be put forward with very great diffidence. He must say, however, that Prof. Lodge's experiments had seemed to him to be likely to have most important practical applications to lightning conductors (applause). He could not see how experiments dealing with the thing of all others most like lightning that they could produce in the laboratory could fail to have such an application. Prof. Lodge asked one question, and he thought mentioned his (Lord Rayleigh's) name in connection with it, as to how it could happen that an oscillatory electric current—that was, say, an alternate electric current beginning at a finite magnitude and gradually dying away—could produce magnetising effects such as they well knew it did in some cases; and he instanced the very opposite behaviour of slowly dying away alternating currents in the experiments of Prof. Ewing and of others, in which such an arrangement was precisely the one adopted in order to get rid of even the last traces of magnetism. The question was a difficult one certainly, and he had intended, in fact, to make some experiments upon it himself; but he was inclined to think that the explanation might, perhaps, be sought in a circumstance very much akin to the one with which they were now dealing, namely, that the steel needle, which was to be magnetised, say, by the discharge of a Leyden jar flowing through a spiral enveloping the needle, was itself a conductor of finite dimensions, in which circumferential currents would be induced. These circumferential currents would, at first, at any rate, protect the interior of the iron from the direct magnetising action of the enveloping helix. They must think not only of the action of the oscillating current in the helix upon the various parts of the needle, but also of the action of the currents developed in the steel needle itself. It ought to be well known, at any rate it had been well ascertained, that at different depths in such a steel needle they would find very often different degrees and even different directions of magnetisation. It seemed to him possible that if this was thoroughly followed out they would be better able to understand what was certainly a fact—that a current whose whole value, in some cases measured algebraically, is zero, and is certainly alternating and gradually dying away, does, nevertheless, produce and leave behind it the effect of strong magnetisation. In connection with the development of atmospheric electricity, he would like very much to hear some meteorologist express his views upon that subject. Mr. Preece spoke of the energy which they had to draw upon in the condensation of large quantities of vapour into water. Doubtless there was no difficulty as to the total amount of energy which worked in the atmosphere, but the difficulty was to see how any of that energy took the electrical form. He was reading only the other day a pamphlet by Prof. Soncke, a man who had done very good work in other departments of science, in which he develops the theory that atmospheric electricity is due to friction between water and ice. There is no doubt that many clouds (cirrus clouds, he believed, nearly always) were ice clouds and not water clouds. They consisted of spicule of ice, and the fact is proved by the peculiar optical effects of ice crystals in producing various kinds of halos and corona. There was no difficulty, optically, in distinguishing an ice cloud from a water cloud. Dr. Soncke's view was that at a certain level in the atmosphere ice clouds and water clouds could meet, and that under those circumstances this friction must occur; and his view was that the atmospheric electricity was the result of such friction, and he quoted experiments by Faraday on the friction of ice and water which had a positive result. But that was perhaps not the main question before them. He would rather hear from some more experienced and practical men, those who had been at work on lightning conductors especially, any instances of the kind that Prof. Lodge asked for of actual failures of lightning conductors. It seemed to him that it was only by actual experience of lightning conductors that the question could ever be finally settled. The laboratory experiments must be most important as suggestions, but he thought no one would wish finally to adopt any system or to change any system of lightning protection without actual experience upon a large scale (applause).

Sir WILLIAM THOMSON said that he felt like a highly-charged Leyden phial until Lord Rayleigh had beneficently acted as a lightning conductor, and almost wholly relieved him in respect to the questions raised between mathematicians and engineers by Mr. Preece. He thought that they as mathematicians might have felt very angry, but they did not feel so, and he did not think that Mr. Preece had ever succeeded in making anyone very angry, and he was sure he did not intend to do so. He would just like to say this emphatically, that it was not a mathematician but a very great engineer who predicted that the Atlantic cable could not be laid. A good many sailors predicted that the Atlantic cable could never be laid. Some sailors thought it could be laid, and took part in it and did lay it. No mathematician ever predicted that it could not be laid; some, on the contrary, rather calculated beforehand that it might be laid. Their calculations, of course, were not of any value in the face of the practical experience which led to the laying, but he well remembered how one great engineer—the greatest engineering name of the day almost—had announced that it was impossible that gutta percha could stand the pressure, and altogether that the whole thing was a chimera, and that the Atlantic cable could not be laid. While that engineer was on board ship in the roadstead of Cherbourg in 1858, on the occasion of the Queen's visit to France, the news came across that the Atlantic cable

Digitized by Google

had actually been laid, and it was like a discharge of lightning to him. It was only right that the mathematicians should be exonerated from the charge that they had predicted so many failures; because, as a matter of fact, they had not predicted any one failure in any one of the instances adduced; but he did not think that was a matter of very great importance now. He was, however, interested in what Mr. Preece had said, and also very much interested in Lord Rayleigh's remarks calling attention to the genuine alliance between mathematicians and engineers.

In respect to the very marked difference between Prof. Lodge and Mr. Preece he might say that he considered Prof. Lodge to be in the American stage with reference to the judging of the functions of inertia, and Mr. Preece to be rather in the English stage (laughter), as described on Friday evening by Prof. Ayrton. The functions of inertia were to prevent anything from getting into motion, and when in motion to keep it going; and both those functions are perpetually being performed in this electrical influence. He could not but think that if Prof. Lodge continued his work he would find the explanation of the discovery he had made, that iron wire affords a better discharge, or an easier path in the circumstances that he has minutely defined, than does copper. He hoped Prof. Lodge would pursue the investigation, keeping the circumstances in all respects as similar as possible, comparing, for instance, a thin iron wire with a thin lead or brass wire of precisely the same ohmic conductivity. Prof. Lodge had done a good deal already, but a good deal more might be done by taking a proper account of inertia and of the other point Prof. Lodge had very importantly accentuated that the energy must be got quit of somehow and somewhere. It must be got rid of either in the conductor or elsewhere; if got rid of in the conductor then there must not be energy enough to melt the conductor.

It was an interesting fact about the number of horses in a row, where the first and last in the row were killed and the others not injured by a lightning discharge which seemed to pass through them all. A very common lecture-room experiment was to give a Leyden-jar shock to a hundred or two hundred students sitting on the benches, making them all join hands and completing the circuit. He had no doubt that those next to the ends of the line experienced the shock much more potently than those in the middle of the line. There was one very marked influence here, and that was want of perfect insulation; but there was another influence, also potent—self-induction. The influence of self-induction might be tried, and it would be a very interesting experiment. He thought they might try this same thing with as nearly as possible similar insulation with the same number of people spread out in a large circle. Then self-induction would be much more influential in causing the discharge not to keep through the line of the comparatively good conducting bodies, but to spread through the floor or ground under them. Take the case of persons ranged in a row and receiving an electric shock. If the row is zigzag then self-induction will not have the same tendency to cause the lightning discharge to leave the line of the best conductors, as it will have if the conducting bodies are placed in a wide circle. He believed, the imperfect insulation of standing on the floor would be much more potent, and he should expect that those who were in the middle of the row would experience less of the shock in the case of standing in a wide circle than in the case of standing on similarly good conducting material in zigzag rows. At all events, that was an experiment worth repeating. Mr. Preece had spoken of the impossibility of conceiving of the enormous augmentation of potential in these actions. Take the name "inertia" which Mr. Preece used; he fully agreed in the judiciousness of that term. Apply the word "inertia" to the steam hammer and the hydraulic ram. You begin with a comparatively gentle force, its weight bringing down the steam hammer, till it produces an exceedingly intense action at the blow. Take the hydraulic ram, the well-known analogue for getting up a high potential for self-induction in an electric circuit, and then, he thought, they would see that Prof. Lodge's explanation of the phenomena he had brought before the meeting was altogether valid.

Exceedingly interesting questions had been put, and remarks made, about oscillatory discharge in ordinary lightning, and also with reference to the duration of the charge and to multiple flashes. He thought Prof. Lodge distinguished these more or less from one another. There might be a slow discharge. Mr. Abercromby had referred to a ball of lightning running about down the street and so on; and there was a curious description in Arago which Prof. Tait credited (although he himself scarcely thought it worthy of being credited) so far as to quote it in a lecture he gave at Glasgow some time ago. It described a ball of lightning coming in at the window, running about amongst the people, and brushing up against their legs like a cat, and after that going out by the chimney (laughter). This slow discharge by ball lightning had been described very graphically by many people. He never saw any description so minute as that of Arago's, and he must repeat that he scarcely believed it. It was a tailor who reported it, and he thought he must have been an imaginative tailor, and let his imagination run away with him when he described a ball of lightning rubbing up against his legs as if it had been a cat purring. In respect to the duration, what Mr. Abercromby had called attention to was probably the true explanation. When people see a ball, as it were, coming in by the door, passing along the floor, going up the wall and out of the window, he believed it was altogether a physiological fact. They had been looking in some direction or the other when the flash came. At the instant that the flash came there was an intense action on the centre of the retina, especially if they chanced to see the flash in the sky. Naturally, after such a startling incident all eyes are moved, and each person after seeing the flash looks about to see what has happened; looks along the floor, looks up the wall, or turns his eyes towards the fire-place or towards a window, and a spot of light (the persisting impression on the retina) follows (applause). So that he believed this marvellous ball of lightning could be seen by very person present going out of his own window or any window that he happened to look out of, or going away up the chimney if he had chanced to turn his eyes towards the fire-place (laughter). He thought Mr. Preece was perfectly right in speaking of the multiplicity of flashes of lightning. He had given some unmistakable experimental and observational evidence of it, which agreed altogether with what he had himself noticed. The first time he distinctly remembered noticing it was in the summer of 1840 at Frankfort, where he had the pleasure of seeing a great many thunderstorms. He then remarked what he did not remember noticing before, triple and quadruple flashes frequently,* but at such short intervals of time that one could not but think they were somehow connected, and yet at certainly long enough intervals of time to allow him quite distinctly to see that they were not one flash, but several flashes. It was impressed upon him then, and had been since, because he had frequently seen similar phenomena since that time. As Mr. Abercromby had said, it did not seem to be repetition of flash along one and the same course, but a succession of connected flashes; a sort of breaking down along many lines and all over the place. One flash seems to cause many others. It is something like setting up a set of bricks or toy soldiers; tumble down one of them and there is a commotion all along the line, with a sensible time interval. He thought something must be allowed for sound in this case. Light had been spoken of; the light of one flash tended to produce another flash; if there was a flash ready to take place between two knobs *here* [illustrating], a flash *there* would cause it to pass, according to an experiment which Prof. Schüster had shown him, and which had been referred to by other speakers. It seemed that the very fine oscillations of light actually put the air into a condition which was more easily disrupted than air which is not agitated by light; but that would not account for the time interval between the different flashes which was spoken of by Mr. Preece, and which he had noticed himself repeatedly. He thought this might depend on the velocity of the propagation of sound in the air. The first flash did produce certainly a tremendous disturbance in the air, a tremendous disruption of the air probably causing a very perfect vacuum in the place of the flash, and after that a knocking together of the air. He thought they could not account for an electric flash through air otherwise than by supposing a crack in the air suddenly filling up and that producing an exceedingly sharp elastic disturbance. It was quite possible that that elastic disturbance, propagated at a rate nearly equal to the ordinary velocity of sound to another place where the air is in a state of high-tension, ready to break down, caused it to break down. Thus it might be that one flash caused considerable numbers of others at intervals of a quarter of a second, or a few quarter-seconds from its initiation. That was a thing that might be experimented upon. Referring to the photographs exhibited by Mr. Abercromby, he had noticed a great multiplicity of flashes in one of them. Query, were they simultaneous? Perhaps Mr. Abercromby might say?

Mr. ABERCROMBY: We have no evidence; the photograph was sent to us without any particulars.

Sir WILLIAM THOMSON, proceeding, said the subject had always been a most interesting one, but as it was now coming within the range of experimental investigation, which could not have been the case before the photographing of flashes of lightning was practised, he thought it would be worth while to make experiments distinctly, to ascertain whether such a group of flashes as that is or is not simultaneous. There was a very ready way of doing it. Let them put up two or three or four cameras with revolving shutters. Suppose they had on each camera a shutter with one hole in it for simplicity, and revolving ten times per second, or with more holes and a smaller number of revolutions. In looking for lightning, consider one camera left exposed with a shutter arranged in that way; stop it the moment a bright flash is seen, and remove the plate and examine it afterwards. If the whole of a group of flashes took place within the time of exposure, all would be recorded on one plate: if not so, then, for example, only one flash out of a group of four might be recorded by that arrangement. But suppose there were four cameras side by side, each with a revolving shutter, one exposed when the other was cut off, then, with flashes occurring at certain intervals, one of them would be seen on one of the cameras, and another on the other, and so on. It would be easy to make any kind of time analysis they pleased, or by, in the first place, being content to lose with a single camera a considerable number of flashes, they would, by aid of a revolving shutter, be able to see whether they got groups or single flashes. But to do it properly they ought to have a sufficient number of cameras to lose nothing, and the result would tell its own tale as to groups of flashes, whether simultaneous or not (applause).

There were some very interesting points with regard to the magnetisation of steel needles by a helix in which there are electric oscillations. If he remembered right, Riess experimented on the subject some time prior to 1853. Riess found that when a Leyden jar is discharged through an insulated wire wound up in a helix in the ordinary way, steel needles are found sometimes magnetised in the direction that would be expected, from the direction of the main discharge, and sometimes in the contrary direction. He believed, as Lord Rayleigh had stated, that experimenters had actually found differences of direction of magnetisation in different individuals of a group or bundle of steel wires thus actuated, or rather thus exposed to this kind of magnetising action. If they had a very powerful current going in one direction, followed by a current of half that strength going in the opposite direction, a current of a quarter the original strength going in the first direction, and so on, then they might expect the needle to be left magnetised by the current going in that one direction, corresponding to the last time that it had magnetising force enough to magnetise or to reverse the magnetisation of the needle. So that he thought by repeating Riess' old experiment with the same degree of electro-magnetic inertia in different successive cases but with different degrees of ohmic resistance, and, therefore, different rates of extinction of the oscillation, probably a full investigation might be made.

He was afraid that he was occupying too much time, but there was still what seemed to him to be rather an important point, namely, the protection of buildings (applause). It was rather disturbing to find that a lightning rod has so little protecting power as, according to Prof. Lodge, experiments seemed to prove. With reference to the distinction between iron and copper he would ask Mr. Preece whether he had experimental evidence of any superiority of copper. It was an exceedingly difficult question. Mr. Preece had told them that his experience generally was that lightning conductors are efficacious either with copper or iron as their material. There were certainly a great many iron conductors; and he, himself, did not know any experiment which proved that they were less efficient. But they could not say anything certain at the present time. Experiment after experiment, as Prof. Lodge himself had pointed out, must be gone through before they could say which it would be safer to recommend for lightning conductors—iron or copper. There was one point upon which iron had greatly the advantage—that is, that it takes a great deal more heat to melt it. Take iron at a given price, and compare the cost of iron and copper; they could get four or five times as great a mass of iron as of copper for the same money. Take also the higher melting point of iron, and they would see that for the same expenditure upon the lightning conductor they would provide for the consumption of a great deal more energy within itself without destroying it by using iron than by using copper. Then the question of self-induction bearing on magnetisation must be considered before they could say for certain that in all circumstances the iron lightning conductor is as safe as copper. One conclusion seems quite sure—namely, that a sheet-iron house, a sheet-iron roof, with sheet-iron walls and sheet-iron floor, is the very safest place that we can possibly be in, or that gunpowder can possibly be in, during a thunderstorm. Here he might say something which perhaps was absolutely wrong, but he would hazard it. The subject was full of pitfalls: but he would venture to say that the magnetisability of the iron seemed in this case rather to prevent the danger—to prevent the current coming into the inside rather than to facilitate its coming into the inside. He thought he might safely say this: that within an iron funnel—an iron vertical funnel, say—and within a copper vertical funnel, the interior would be protected in the case of the iron funnel by the magnetic susceptibility of the iron; whereas in the interior of the copper funnel there would be no protection from this cause, although in each case there would be a very potent protection from the conductivity of the metal. However, he thought with what Prof. Lodge had put before them they knew quite enough about iron to say that an iron building would be as safe as safe can be—as safe as science can make it. He thought that was rather an important thing for powder magazines; and that the rule should be to have no special lightning conductors at all, but iron roof, iron walls, iron floor—wooden boards over the floor naturally to prevent people setting fire to the gunpowder by walking over sheet iron; and a complete roofing of iron. This iron magazine might be placed on a dry granite rock, or it may be placed on wet ground; it may be placed on anything they pleased, it might be placed on a foundation under water; no matter what the surroundings are, the interior will be safe. He thought that was a somewhat important practical conclusion which might safely be drawn from consideration of these electrical oscillations and the experiments regarding them, and the trials for mathematical theory of them, mathematical calculations of which they had heard so much (loud applause)

Prof. ROWLAND referred to the photographs in connection with Prof. Lodge's experiment. The question seemed to be whether that experiment actually represented the case of the lightning. He was very much disposed to think that it did not. In Prof. Lodge's experiment the whole of the circuit between the condensers was a material of copper and iron, whereas in the case of the lightning the greater portion of the flash was in the air, and, therefore, it might be an entirely different phenomenon in the case of the lightning from what it was in the case of Prof. Lodge's experiment. Furthermore, he was not entirely disposed to think that the length of the spark was an index of the resistance of the conductor in that case, for the reason that they did not know what the length of the spark was when there was an oscilating E.M.F. acting on it. He was not disposed to say that the discharge would take place at the first moment. There might be considerable oscillation, and finally the air might be broken down. The oscillation might take place before the spark goes, in which case the length of the spark might not be an index altogether of what they might call the temporary resistance of the conductor to the passage of the spark. The presence of iron might change the time of oscillation in the same way, so that it might give a different length of spark in that case from what it did in the copper. But he thought the fact should be remembered that in the case of lightning the greater proportion of the spark was in the air, which was a very bad conductor, and that therefore the passage of the lightning might not be oscillatory but might be of the nature of a swing, in which case a solid conductor or a conductor of copper would probably be better than a tube of iron. With regard to the photographs, he noticed many curious phenomena which he thought should be guarded against. He was happy to say that the best one, which might form the text of his remarks on the rest of them, was an American photograph. In that we had the whole plate exposed and the lightning in the centre of it. He did not suppose that all those were taken at once, but as Sir William Thomson had remarked the plate must have been exposed some time, and have had several discharges upon it. But looking at it he noticed that near the centre the line of discharge was perfectly sharp. As he wandered off towards the edge, he saw some phenomena which were very similar to those that he saw upon these other photographs, which therefore he would say was due to the astigmatism of the lens in some way. As they wandered from the centre the image was blurred, and they saw a number of hazy effects around the spark which might very well be due to the astigmatism of the lens.

M. DE FONVIELLE (who spoke in French) observed that Sir William Thomson had said most eloquently that Mr. Preece was taking the English side of the question and Mr. Lodge the American side, but he must say that Sir William Thomson himself had taken the French side, and he had proposed a revolutionary system which consisted in the building of iron houses. He took the liberty, though being a Frenchman, to disagree with the great electrician, and to stand with Mr. Preece as an English conservative, with reference to lightning conductors. Lord Rayleigh said that mathematicians and physicists should unite together, but he supposed Lord Rayleigh would agree with him in remarking that Mr. Preece was realising that alliance in a very remarkable manner, for on the one hand he dealt with a large number of experiments and observations of natural facts, and on the other hand he introduced statistics, or rather the calculation of probabilities, which was one of the highest branches of mathematics. The experiments done in laboratories were different from those which were presented by nature only so far as they were conducted on very widely different scales. He congratulated them on the aid they were now receiving from photography He should advise the meeting to delay its opinion for a time until the completion in Paris of the Eiffel Tower, which would be the most extraordinary lightning conductor in existence, being 1,000ft. high, and which would supply unprecedented observation and experiments. He must, moreover, state that Paris was practically free from calamities produced by lightning. They had erected a sufficient number of lightning rods, according to the principles so admirably advocated by Mr. Preece, and that was a strong evidence that Mr. Preece was altogether travelling in the right direction, quite irrespective of any mathematical or physical demonstration (applause).

Prof. GEORGE FORBES said as to the question which had been raised as between engineers and mathematicians, some people were apt to take a different view of what Mr. Preece meant from that which he did mean. He thought no man would be more likely than Mr. Preece to mean this, that when a mathematician started from a number of data and worked out mathematically a conclusion, that that conclusion was absolutely right could not be gainsaid; but what Mr. Preece would mean to say was that the mathematician might happen to take insufficient data for his premises, and so might eventually arrive at giving advice which was not the best advice which could be given. He thought that that was all that he meant. He thought that Mr. Preece would admit most readily that the conclusions of a mathematician were absolutely correct, and could not be wrong; but it was in the choice of the data that he might make a mistake. It reminded him rather of Lord Westbury's advice to a young lawyer. He is reported as having said, "In arguing a case never deduce wrong conclusions from your premises, the facts are at your disposal" (laughter). Let them keep before their minds in this discussion what the question was which they wished to determine. The question had arisen from Prof. Lodge having come with those experiments to prove that the views of the Committee on Lightning Rods were erroneous. The Committee on Lightning Rods had come to a definite conclusion to make a recommendation that copper should be used for the lightning rods, and Prof. Lodge had come to say that if iron was not better it certainly was as good, and that was the question which had to be decided. Now, Prof. Rowland had already said that it was not quite certain that the experiments which Prof. Lodge had brought forward were perfectly conclusive on this point. No one could fail to be deeply impressed with the beauty and the value of those experiments from a scientific point of view, but he thought it was quite a fair position for Mr. Preece to take up to say that at present they had not proved the fact that the conclusions of the Committee on Lightning Rods ought to be given up. He would illustrate what he meant in this way. They had heard one of Prof. Lodge's experiments very clearly put before them, in which they had an alternative path either of copper or of iron. Previous to those experiments, most persons would have expected that copper would have been the better conductor for the alternative path. Prof. Lodge assured them, as the result of his experiments, that copper was the worse of the two. He had not, however, given them an explanation of this fact—why it was so.

Prof. LODGE said that he did so in the section on Friday.

Prof. FORBES begged Prof. Lodge's pardon. He was going to say that until they heard the explanation of it they would not be in a position to see whether it extended to a flash from the clouds or not. The reason why he thought they were not fully able to accept this experiment as sufficing to abolish copper rods for lightning conductors was this: In the experiment Prof. Lodge had used two condensers, and he used a special case in which there were two sparks produced beside the alternative path. He had doubtless tried the experiment in a much simpler way, and more resembling the conditions which existed in the actual phenomenon. Supposing, instead of using those two condensers they used the two poles of the Holtz machine; or, instead of having two pairs of knobs, suppose they used only onepair of knobs. They might connect the poles of the Holtz machine with a large battery of Leyden jars, and they would get all the better effect. The arrangement then was that they got a spark between the two knobs of the Holtz machine. They put an alternative path in the course of the spark, and then they tested to see at what distance a spark was just possible to take place. He wanted to ask Prof. Lodge when that experiment was being performed whether an iron alternative path or a copper alternative path was best. The circumstances seemed to him to more resemble the circumstances in nature than the arrangement which he had described in his experiment, and he thought the conclusion was that the copper alternative path was the best, which would be an argument in favour of Mr. Preece's view.

Sir JAMES DOUGLASS said that the few remarks which he had to make upon this matter were in relation to experience with a large number of conductors in exposed stations now extending over about 40 years. He might say that his experience was comforting to the committee. It had been with lighthouse towers, and there they had

Digitized by Google

been following out for nearly the last 50 years the advice of Faraday entirely. For protecting a lighthouse Faraday advised them to start with the base of the *metallic lantern*. The conductors were an inch and a half by three-quarters half round—that was to say, the half, of an inch and a half copper bar. They were carried down the interior of the tower on the internal surface of the wall, with branches to all metal work. He thought much of this was given in the report of the committee, but perhaps there was no harm in repeating it. The earth is obtained by a copper plate, 2ft. 6in. square and ¼in. thick, buried at a distance of 15ft. from the tower, and about 12ft. below the surface of the ground, generally securing damp contact. At exposed stations at sea the bar is carried down to about 8ft. or 10ft. below low water spring tides, so as to be always immersed in the waves. He might say that during 40 years perhaps seven or eight accidents had occurred, but no accidents of a serious nature, and in all cases when an accident had occurred they had been able to discover that it was due to a defect in the conductor (applause). Generally it had been found to be due to a mechanic, who had been working at the station, and having disconnected the conductor, had not properly reconnected it. Therefore, those were points that they felt confident were to be got over by more rigid inspection. More rigid inspection now was being carried out, and he for one would feel that he would be perfectly safe in any tower where this system was carried out, and where the conductors were properly looked after. Having the conductors carried down the interior of the building they had every opportunity of examining them, and he rarely visited a lighthouse without inspecting every communication up and down, and generally testing the conductor with a common linesman's instrument from top to bottom. There was one practical point on the question of iron *versus* copper, and it was this: the rapid corrosion of iron, compared with copper. It was quite possible with an iron conductor in an exposed station they might visit that station after an absence of seven or eight years and find very little of the conductor left. He had known bars of iron corroding at a very rapid rate in this country, and of course it was much more rapid in hotter climates. One point he had omitted to mention which would be comforting to Mr. Preece, that during 40 years where those conductors had been carried out on towers surrounded by dwellings, in only one case had an accident occurred to the dwellings, and then it was due to the imperfection of the conductor in the tower. It was not a case of the dwelling being struck from the outside (applause).

Mr. SYDNEY WALKER, speaking as a practical engineer, reminded the meeting that it was the engineer who would have to carry out the work, and he would get the blame if anything went wrong. He mentioned one instance of a chimney being destroyed at a colliery in Derbyshire. The proprietors said it was cheaper for them to have the chimney destroyed than to fix a lightning conductor, because the destruction of the chimney occurred so seldom. In the face of that it would be a very uphill battle to fight to induce people to take up lightning conductors, and therefore he would only too gladly welcome anything which would lessen their cost. He considered that the statements made by Mr. Preece in his address as president of Section G, after the experience and study of a great many years, was absolutely correct. If they had a conductor properly constructed, properly fixed, properly pointed, properly earthed, and properly inspected, the building it was attached to was absolutely protected. He did not think there was any instance of any building having been damaged where the whole of those conditions had been complied with. He thought the cases where destruction or damage had occurred had been where some of the conditions had been neglected; for instance, where the conductor was leaded into a tombstone, and he did not consider a tombstone good earth (laughter). It appeared that the problem they had to solve was exactly similar to the problem involved where the embankment of a huge reservoir of water placed for the benefit of a town was very liable to give way. If the water was allowed to come down its own way, it brought destruction in its path; if it could be carried off harmlessly into another channel or into the deep bed of the river, the town would be saved. But there was this difference in the case of the water—there was only one path to provide. Water has to come down, and there is an end of it; but in the case of lightning they had a double path to find. The lightning flash had to come from the cloud to the ground, and to get back from the ground to the cloud; and that was a point which, he thought, they were rather overlooking. It was here that the importance of a good earth became so apparent. If the conductor ended in a tombstone the return path was represented by the air space between the line of the conductor itself, any moisture that might be on the tombstone, and any portion of ground that this moisture brought into connection with the conductor and the cloud. Whereas, if a good earth were obtained, say such as gas or water mains, spreading out into the surrounding earth perhaps for miles, and in more or less good conductive connection with it, the return path was represented by the air space between this large surface of ground and the cloud; so that its electrical resistance would be very small indeed, compared with that offered where a bad earth ruled. And this had a most important bearing upon the question of side flash, since if the resistance of the conductor and of the return path were both very small, the whole of the work would be done in passing from the cloud to the conductor, so that there should be no appreciable voltage between any portion of the conductor and, say, a gas bracket, just as with electric lighting mains in parallel the voltage between one terminal of an incandescent lamp and the same side of the dynamo was usually very small indeed. If, however, the resistance of the return path were large, say equal to that of the outgoing path, as it may be if the earth is bad, then at any point in the conductor you may still have half the voltage of the cloud left, and should a gas bracket in fairly good connection with the mass of gas mains be within a certain distance of the conductor, this would open the very path it was requiring, and it could not help sparking into it, just as if, in place of bridging a pair of electric lighting mains whose difference of potentials was 100 volts by a lamp of 100 volts, it was bridged by two such lamps in series, there would exist between the junction of the lamps and either main, or either side of the dynamo, half the total voltage, so that a 50-volt lamp connected to that junction and either main must light up. With regard to the question of iron and copper, he was of opinion that electrically it did not matter which was used, as the resistance of the conductor, whichever metal it was composed of, should form only a small part of the total resistance of the circuit; but for durability copper was decidedly to be preferred. As Sir James Douglas had remarked, iron would not stand the weather, and he would also point out that iron would not stand the chemical action of the fumes issuing from the chimneys of iron and chemical and other works. He would like also to call attention to another point, though he did so with considerable diffidence. Dr. Lodge had stated that "Ohm's law was not in it." He ventured to think that Ohm's law *was* in it, if you called things by their right names. He suggested that "impedance," "self-induction" and "electro-magnetic inertia" were merely our old friend "back electromotive force." If you split a rod into a number of filaments in the way Dr. Lodge had suggested, and imagined that a current passed in each, each created its own magnetic field around it, which gave rise to an opposing E.M.F. in all the other filaments, and it was the algebraical sum of all these opposing E.M.F.'s which gave rise to the apparent increased resistance, and which had to be provided for, just as the back E.M.F. of an electro-motor had. He would only mention one other matter. Unfortunately, loss of life and property by lightning was not confined to buildings. It was well known that cattle and human beings were often struck in the open, for no apparent reason, and there had even been cases where animals had been struck when grazing in a valley, though the surrounding hills were untouched. He would suggest that this was due to electrical currents within the earth's crust, possibly in some cases induced by the motion of the cloud itself, the difference in conductivity of the different strata causing a kind of selection to take place, the result being that, notwithstanding the fact of the cloud being farther from the bottom of the valley than the surrounding hills, the increased difference of potentials, combined with the difference in conductivity, made the path by the valley the one selected, rather than that by the hills.

Mr. BROWN, of Belfast, suggested that if one were to use a revolving camera any flashes passing consecutively over the same path would be separated on the plate, and it would be easy to calculate the time interval between them from the rate at which the camera was revolving. He had used a revolving camera himself for the purpose of registering, and he was sure it would be quite easy to determine an interval of less than the thousandth of a second. In order to investigate the other question, as to the time interval between the streams of flashes as they appeared on the photographs shown, that could easily be done by setting up one stationary camera to photograph the thing in the ordinary way, having a second camera revolving on a vertical axis.

Mr. G. J. SYMONS, F.R.S., said he ought, perhaps, to offer some apology for speaking on this subject, but it was one to which he had devoted much of his attention for considerably over thirty years. In fact, as far back as the Aberdeen meeting in 1859 he was one who took part in a discussion upon lightning conductors—at which Sir William Thomson made, as probably he would remember, the very remark which had been repeated to-day, that when he suggested to the Glasgow manufacturers to set up lightning conductors they all said it would be "cheaper to insure." Lord Rayleigh had said that it was desirable to get the evidence of practical men; he had nothing to do with the construction or erection of lightning conductors, but all through his life it had been his hobby to investigate every accident that he could of damage by lightning, and in that way he had got experience which was possibly of some value. Then eventually, when the Lightning Rod Conference was formed, he was one of the delegates, and they did him the honour of making him Secretary, consequently he had a great deal of evidence brought before him; and he must say that the impression left upon his mind, as the result of the whole of his experience, was precisely in accordance with that of Sir James Douglas, namely, that, as far as he could judge, if people would only put up conductors precisely in accordance with the rules, and fulfil all the conditions, those conductors were absolutely safe. He had not a shadow of hesitation in saying so. He admitted that accidents had happened now and then to buildings which had conductors, but a reasonable explanation of every one of those accidents, to the best of his knowledge, was forthcoming; and they all knew how very much easier it was to produce destructive criticism than to construct a system. Prof. Lodge's experiments (and he yielded to no one in appreciation of Prof. Lodge as an experimenter) were, after all, simply laboratory experiments, and it seemed to him that what they wanted was something on an infinitely larger scale. He was not going to suggest how they could make artificial lightning, so that they might deal with the actual thing itself, although the idea had often occurred to him that a great deal of information upon the subject could be obtained if upon the summit of some of those hills which were most frequently struck a series of interrupted conductors was put up where the lightning would presumably strike, on a series of tall masts; without risk to human life, they might learn a good deal more than they knew at the present time. He certainly did feel most desirous, on the one hand, that if possible lightning conductors should be cheapened and rendered more generally accessible; but, on the other hand, that they should not simply, on the strength, as he said before, of those laboratory experiments, allow it to go forth from this great Association that there was any uncertainty in the protection of the public buildings throughout the country (applause). It seemed to him that a very serious responsibility attached to those who would make a suggestion of that nature. They had the experience, not only of this country, but, as M. de Fonvielle had said, of France; they had that of Germany, and that of Austria, and they had also the experience of the United States on an enor-

Digitized by Google

mous scale. Tens of thousands of lightning conductors were erected, and millions sterling had been invested in their erection; and he must say that it would be with considerable regret that he should hear it go forth from that room, simply on the strength of some laboratory experiments, that all that had been done was to be regarded as almost worse than useless (applause). The discussion had already gone on so long that he should be sorry to enter into many points upon which he had made notes, but there were two or three upon which he should certainly like very briefly to say two or three words. He had forgotten who it was, but one of the speakers made, he thought, very justifiable allusion to the extraordinary story about ball lightning rubbing against his trousers, but as to the existence of ball lightning or some phenomenon of slow lightning, he had heard of it from so many persons in all parts of the country, and in all countries of the globe, that he could not dispute its existence. As for understanding it, he did not. He remembered quite well the experiments that were made (he was not electrician enough to say whether they were correct or not) at one of the meetings of the Society of Telegraph-Engineers by Mr. Varley, in which he actually produced something closely analogous to the phenomenon of ball lightning.* Then with respect to iron conductors, first of all there was, as Sir James Douglas said, the question of oxidation. He would be told, "Oh, it can be galvanised"; but he knew enough of galvanised iron to know that it was not an everlasting material by any means. Then another thing, as had been well pointed out, was that the gases coming out from many of our factories were seriously injurious. With respect to the area of protection, he knew that he was within the mark in saying that hundreds of cases had been investigated, and that there were not, as regards the area of protection laid down in the report of the Lightning Rod Conference, more than two instances, and those were a little doubtful, in which anything had been struck within that area of protection. The attacks all round were alarming. It was suggested that lightning could not be trusted to go down a thick copper rod, and that there was no such thing as a protected area. One would be afraid to go to church in a thunderstorm because the conductor on the top of the church would not protect them. Up to the present time there had not been a single case of a church having been struck which was provided with a good and efficient conductor. Churches were struck every year, because they either had no conductor or a bad one. Sometimes, as one of their friends said, the bottom of the conductor was let into a paving stone. At one of the cathedrals the conductor was led into a pickle bottle. Of course it was a great stupidity to allow a country blacksmith to put up conductors in that manner. There is no record of the failure of a properly-made and erected lightning conductor. Mr. Preece, in spite of all his attention (and he did work thoroughly hard upon this report), had not remembered all the details as to the upper terminal. The report suggested that what was called the upper terminal, that was the extreme top, should consist of a blunt point surrounded at about 6in. below the top by a small ring from which very sharp needle points should project. The idea of the delegates in designing that upper terminal was (he was afraid he did not use proper electrical language, because, he was not an electrician), that the acute points, the very sharp needle points down below, were to disperse the electricity, and act as a preventive; but if a disruptive discharge occurred, if the cloud came up so rapidly that the points could not get the potential down fast enough, and a disruptive discharge came upon the conductor, the absolute top of the conductor was there to receive it. The object of the blunt point was this: that if lightning fell upon a sharp point, it invariably heated it, and there were cases on record of the fused metal of the upper terminal igniting buildings. With respect to the proposed use of small wires he felt quite aghast, for this reason, that he had been in dozens of houses which had been struck by lightning, and almost the first thing that was found was that the bells went wrong. The fact was this, that the lightning as a rule got into the bell wires; it dispersed them in dust as a brown mark all round the walls of the room, and every wire was gone. If the old-fashioned conductors, which were as thick as his finger, were to be replaced by something analogous to bell wires, he wondered what was to happen after the first flash (applause).

Mr. WALKER, sen., said the last speaker had expressed a hope that experiments would be made by means of conductors elevated on a hill. He happened himself to have been in such a case. Three or four years ago he read a Paper before the Royal Meteorological Society, on an obelisk being struck. He happened to be half a mile from it, and he was rather inclined to think, from his experience then of what took place, that there were some storms in which no amount of precaution they could take would prevent destruction. The whole of the air on the occasion was an entire environment of light; there was no flash, and although he was half a mile from from it, the obelisk was the only thing that was struck. It broke off at the top; the lightning came out in 14 different places, and it ran out in one case to 100ft., and broke off some rock before it went down and ploughed up the ground in grooves. The theory was simply a theory that the lightning did not come down from the cloud but that it went up from the earth to the sky. Nothing had been said in that meeting to that effect, and it struck him that this must have come down in that form. As those streams [illustrating on the black-board] were merely continuations of the lightning flash, could they imagine any amount of earthy matters conducting that mass of electricity that came down from that column? He would like very much to see what could be done. That had been twice struck, and there was an agitation what to do in building it up.

Mr. PREECE asked if there was a lightning conductor.

Mr. WALKER said there was no lightning conductor upon it (laughter.) They wanted this Association to tell them what to do to prevent those things in future, and he was sure if that were done it would give them a very great deal of pleasure.

* See Proc. Roy. Soc., Vol. XIX. (1870-71) pp. 236–242.

Mr. TRUEMAN WOOD, referring to one of the photographs, said the so-called dark flash, whatever it was, certainly was not the result of over-exposure, as had been suggested, because the white flash, which was presumably on that theory less exposed, over-rode the black one, whereas, of course if the black part was the part of the plate which had received the most exposure, the black one would show over the white one. In a second photograph there was an exactly similar dark line which was evidently the result of *halation* or reflection from the back of the plate, and therefore he thought there could not be much doubt that the dark flash was really the result of *halation* or reflection from one of the other flashes.

The PRESIDENT then called upon Lord Rayleigh, Prof. Lodge and Mr. Preece to reply to the discussion.

Lord RAYLEIGH referred to a suggestion that Prof. Stokes once made, which he did not think had ever appeared in print. He was not quite sure whether he ought now to mention it, but he was encouraged by Sir William Thomson to do so. He thought there was no doubt, as Mr. Wood had said, that the appearance of the black flash did not suggest that over-exposure was the explanation. Prof. Stokes's view was this:—he thought that under the influence of a flash the atmospheric gases of oxygen and nitrogen were combined so as to produce considerable quantities of the oxides of nitrogen; that those oxides of nitrogen, formed along the line of the flash, were opaque to the invisible rays at the upper limit of the spectrum, to which most photographic action was due; and that this, when another flash occurred, illuminating the background of the cloud, would darken the place where the first flash had been; the mark of the flash would appear as a black line on account of its opacity to the general first light of the background (applause).

Prof. OLIVER LODGE said so many things had been remarked, and so much might be said on points which had not been commented upon, that one must exercise selection in what one mentioned. He would first say a few words suggested by the remarks of the various speakers. Mr. Walker, Mr. Symons, and Mr. Preece too, spoke as if he had especially attacked the report of the Lightning Rod Conference. But that he had not done at all; he had made great use of the report, and he thought that conference had done a very valuable piece of work. They had collected together all manner of details of destructions and of failures of lightning rods. The whole of the report is bristling with failures of lightning rods, so that he was at a loss to understand—no, he did understand—how they could say that rods never fail. They say that a "properly" constructed lightning rod never fails, because whenever a thing fails they always say there was something the matter with it (laughter). They generally say bad earth, but why a thing ought to have such extraordinarily good earth he never could tell. What was the difference between one end of the conductor and the other? You stick three points at *that* end, and you want a lot of roots at *this* end; suppose it was up-ended, why not have the roots in the sky and the points down below? Why should one end have to be treated so very carefully and the other end be left to itself? So far as protection is concerned the points at the top and the three points at the bottom ought to do equally well. Of course it may be inconvenient to have the ground ploughed up and things of that sort. You may have the ground and the water pipes broken if you have not good earth. They ought therefore to have a good deep earth; but even if they had no earth flashes ought not to spit off from the conductor to such things as safes and gunbarrels and rain-water gutters. It did that because it met with obstruction—impedance—he did not care what they called it—a spurious resistance. They might use the word resistance if they liked, but it was not what they ordinarily called resistance, it was like inertia. It was like having to move a great freely-suspended weight; there was no resistance to its motion; you knock it with a hammer, and expect it to fly to the other end of the room, but it scarcely moves. You may knock the hammer to pieces; you may do a great deal of damage, but you cannot move the weight suddenly. That was the kind of obstruction that was met with in a lightning conductor. As regarded failures of properly constructed lightning conductors, he wanted to know from Mr. Symons—there would be plenty of opportunities for continuing this discussion in print—why the Hotel de Ville at Brussels was set on fire by a lightning flash, because if anything was well protected, and even admirably and thoroughly protected according to orthodox principles, that building was so. He himself thought it was protected. When he said that a building was not completely safe he did not mean, and had never thought of meaning, that lightning protectors are of no use; they are of very much use, but they may occasionally, and he believed do occasionally fail. M. de Fonvielle referred to the great experience that Mr. Preece had had, and also of the experience gained in France of all sorts of conductors, telegraph posts, and things like that. It is true they did not fail much, but then a telegraph post, and an obelisk, and a lighthouse were the easiest possible things to protect. There was just one column, and if they stuck one conductor down, there was not much chance of its spitting, or its doing much damage, or anything else. In the case of the Monument, in London, he believed that the handrail of the staircase was the lightning conductor. He did not know how it would feel if it was struck; he dare say it had been struck, probably in the night when nobody was there; but it had never been damaged in the least. It was not so easy to protect powder magazines, or houses where there was escaping gas. If the lightning flash was only a little bit away from a leaden gas pipe, it would very likely fuse it and light the gas, and they would have the house burnt down. They might not know that it had been struck, but they would wake up in the morning and find themselves burnt. Prof. Forbes had asked him to say why he did not use one pair of knobs instead of two pairs of knobs to try the experiment. If Prof. Forbes tried it with one pair of knobs he would find that he could not do it at all. There must be two pairs of knobs somewhere. *Here* [illustrating] are the two knobs of the Holtz machine, and *here* the alternative path. How were they to get sparks between these knobs? If they were to put an alternative path to an air,

Digitized by Google

space they must have another air-space somewhere to enable them to do it, but it need not be done exactly as he had done it. He would not go further into that point now, as the discussion could be continued in print, but he might put his views briefly thus :

These discharges are oscillating currents of extraordinarily great frequency—something like a million a second. For those currents it is only the outer surface of a rod that conducts, therefore its obstruction was due to the space surrounding the conductor, and it was not due to the material of the conductor. It is only the outside tube of the conductor that conveys any current, and therefore the conductor, whether iron or copper, did not get magnetised at all. It did not matter about its permeability, or about its conductivity much. The current is very great ; even from an ordinary Leyden jar the current produced when discharged through an ordinary tongs is about 3,000 amperes. The current in a lightning flash is, no doubt, enormous—he thought a million amperes for the time it lasted. That it was very great was shown by the heating powers and the destructive powers it had, though its duration is so extremely small ; and hence it is that the impedance being also very great, they had this large amount of ohms and the tremendous current, and so they got a tremendous difference of potential at the end and the liability to spit off.

Seeing that only the outer surface conducts, what is the good of the inside of the rod ? It may be able to conduct some heat away and so prevent melting, or it may not have time to do that. Probably there is no very great good in it, but if they were going to have a tube they had better have it spread out flat. Or, better still, have a strand of separated wires, or have a series of wires about the size of telegraph wires. Mr. Preece knew very well that the iron wire conductors on the telegraph posts protected them, and a house would be protected in a similar way, and cheaply, by putting a great number of common galvanised iron telegraph-wires up. That was his view ; but it was not authoritative. If what he said would be authoritative, and would go forth as a statement from that room, of course he would hold his tongue ; but, as it was, he simply said that which he thought true at the time. It was found that all the failures in the case of lightning conductors were due to the spitting off from them ; were due to this high potential ; were due to the impedance of it, the obstruction of it, to the fact that it does not conduct easily away as they would expect it to do ; not due to the melting of it. Mr. Symons, in his report of the Lightning Rod Conference, gave, in an appendix K, a list of conductors which had been melted by the flash, and he apologised for the shortness of the list. No apology was necessary ; the list was short because they very seldom got melted. If they analysed those which Mr. Symons gave they would find in every case but one that it was only the upper terminals which had been melted, not the full length of the conductor. There was only one case of complete destruction, and that was a bell wire, and even so it exerted a protective influence. So then we learn that when they are bell wires they are melted ; but he did not want the wires which were to be put up to be of the thinness of bell wires.

Iron buildings, as Sir William Thomson said, are practically safe for powder magazines, and the safest things they could make, but even with them some little care was wanted ; the iron must be in absolutely good connection all through. If there was a gap left anywhere there might be a spark in that gap. When an iron building is struck they would have the thing surging about in all directions, and they might get sparks in the most unexpected places, and for the most apparently ridiculous reason. It might be only half an inch long or a quarter of an inch long—that would be quite sufficient to light gas and do all the damage. There was in houses the danger of gas, and there is danger in powder magazines—not from sparks a yard long, those might be guarded against—but let there be a gap of a quarter of an inch, and they might get the sparks where they least expected them.

As regards the possible effect of sound waves—sound waves produced by these sparks—might he just call attention to one little experiment which was not his own, but which was first made by Dr. Guthrie ? It had been called attention to at the Physical Society afresh and independently by a Dr. Cook. There was a discharging Leyden jar which, as he had often said, gave ether waves of a calculable length : well, if a plate of fine powder is put near its spark it gets thrown into ripples. This modification of the experiment had been made by Mr. Chattock—he took a little tube like a resonant tube and sprinkled powder in it ; when the spark occurs near the mouth of that tube, there are ripples on the sand indicating that a series of longitudinal wave had traversed the tube—longitudinal waves which were extremely short—about a millimetre in length : sound waves being practically one millionth of the length of light waves. The oscillating heat no doubt of the spark was able to send longitudinal vibrations down the tube—sound waves about a millimetre long which threw the sand into ripples. It might be those longitudinal sound waves which Sir William Thomson mentioned, and which might in some way precipitate a discharge in the neighbourhood ; but no doubt there were other causes (loud applause).

Mr. PREECE said he introduced at the commencement of his remarks an unfortunate allusion. He compared Prof. Lodge to their old friend Balaam, and he said that there were three persons, or three quantities, mixed up in that transaction, Balak, Balaam, and the donkey ; but there was a fourth. Now there were a good many errors of translation in our Scriptures, and he was strongly inclined to think that the word "ass" should have been translated "phonograph." What really communicated with Balaam was a voice, and that voice was right. Balaam had made a mistake, as Prof. Lodge had made a mistake. The voice came directly from Heaven, and it was with the voice that he claimed relationship. There was very little for him to say. Prof. George Forbes had put his view of the question of mathematicians *versus* practical men very much on the right footing. It would be folly and absurdity on his part to call into question for one moment the conclusions of their masters in mathematics. They were all students, who lay at the feet of their Gamaliel at the end of the room, Lord Rayleigh. Everything Lord Rayleigh wrote, everything he said, and everything he did, was studied with the very greatest care, and he (Mr. Preece) would be very grieved if anybody left this room and thought that he had called into question anything that masters like Lord Rayleigh and Sir William Thomson, or Prof. Rowlands, had ever said. As regards Sir William Thomson, he was one of themselves. He was not a physicist—he might know a little about it (laughter) ; he was not a mathematician—he might know a little about that ; but what he was was an electrical engineer ; he was the head of the profession, he was the first electrical engineer in the world (loud applause). There was no doubt that we all made mistakes, engineers and mathematicians as well. What he meant to imply was this, that in the present day, what with Technical Institutes, what with the innumerable students that were sent into the world, specially into the electrical world, every year, they found some of those young fellows coming out with a smattering of mathematics ; they wrote Papers for the technical journals, and they thrust upon the electrical world conditions and conclusions arrived at by their mathematics with a coolness and an effrontery that were simply appalling. It was to try and check that sort of thing, that was growing to a very serious extent, that he had made the few remarks he had about the necessity of being excessively cautious in acting upon any conclusion that might be derived from mathematical development, unless (and mind, he had always put in this) confirmed by actual experience (applause). The true mathematician would never come to a conclusion, and never thrust his conclusion upon the world, unless he was sure of his ground, but the imperfectly trained gentlemen were too fond of throwing out conclusions, without the least confirmation by experiment or anything else. He would not occupy their time any more, because there would be other occasions when the points at difference between them could be argued. He might say that they had dwindled down to a very small thing indeed. As regarded the question of iron and copper, in answer to Sir W. Thompson, he would say that most—in fact, all—of those lightning conductors of which he had actual experience were of iron—(hear, hear)—and always had been, as most of them knew who had read the reports he had written. He was a great advocate of iron. He thought the use of copper to the extent that it was used introduced a needless expense into the erection of lightning conductors. His own impression was that every private house could be thoroughly protected, according to the recommendations of the Lightning Rod Conference, for at least a pound. Anybody could buy a coil of stranded iron rope, and if they took an iron rod about a quarter of an inch in diameter with the finial Mr. Symons had referred to, he believed that they could safely protect their houses with lightning protectors for a few shillings, instead of now, where copper was employed, indulging in the expenditure of a few pounds (applause).

The PRESIDENT said he was sure they had all heard with very great pleasure the discussion that had taken place, and it was with very great diffidence indeed that he felt called upon by his position, rather than by any desire to do it, to say a few words in summing up what seemed to him to be more or less the result of the considerations that they had come to. He was glad to say that he had had no experience of lightning. It was not an agreeable thing to have anything to do with. However, it was most closely allied, there was no doubt about it, to static electricity, which he had heretofore looked upon as one of the most beautiful of the vast forces of nature ; and he hoped now that their experiments in what had been hitherto called static electricity would gain fresh interest from the practical applications that were likely to be derived from it. He thought, as far as Prof. Lodge's position was concerned, it was very important to observe that there were a number of experiments that have taken place, especially in connection with some tramway lines, with telegraph instruments and with telephones, with effects that have taken place at terminal stations at considerable distances from the lightning, which required to be investigated, and about which they knew very little, and which had not been considered very much.

Mr. PREECE said he had meant to point out what Prof. Fitzgerald was now saying, that they had experienced sparks in their telephone exchanges and in their electric light installations where there was a mere metallic circuit. What Prof. Fitzgerald now referred to was the practice exactly, and it was a most interesting point.

The PRESIDENT said they were all very much obliged to Prof. Lodge for his experiments, because heretofore he thought there had been little or no experimental observation of this particular point, and it was a very important thing to see, especially if telephones were likely to become of very great use on a large scale, that during thunderstorms, if they could possibly do it, they should protect people from injurious effects owing to the presence of a thunderstorm, perhaps at a considerable distance from the person that was observing it. It was very analogous, it seemed to him, to Prof. Lodge's experiments, and they were very much to the point in that explanation ; but he was inclined to think that the experiment that he had performed was not exactly analogous, and in many ways was not at all analogous to a lightning flash. Mr. Preece had called attention to the fact that a lightning flash was very much more like a discharge between the plates of a condenser, much more like the breaking down in the insulation in a Leyden jar when it bursts through the glass. Prof. Lodge's experiments had not been on the effect of putting a point upon one of the plates of an air condenser, and if he did make some experiments on it he thought he would find there would be a considerable diminution in the amount of sparks.

Prof. LODGE : If you read my Paper you will find those experiments done, too

The PRESIDENT said he was afraid he had not studied the thing completely ; but the experiments that were alluded to to-day were not exactly analogous.

Prof. LODGE : No.

The PRESIDENT thought it would have been well if they had been

Digitized by Google

told of experiments which were exactly analogous. There was a question with respect to the alternation of currents. He would call Mr. Preece's attention to this, that even though there might not be millions of alternations per second a great many of the effects of an alternating current would by produced by an extremely sudden current of very short duration—that the effects that had been observed were due to the very sudden change in the strength of the current. Now, the effects of a very sudden change in the strength of the current could be produced by a single spark, whether there was an alternation or not. So that a great number of the effects that Prof. Lodge had observed, and in reference to which he seemed to think it was necessary to have an alternation several million times a second, would be produced by a single sudden discharge of a millionth of a second.

Prof. LODGE: Not quantitatively.

The PRESIDENT: It might not be an exactly similar case with all of them, but a great number of the effects would be produced; and he thought a great number of effects, similar to those that Prof. Hertz had observed, would occur, where at a distance from a spark he had observed electro-magnetic effects. That might also cause electro-magnetic effects in the inside of the house due to a spark of electricity going to the outside of the house. He would like to make one more remark. Globular lightning would possibly be due to the dissociation of molecules of the air, and of there being a region of the air in which there were atoms going about by themselves, and combining amongst themselves and producing an illuminating part of the air, the original dissociation of the atoms having been produced by some electrical effect. He was not sure that it was worth considering, but it was a thing that was possible, he thought. In conclusion, he thought that the principal thing for them to pay attention to was that prevention was better than cure, and as M. de Fonvielle had called their attention to it, there was very little doubt but that the presence of a considerable number of lightning conductors unquestionably afforded a great deal of protection to the area within which they existed. As he had remarked, in the city of Paris they hardly ever had any accidents from lightning, and it had been observed on a larger scale that the existence of lightning conductors actually as a matter of fact produced a discharge which, to a great extent, probably neutralised the clouds, and thereby prevented the lightning flash occurring at all; so that it was very desirable that, if possible, the whole country should be covered with lightning conductors, and that they might have as many points as possible, and thus, as far as they could, prevent the occurrence of lightning. There was no doubt that when a flash occurred it was extremely disagreeable, and they had better adopt the old rule that "Absence of body was better than presence of mind," and avoid being near it if they could (app'ause). That led him to the point that Prof. Lodge had mentioned, which reminded him of the effects that they had in a room, when each person wished his neighbour to open the window in order that the draught might be upon his neighbour and not upon himself. Mr. Preece, he thought, would suggest that everybody in his neighbourhood should put up lightning conductors, and that he should not have a lightning conductor, in order that he should be protected by other people's lightning conductors. That would be a very pleasant arrangement, but he was afraid they could not have that exactly, and that the next best thing was for them to have as large a number of lightning conductors as possible, because he did not think there was any doubt at all, quite independently of any experiments of Prof. Lodge's, as far as he could see, that as a matter of experience lightning conductors had protected buildings, whatever the explanation of it was, and that there was no doubt but that they had been right on the whole. Perhaps there were improvements possible; perhaps they might be able to protect themselves from those unfortunate discharges that occurred in telephones and so forth; but as a whole lightning conductors had been a great protection to mankind from danger from lightning (applause). That was undoubtedly the result of their experiences.

Dr. JANSSEN, immediately after the discussion, made a communication in French on some attempts at photographing lightning which he had made with a double-nozzled camera, having one plate fixed and the other spinning on an axis, as suggested by Prof. Lodge in *Nature* at the beginning of July, apparatus of M. Marey being used to maintain the rotation. The results obtained at present were only preliminary, but they showed that flashes were often multiple, constituent flashes being well separated on the moving plate; while each flash itself was practically instantaneous, being quite unaltered by the rate of spin adopted, which was 30 revolutions a second.

THE CANCE ARC LAMP.*

The principal feature of the Cance arc lamp is a central screw, V, (Fig. 1) which is embraced by the female screw A, forming part of the positive carbon-holder B. The screw A tends to descend, but as the rods C C prevent it turning, it gives a movement of rotation to V. At the upper part of the lamp there is a second female screw, D, resting on the rim E, which forms part of the plate F. The plate F is supported by the cores G G of the solenoids H H. These coils are in series with the the main circuit. The springs R R are fixed to the lower ends of G G by means of stirrups, and regulating screws secure it to the lower plate of the lamp. The action of the lamp is very simple. When the current traverses the solenoids, the cores G G are projected violently against the plate F; F is consequently lifted and pressed against D, the screw V is rotated, A is lifted and the arc is struck. When the strength of the current is diminished by reason of the lengthening of the arc, the springs R R pull down the cores G G, the plate F falls, the screw V turns in the reverse direction, and the upper carbon holder is allowed to descend until the arc attains its proper length. In practice regulation is obtained by a very slight difference in the pressure of the plate F against the female screw D, and the positive carbon falls continuously and slowly, so that the arc is remarkably steady. The lamp is self-focussing, the fixity of the arc being obtained by the usual arrangement of pulleys and tackle. In Fig. 2 is shown the general appearance of the lamp without the globe. In Fig. 3 are given the details of the screw D, and Fig. 4 is a sectional representation of a solenoid and its core. The screw

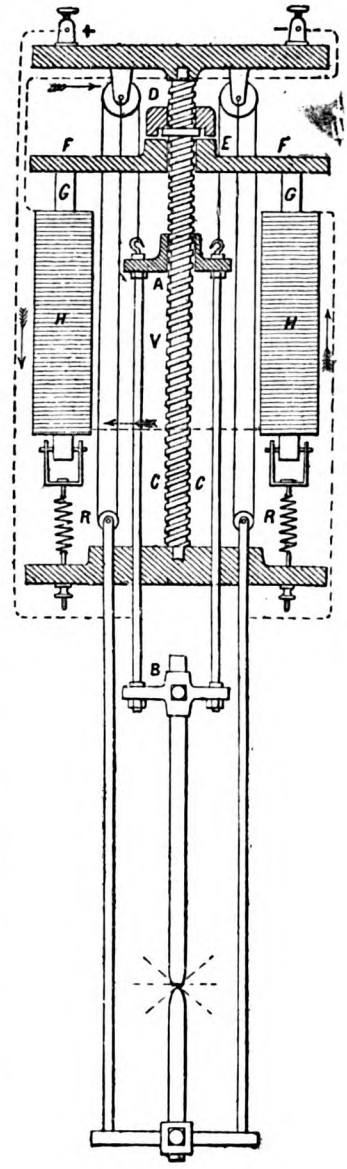

FIG. 1.

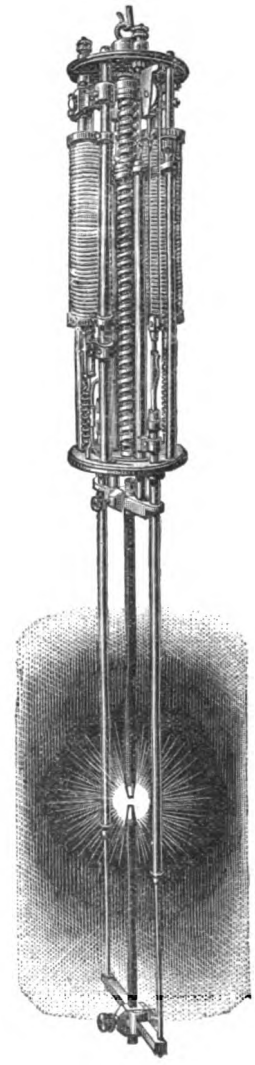

FIG. 2.

shown in Fig. 3 is made in two parts, D and D′, joined together by three small screws. The inside is not threaded, but is furnished with three slightly conical studs, K, which penetrate into the bottom of the grooves of the central screw, and prevent it from turning so long as the studs remain steady. The ring E is fixed to the central screw, and prevents D from falling lower than its upper surface. The carbon holder screw (Fig. 1) is constructed in the same way as D, and owing to this device of conical studs, the abnormal friction and jamming of ordinary screw arrangements is avoided. The solenoid H (Fig. 4) has an iron tube S at the top, inside which the core G G moves; the core G G is about 15 millimetres in diameter at the bottom and 6 millimetres in diameter at the top. The spring R is in a very accessible position, and it can be easily given the required tension by means of a regulating screw.

These few details show the minute care which has been bestowed upon this much-used lamp, of which the Bon Marché alone uses nearly three hundred. M. Cance recommends as a general rule that the lamps should be arranged in parallel, rendering them independent of one another and allowing incandescent lamps to be run off the same main.

ELECTROMETRIC DETERMINATION OF "V."*

BY SIR WILLIAM THOMSON, PROF. AYRTON, AND PROF. PERRY.

The standard measuring instruments used were an absolute electrometer and a centiampere balance, with a resistance coil for measurement of potential. Their indications of potential in electrostatic measure and in electro-magnetic measure were compared by aid of two electrostatic voltmeters (A and B), which had been carefully compared in Glasgow, and which were used as intermediaries. The absolute electrostatic value of the scale of one of the intermediaries (A) was determined in London by Messrs. Ayrton and Perry, using the absolute electrometer. They consider that as neither of the two instruments is capable of very minute accuracy, their determination might be three-quarters per cent. wrong, but they believe that it may be quite trusted to be within one per cent. of the truth. The voltage of the other electrostatic voltmeter (B) was determined from a potential of about 80 volts between the two ends of a resistance of 600 ohms, with a current of about 133 milliamperes through it, very accurately measured by a centiampere balance. The 80 volts multiplied 16 times by the method of condensers in series described by Sir William Thomson to Section A at Aberdeen in 1885 gave the voltage of the B electrostatic voltmeter. As this instrument is not capable of very minute accuracy, the determination may have been wrong half per cent., but it may be trusted as probably not three-quarters per cent. wrong.

The comparison of these measurements then gave the voltage corresponding to electric potential reckoned in electrostatic units. The final result is that the electrostatic C.-G.-S. unit of potential is equal to 292 volts—that is to say, 292×10^8 C.-G.-S. units of electromotive force in electro magnetic measure; in other words, "V" is 292×10^8 centimetres per second. This result may, we believe, be trusted to as within $1\frac{3}{4}$ per cent. of the truth. It therefore seems that "V" cannot be greater than 297×10^8, nor less than 287×10^8. We present it merely as an approximate result, and look forward to measuring this very important physical constant within one-quarter per cent. by the purely electrometric method carried out by an absolute electrometer, and intermediary electrostatic voltmeters, capable of greater accuracy than the instruments which we have used hitherto.

* Paper read before the British Association meeting (Section A) at Bath, September, 1888.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *September 15th*, 1888.

During the three weeks that have just passed, New York has been the rendezvous for all those who are actively interested in the electric light and the telephone. The meeting of the National Electric Light Association, held during the closing days of August, was attended by about 400 gentlemen connected with electric lighting, and at least half as many more were drawn to the Convention by indirect relationships or by curiosity. By this time you have probably published some of the Papers which were read, but a few cursory notes of the meeting, as a whole, may not be out of place. Some idea of the intetests represented may be formed from the figures presented by President Duncan, of Pittsburgh, who estimated that there were at present 5,351 plants and stations operating 192,500 arc lights, and 1,925,000 incandescent lights, requiring a total of about 450,000 horse-power, besides 34 electric roads running, and 49 in process of construction, making a total of 83 roads, with 327 miles single track, and 467 cars, requiring a total of 9,000 or 10,000 horse-power. The President did not present any figures as to the mileage of overhead and underground wires, but it appeared from the statement made by Dr. Wheeler, expert of the Board of Electrical Control, later in the meeting, that New York had more wires underground already than any other city in the world, there being in operation underground about 4,000 miles of telephone and telegraph wires, several hundred miles of incandescent electric light conductors, and a considerable quantity of police and fire telegraph wires. The Metropolitan Telephone Company alone has 3,697 miles of single wire underground, and in September and October there will be put down about 12,000 miles more. During the Convention members were invited to inspect the drawing in of a large 8-conductor lead-covered cable for the local Brush company for electric lighting, but it may be mentioned here that it is not the intention to bunch the arc light wires in this way again. They will be run singly through the duct, which certainly seems to be the wiser plan. It may be said that underground wires occupied largely the time of the meeting, but there was very little that was new to be brought out. The opportunity was seized, however, by Mayor Hewitt, to make a very shrewd and able vindication of the policy he had pursued in not harassing the electric light companies with regard to the underground wire question. The members appreciated the points made by the Mayor, and will see to it that his remarks are pretty widely disseminated where they will do the most good. An interesting Paper was presented by Mr. Leonard, of Minneapolis, as to the advantages in the use of petroleum fuel. The showing was a favourable one in spite of some adverse criticism, and I fully expect to see an increase in the use of crude

Digitized by Google

petroleum in electric light stations. There promises already to be a very large use of it in Chicago. It may, perhaps, be remembered, that at Lima, Ohio, the electric railroad burns crude petroleum under its boilers. Another interesting Paper was read by Mr. Lufkin, on the basis on which to calculate charges for motor service. Mr. Lufkin presented some noteworthy figures as to the actual running time for motors in different classes of service, and also made some points as to the relative value of electric power in large and in small units. He concluded, for example, that an electric light company could make money by presenting a customer with 30 small motors, charging him at the rate of $1 per month per motor for current, rather than let him buy a single 2 horse-power motor to operate the same machinery with shafting, with a charge of $18 per month for current. In other words, Mr. Lufkin was favourable to sub-division, and to furnishing power by small motors. He held that 50 cents per month for small moters driving sewing machines gave a better profit to the generating company than $10 per month per horse-power with the large motors, leaving out of consideration the advantage which the small motor possesses of keeping the work in better balance, avoiding the fluctuations due to the stoppage and starting of large motors. "One electric light company," he said, "making rather a specialty of these small machines, rents the motor and supplies the current for $1·25 per month per sewing machine, and reports that at this price the motor service pays them a better percentage of profit than their lamps. This company has some 200 small motors on its circuits." As to the actual time that the various classes of service are consuming current, Mr. Lufkin reported as the result of his investigation that in machine shops in no case would the service by motor exceed 65 per cent. of the contract. In laundries 75 per cent. service would be the exception, and the average might reach 50 per cent. Printing offices run about 40 or 50 per cent.; opticians 20 to 30, picture frame and moulding manufacturers 60 per cent.; nickel and silver platers and buffers about 45 to 50 per cent., and sometimes as low as 20; ice cream freezers 25 per cent., coffee mills 40 to 60 per cent., model and pattern makers 50 per cent., and running as low as 20; church organs 10 to 20 per cent., sewing machines 75 per cent. From such data as this it is comparatively easy to arrive at some idea of the basis of charge and as to the details of service. It cannot be said that the motor men as a rule are inclined to accept Mr. Lufkin's conclusions as to the preference that should be given the small motor, but his Paper was, on the whole, very well received, and was amongst the most useful and suggestive of those presented.

Following the Electric Light Convention came that of the National Telephone Exchange Association, presenting in many respects a marked contrast. That which strikes one in this country with regard to the electric lighting business is the predominance of young men in it; what may be called the superabundance of vitality which manifests itself on every fit or unfit occasion. In the telephone business they who control affairs are certainly not in their salad days, though there are to be found some very able juniors among them. In the electric lighting business, there has been, and even is to-day, a giddy and confusing whirl of competition, so that a company has to meet attacks in every direction, and is continually throwing its forces into open square formation. In the telephone business, as everybody knows, the struggle is not from the outside, but from the in. Nevertheless, at the last meeting here, there was not a little talk as to the competition which would arise a few years hence, when some of the leading patents expire, and when, in various ways, telephony will be more generally open to the public and to new capital. The subject was touched upon very ably by President Metzger in his opening address, in which he said "the competitor of the future will be no less relentless than the infringer of the past; watching every movement that you make, noting every step of progress, he is but waiting for the day and the opportunity to divide the business, or perhaps to absorb it entirely." Hence the timeliness of his exhortation to be prepared by efficiency of service, economy of operation, and general solidity and stability of construction, for the conflict which must inevitably come three or four years hence. It is not at all improbable that the men who are in the field to-day, with their experience, their familiarity with the subject, the wealth that they have acquired, and the various franchises and rights that they have obtained, may be able to hold their own, but a big struggle for the patents there will be, which may ruin the new comers, and cause the companies to go for many a quarter without dividends. The yield of the telephone patents has been so great as to excite covetousness in every quarter, and if we see already such a struggle made during the lifetime of the patents, what will it not be when the field is open to everybody?

Several Papers of interest were presented to the Telephone Convention. One of them, by F. A. Pickernell, dealt with the subject of batteries for transmitters, in which mention was made of the good results obtained from storage cells. Mr. Pickernell remarked:—"Many modifications of the Leclanché battery have recently been introduced, some of them having remarkably low resistances, but they all polarise more quickly than is desirable. I think that if we have not already a modified Leclanché battery that combines low resistance and constant E.M.F. we shall soon have one, and this will be beyond question the telephone battery of the future. I see no reason why a battery of this kind could not be made having an internal resistance of considerably less than 5-10ths of an ohm, and a constant E.M.F. of 1·48 volt." The Paper provoked an interesting discussion, in the course of which Mr. Lockwood remarked that the demand had come for a Leclanché battery of about twice the size of the present cell, and he was surprised that the companies manufacturing batteries were not already in the market with something to meet the want. A subject which attracted a good deal of attention, and was discussed in two Papers, was that of the interference of electric light and power circuits with telephone service. One Paper was read by Mr. M'Cluer, of Richmond, who has had to deal with the troubles induced by the big Sprague electric road there, and the other was read by Mr. T. D. Lockwood, who has long given the subject his study and attention.

It appeared from the Papers and the discussion that great relief had been afforded by the use of the common return wire, and that this was the device likely to be resorted to in the future, in order to meet the difficulties arising with the rapidly-growing number of electric light circuits, and especially with the new electric roads which are going in everywhere. Mr. Lockwood recommended that the telephone companies should exert their influence in favour of the double overhead wire on the roads, preventing, as far as possible, the use of the rail as a return. Interesting Papers were also presented by Mr. W. D. Sargent as regards Brooklyn, where the Telephone Company has 2,000 miles of conductor underground, supplying 1,913 subscribers, and by Mr. L. F. Beckwith, on the works in New York. Mr. E. F. Sherwood gave some statistics as to the Telephone Exchange in this city. He stated that the big new switch-board at headquarters in Cortlandt-street, consolidating seven exchanges, is wired for 5,100 subscribers, and 900 trunk wires. Each operator will attend to 50 or 75 wires, according to the bulk of business at each section of the board. Trunk-calling circuits to the other exchanges will also be in operation, each receiving trunk operator attending to 50 wires. The local battery of each operator's outfit will be two cells of storage, one for day and the other for night. The one in use during the day will be charged in the night from the main storage battery, and the night battery will be charged from the dynamo during the day. All wires to the exchange come underground, and they are carried from the cellar to a distributing board in the exchange by cables of 334 conductors. The consolidation will greatly reduce the complexity of handling business, and will also cut down the running expenses on the same quantity of work over £500 per month.

It is needless to add that both conventions were accompanied by innumerable festivities. One feature of each occasion was the attention given to it by the daily papers. Day by day the morning and evening papers devoted a large portion of their space to the reports of the proceedings, and those reports were, on the whole, very fair and accurate. The effect of all

Digitized by Google

this in advertising the growth and prosperity of the two branches of electrical industry must be enormous, and the effects are, indeed, already seen in the greater respect and care with which electrical questions are discussed. It ought no longer to be difficult for any electrical invention of merit to obtain hearing and consideration in New York. The danger lies the other way.

As many of your readers are interested in the phonograph and graphophone, they will doubtless be glad to hear an amusing little incident which has just occurred here, illustrative of the use to which the apparatus may be put. An industrial exhibition is being held at Toronto, and it was proposed at first to have an address by Mr. Erastus Wiman, of our city, on commercial union with the United States. Mr. Wiman, as you known, is an energetic Canadian, who has made his home in this country, and is not only well to the front in commercial matters, but is actively connected with various electrical interests. One of Mr. Wiman's hobbies is the desirability of closer union between the United States and Canada, and his sentiments are not altogether palatable to everybody in the land of his birth. Under these circumstances, the Board of Managers voted against the address; when it was suggested that as the phonograph was to be exhibited, Mr. Wiman should eloquently express his ideas on that instrument before it left New York, and that they should then be ground out in Canada. In some way the Mayor of the city got wind of the project, and wrote to the managers requesting that no politics be imported from the United States on the phonograph. I understand that Mr. Wiman, therefore, was requested to change his subject, but it is reported here that he did after all contrive ingeniously to say what was in his mind, and, of course, it was impossible to discover what was in the cylinder until it actually repeated its little speech on Canadian soil. If this sort of thing goes on, there is no telling where it will stop, and we shall soon have established in every country a Government bureau for the examination of phonograms on their arrival. For instance, I understand that O'Donovan Rossa's paper is stopped when it reaches Ireland; but what is to prevent the O'Donovan from talking into the phonograph a bloodthirsty speech calling for Saxon gore, passing it through the mails, and then having it ground out again to an excited audience at Tipperary? If a man can do this, will it be worth while to exile him?

I think it has already been reported in your columns that the Westinghouse Company has purchased the patents of the Tesla alternating-current motor. It is now stated that they propose to take up the question of electric power, introducing these motors on their alternating circuits as soon as possible, and that they are also making experiments with it for street railroad service.

The condition of the Western Union Company continues excellent, and the executive committee have just recommended the payment of the usual quarterly dividend of 1¼ per cent. The income of the company shows a steady upward tendency, the receipts of the test offices for the first week in this month aggregating $232,000, an increase of no less than $44,000 over last year.

Under date of August 24th the Richmond *Whig* devotes 2½ columns to a *résumé* of the work done on the Sprague Electric Road in that city, which has recently been attracting so much attention all over the world. This well-known newspaper is quite jubilant over the fact that Richmond is a Mecca to which the eyes of all interested in electric power are turned, and it reports that large numbers of visitors daily inspect the road, with the object of introducing electricity for street car service somewhere else. The road is carrying, it states, on an average, about 8,000 passengers a day, and its success is so marked that the old horse car line is to be made an electric road, while a contract has also been made for the Manchester and Richmond line. I hear, by the way, that the Sprague people have just closed their twenty-sixth contract for the equipment of electric roads. This is a pretty good record, from the fact that on the 1st of February the Sprague Company did not have a single road in operation. The truth is all the electric railway companies are busy, and we are going to see a very rapid development in this field.

Ex-Governor A. B. Cornell, of this State, has recently been attacking the high-tension lighting companies, and recommending that the use of arc lighting circuits with current of high E.M.F. be altogether prohibited. Mayor Hewitt, being interviewed on the subject, says that Mr. Cornell does not know what he is talking about, and that he is also influenced by his interest in a company using low-tension current.

CORRESPONDENCE.

THE THEORY OF LIGHTNING CONDUCTORS.

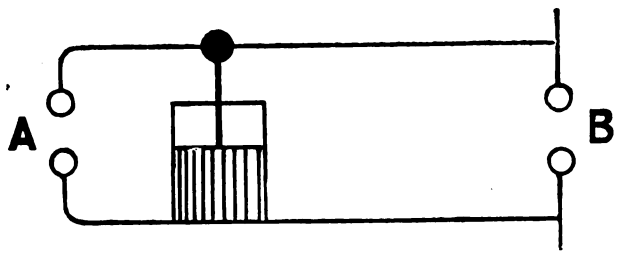
TO THE EDITOR OF THE ELECTRICIAN.

SIR: The enclosed letter received from Prof. Hughes seems to me of general interest, and I have therefore obtained his consent to its appearing in your columns.—Yours, &c.,

19th Sept., 1888. OLIVER J. LODGE.

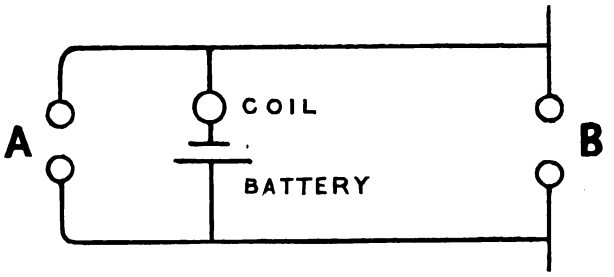
"DEAR PROF. LODGE: I returned to London last evening after several weeks' holiday on the Continent, and found your most interesting Paper on the 'Theory of Lightning Conductors,' which you have kindly sent me.

"I have only had time to glance rapidly over the Paper, but intend to give it more serious attention as soon as time permits.



I noticed a typographical error, as regards the date of Prof. Guillemin's Paper in *Comptes Rendus*. Page 225, 8th line, says see *Comptes Rendus*, 1886; this should have been 1866.

"In your experiment of the recoil kick, page 226, you say, 'The jar discharges at A in the ordinary way, and simultaneously a longer spark is observed to pass at B, of two long leads.' This quite agrees with many of my experiments, only I have always regarded this as Faraday's extra current, and that the longer spark at B was *not simultaneous* with A, but later; due, in fact, to the extra current produced by the *previous* passage of the spark at A. And I think you admit this in your following paragraphs.



"My experiments on the extra current had, however, a different object, and hence a difference in the result. Thus:—In place of your Leyden jar I used a coil and a 1-cell Daniell battery, and I used a special thermopile of my own at B, to observe the amount of heat produced by the passage of a spark at B:—

"1st. No spark occurred on closing the circuit at A, but on opening A the extra current from the coil would rush through B, giving, of course, with a coil a strong spark.

"2nd. If we suppress the coil we still have a spark at B on opening A. In fact, it is impossible to close the battery circuit with the shortest possible connections, say, 1 centimetre, but

Digitized by Google

that the extra current on opening rushes through B, giving strong measurable results.

"I take it for granted that this is well known, theoretically since Faraday. But here the effect on B is not *simultaneous* with the closing of the circuit, but an after effect or extra current, the result of a previous passage of a current through the circuit A; and this makes me ask if your spark at B can possibly be *simultaneous* with that of A?

"No doubt when I read your remarkably interesting Paper with greater care I shall seize better your true meaning.

"I regret that I shall be unable to visit Bath and take part in the proposed discussion on Lightning Conductors, but as the subject is one of great interest, I hope next winter you will bring the subject forward again by a Paper to the Society of Telegraph-Engineers, for which I am sure the Council and Members would be most grateful.

"With thanks and best wishes.—Sincerely yours,

"D. E. HUGHES.

"108, Great Portland-street, W., Sept. 5th, 1888."

OVERHEAD AND UNDERGROUND WIRES IN NEW YORK *

BY W. S. WHEELER.

In 1885 the Legislature of the State of New York enacted a law providing for the establishment and organisation of a commission to provide a plan by which electrical conductors in the cities of New York and Brooklyn could be placed underground without interfering with the efficiency of the electrical service.

The results of the investigations of the commission were summed up in their second report, dated June 30th, 1886, as follows:—

The principal systems of electrical subways may be divided, first, as to their material composition, and second, as to their mechanical construction, and the manner in which the wires are placed in them.

As to the material composition, subways are:—

1. Of insulating material, such as wood, glass, concrete, &c.
2. Of conducting material, such as iron.

As to mechanical construction, subways are generally speaking:—

1. Tunnel systems.
2. "Drawing in" systems.
3. Solid systems.
4. "Dropping in" systems.
5. Combined systems.

Tunnel systems, or those where space is provided underground sufficient to allow the passage to and fro of men who place the wires within the subway, could be recommended, were unlimited time and money at the disposal of the commission; but the expense of such a system and the crying need of immediate action preclude the adoption of such a plan. If ever underground railroads become a feature of our city transportation, then, perhaps, the tunnel can be used for some of the future trunk line cables.

In Paris, where the foundations of the city are honeycombed in all directions by large sewers, such a plan is practicable and admirable, but not to be thought of in New York.

Drawing in systems, or those where manholes are provided in the streets, connected by tubes or pipes, through which the wires can be drawn, are next in prominence and convenience to tunnel systems.

In Chicago there were seen in successful operation nearly twenty miles of conduits of the "drawing in and out" pattern of various materials, containing all kinds of wires, as follows:—

Eight miles of the Dorsett system of concrete conduit divided into ducts, and containing in the separate ducts wires of the city telephone, telegraph, fire service, and electric light wires, and wires of different telegraph companies.

Four miles of the Johnstone system of iron conduit divided by metal shelves, and carrying the wires of the Postal Telegraph Company.

One mile of 3in. iron pipes, four in number, carrying the wires of the Western Union Telegraph Company.

Three miles of iron pipes, carrying the wires of the Bankers' and Merchants' Telegraph Company.

In Philadelphia a comprehensive "drawing-in" system of iron was seen, containing electric light and telephone and telegraph wires.

In Boston some two miles of such "drawing-in" iron systems are in operation.

In London 9,000 miles of wire are underground, bunched into cables and drawn into 3in. iron pipes.

Solid systems, or those where wires are permanently embedded in insulating material, and incapable of being reached except by tearing up the streets and the insulation, have been found to work with more or less success. The Commissioners saw several miles of this conduit in successful operation in Chicago by the Telephone Company there, where wires were buried in an asphalte or coal tar cement, laid in a wooden trough.

Several miles of similar conduit are in use in Washington for electric lighting, and there are other instances of the successful operation of this description of conduit.

In this city of New York there are several systems in use underground, each more or less satisfactory to those employing it.

A prominent example is the Brooks system used by the Metropolitan Telephone and Telegraph Company. It consists of an iron tube in which cotton-wrapped wires are drawn, and the tube filled with oil, the oil acting as an insulating medium. It is kept at a desired pressure—the tubes constantly full by means of a standpipe. They use a 2½-inch iron pipe, and the system is cheap, costing less than 11dols. per mile of wire, because into such a pipe they can draw 300 telephone wires. Wires for telephone purposes, and those used in the American District and other call boxes, are of a very light intensity, and do not need as heavy insulation as do all other kinds. This system is claimed to give perfect satisfaction for telephone conductors.

The Western Union Telegraph Company has many wires already down in this city, laid in 3-inch iron pipes, into which they draw cables manufactured from okonite or kerite insulation. These pipes are lead-jointed, are laid in Broadway, and have manholes occasionally for taking out the wire.

To sum up as to the form of subway, and the manner in which the wires are to be placed in it:

We are convinced that from the standpoint of an electrician simply it may be said, that almost any plan or system can be made work, from a single lead-covered wire laid directly in the earth to a great tunnel upon whose walls the insulated conductors can be hung. Within certain broad limits any system is electrically practicable; retardation and induction can be overcome. It is only when we face in this city the mechanical, engineering and chemical questions of interference with water-pipes, gas-pipes, and sewer-pipes, of obstructions from vaults, or danger from steam-pipes, of the action of sewer and illuminating gas, that the necessity for careful discrimination presents itself.

Leaving out of consideration all tunnel systems as too expensive, we must also discard any system which calls for the simple laying of insulated cables in the earth. They would not stand the chemical action of the gases and acids; the streets would be continually torn up for new connections and repairs. We are thus shut up to the question of electric subways or conduits, in which the wires or cables, insulated or otherwise, must be placed, and which once laid down should meet all the demands of the present and near future.

Of conduits it may be safely predicted that, so far as the experience of this and other cities is a test, some form or other of a "drawing-in" system is most convenient. The life of the best cable is by no means satisfactorily decided, and, of any particular cable, to predict how long it would last would be purely speculative. Of wires not contained in cables it may be said that they are equally more uncertain in their length of life and usefulness. At all events, for purposes of distribution it is desirable that the wires should be easily approached at frequent intervals, and the Commission cannot countenance any plan that looks to the disturbance of pavements more than is absolutely necessary.

It may be that through lines of wire could be better protected laid in permanent beds of insulating material; but a "drawing-in" conduit system allows space to be provided for new wires without the frequent tearing up of pavements.

The Commission can therefore give their approval to a "drawing-in" system with frequent manholes, as the general form of subway best adapted to meet the requirements of the electrical service of the present.

Up to this time it was the general impression, which had not been contradicted by experience, because there was none, that the conduits must be built of a non-conducting substance, and not of metal, because the latter would be liable to chafe through the insulation on the wire and cause a ground, and because the companies using the more delicate currents—particularly the telephone company—declared positively that the presence of the large mass of surrounding metal would interfere by induction with the working of their wires.

The best known plan at this time for building ducts of insulating material, and without the use of metallic tubes, was the Dorsett system, which had been laid to some extent in Chicago.

This consists of a bundle of parallel tubular ducts about two and a-half inches in diameter, built of blocks formed of a combination of coal tar, pitch, and fine gravel, cast with tubular openings running through them from end to end. These blocks were placed together, end to end, with the holes in line so as to form continuous tubes or passages, and were cemented together by pouring a mastic

* Abstract of a Paper read before the National Electric Light Association at New York.

Digitized by Google

softer than was used in making the blocks, into the cracks between them. The blocks were made to adhere to this by warming their ends with hot irons and allowing them to cool after this mastic is poured in. To prevent the melted mastic from closing the ends of the passage, tubular pieces of metal or paper were inserted in the ducts at the ends of the blocks, making a sort of internal sleeve coupling. The conduits so formed terminate in brick manholes at the street crossings.

The objections to this material, as it was afterwards found, are that it is brittle, porous, requires care in laying, and, having no elasticity, cracks with changes of temperature, so that it is not likely to be made water-tight with average workmanship.

A conduit was laid in New York upon this plan on Sixth-avenue from Twenty-third to Fifty-eighth streets, a distance of 1·6 mile. And the objections were then found, as far as arc circuits were concerned, that its numerous joints were liable to open, and it might leak as mentioned above.

The next plan proposed for New York was to use a similar mixture without requiring it to be made so hard, with the object of preventing its cracking, and to preserve the openings or ducts by casting this bituminous mastic or mixture of bitumen and sand around long pasteboard tubes. But no tubes could be found which would not absorb moisture, and the heat of the mastic caused the ones tried to swell up and disintegrate. The manufacturers of indurated fibre wares were confident that satisfactory tubes could be produced, but it required special machinery and a long time for experiments. Tin and sheet iron linings were then suggested, but objected to, on account of the difficulty of making good joints. Zinc, however, was considered unobjectionable, and an experimental tube of the Averil system, consisting of soldered zinc tubes in bituminous mastic, was laid in the yard of one of the manufacturers, but it was found that the heat of the mastic melted the solder of the tubes. This difficulty was met by substituting a lap or fold over seam, and then it was found that the heat of the mastic also affected the nature of the zinc, impairing its durability. On account of the certainty of the zinc tubing rusting and finally crumbling away, it was next thought best to insure the permanence of the bore of the ducts by substituting for the soft mastic some substance which would set, after being poured in, and become hard and durable. For this purpose, a hydraulic cement concrete filling was substituted for the mastic. And then a line was laid in Fifty-eighth-street. In laying, the thin zinc tubing was found very frail, liable to be dented in handling, and therefore undesirable. But the idea of the concrete was that it would maintain a hard, solid, smooth bore even after the thin sheet metal lining had rusted out.

After a thorough investigation and discussion of all the different materials, and the advantages and disadvantages of each, it was finally concluded that a conduit or subway for electrical conductors underground is merely a mechanical protection for the wires to be placed therein, and should afford the very best protection possible to be procured, while the electrical protection or insulation may be safely left to the manufacturers of cables and wires to be placed in subways.

It was decided that the use of metallic tubes would not seriously interfere, by induction, with the working of the wires, and were to be preferred, because the continuous conducting shield so formed will carry off any escaping current, and prevent damage to other cables. Accordingly, conduits of iron gas pipe embedded in concrete were put down, and these seem to be about the best kind so far constructed. They are best, first, because there are plenty of workmen who understand gas pipe fitting and laying concrete, and because they are durable and entirely non-combustible. The purpose of the cement is to prevent the iron from rusting, which it does very effectually. If in time the pipes are destroyed by rusting from the inside, the solid hydraulic cement concrete will remain, furnishing a permanent duct with a hard, smooth bore.

The manholes used in connection with these various kinds of ducts have nearly all been built of brick laid in hydraulic cement, and capped with an iron casting to form a seat for the water-tight lid. The lids are usually bolted down upon a rubber gasket, but unlike the Edison manholes, instead of being held by a single thrusting screw which passes through a crossbar, presses down upon the centre of the cover. Some of the lids have been made funnel-shaped, so as to cause water to drain away from the edge and collect in the centre. By this means the liability to leakage at the gasket is diminished, because there is less chance of water standing over the joint. The facility of opening the manholes afforded by this method of fastening the lid with a single screw is of great value in reducing the labour and time required to open and close a line of conduit when laying a wire, and is a material advance in the solution of the problem.

In regard to moisture in the conduits. In the iron tube plan, which is the best, there is, of course, no leakage, because the tubes themselves are water-tight, could even be made air-tight, and because they are covered with cement, which is in itself water-tight. The manholes are made of water-tight materials, and there should be no leakage under the lid. Lookers-on find that a great many of the manholes have a great deal of water standing in them; this is simply because the lids are not fastened down, but simply laid in place by the builder, often without any gasket, and the manholes fill with rain and stay full until cleaned out for use. When cleaned and closed properly they appear not to receive any water by leakage. To satisfy myself of this I had an ordinary brick manhole which had been thoroughly cleaned and dried by letting the sun shine in, on a bright day, marked on the inside with lime all the way round under the cover and then closed. This marking was to show whether any water came through the joint of the cover, in which case it would have run down over the lime mark and discoloured it, or whether it soaked in through the bottom or sides. But after a rainfall sufficiently heavy to test the leakage, the hole was opened and found perfectly dry and the lime undisturbed. This proved that there was neither leakage through the brickwork nor under the cover.

There is, however, another source of moisture which is hard to overcome, the condensation of vapour from the air which the manhole and ducts contain. Every time a hole is opened it refills itself with warm air, containing more moisture than it can keep when cooled down to the temperature of the masonry; consequently, as soon as the lid is screwed down this fresh air deposits a dew on the inside of the manhole. As it is impossible to open and dry out a manhole without putting in new air, which will condense in turn, no amount of cleaning will overcome this difficulty. The presence of moisture tends to corrode exposed wires, and therefore the question of whether it is better to protect the splices and make the insulation of the wires so that they will not be injured by this moisture, or to dry out the entire system of conduits by a system of ventilation, is unsettled. But this question, fortunately, is one of minor importance.

Having decided the question of the kind of conduit to use, the commission proceeded to have subways constructed according to these plans. It was decided best, as a matter of expediency and to prevent accident, that electric light subways should be distinct from those intended for telephone and telegraph service, and it has, therefore, been the practice of the authorities in New York to build subways for one class of conductors upon one side of the street, and reserve the other side for those of other service.

The telephone people were the first to realise that underground wires were sure to be ultimately a success. Their business had grown enormously, they had reached about the capacity of their pole lines, and it was not easy to get the use of additional streets, because the streets were crowded with wires, both their own and those of other companies. It was found that the growth of the telephone business was practically put an end to by the fact that no more room could be found in which to string wires. House-owners were charging a rental of one dollar per wire per year, which, in some cases, amounted to a very large rental in the case of a building, and the telephone people had reached the point of refusing subscribers. They came forward, and were the first to declare for underground wires.

After some resistance, the telegraph and electric light companies have come to the conclusion that it is as well for them to comply with the demands of the public and place the bulk of their conductors underground. And, as a matter of fact, in the city of New York to-day there is but one single company out of the large number doing business here which refuses absolutely to comply with the provisions of the Subway Acts, and nine-tenths of the opposition and outcry have been caused by this company.

At the present time the total construction of single duct in the city of New York amounts to 420 miles. In these subways there are already in operation some 4,000 miles of telephone and telegraph wires, and some hundreds of miles of incandescent electric light conductors. Cables for arc lighting are to be drawn in on Broadway from Fourteenth to Thirty-fourth streets by the Brush Electric Illuminating Company within the present week.

PATENT RECORD.

APPLICATIONS FOR PATENTS.

NOTE.—*The undermentioned applications are not open to public inspection until after the acceptance of the complete specification. The names within parentheses are those of communicators of inventions.*

COMPANIES' MEETINGS & REPORTS.

Direct Spanish Telegraph Company (Limited).

Report and accounts of the Directors for the half year ended 30th June last, to be presented at the general meeting of shareholders, to be held at Winchester House, 50, Old Broad-street, London, E.C., on Tuesday, 2nd October, 1888, at twelve o'clock :—

1. The accounts for the half year ended 30th June show, after providing for debenture interest, a balance to the credit of profit and loss of £5,529. 19s. 4d.

2. The traffic receipts show an increase of £851. 2s. 6d. as compared with the corresponding half year of 1887.

3. Both the Company's cables and the land lines in connection with them have continued in good working order throughout the half year.

4. The special wire erected by the Spanish Government between Bilbao and Madrid, referred to in the last report, has now been put at the Company's disposal for the exclusive use of their Bilbao cable traffic.

5. In consequence of the fleets of several nations assembling outside Barcelona, on the occasion of the opening of the Universal Exhibition in that city by the Queen of Spain in May last, it was necessary to take special precautions for the protection of the shore end of the cable. The cost thus incurred, as well as that of the new cable house at Barcelona, is being charged to revenue.

6. After putting the sum of £2,500 of the balance of profit and loss to the reserve fund, which now amounts to £11,028. 5s. 7d., there remains £3,029. 19s. 4d. Out of this amount the Directors recommend the payment of the dividend at the rate of 10 per cent. per annum on the Preference Shares, and a dividend at the rate of 5 per cent. per annum (free of income tax) upon the Ordinary Shares, carrying forward £274. 7s. 4d. to next account.

The dividend warrants will be issued on 3rd October.

The Maxim-Weston Electric Company.

We give below the text of the report of the Directors to be submitted to an extraordinary general meeting of the shareholders on October 3rd, together with letters from Mr. Watt and the late accountants to a financial contemporary :—

The Directors take the earliest opportunity of laying before the shareholders a statement of the position of the Company's affairs. Immediately after the election of the new Directors on 19th July last, the Board met at the Company's Office in Queen Victoria-street, and Mr. John Marks was elected Chairman. No assistance was rendered to the new Directors by the Managing Director, Mr. Hugh Watt, or by any of the officers of the Company, and it soon became clear that it was quite impossible to carry on the business of the Company with the then existing officials. The Directors were on several occasions unable to obtain admittance to the Company's Offices, Mr. Wright declined to fulfil his duties as secretary, and the clerks, though paid their salaries out of the funds of the Company, declared they were in the service of Messrs. Hugh Watt and Co. On the 3rd of August last the Board decided to have the affairs of the Company investigated, and the principal books were accordingly sent to the office of Messrs. Boyce and Ramsay, Chartered Accountants, 2, Metal Exchange-buildings, with instructions to investigate and report to the Board. On the same date Mr. Watt caused the books and papers remaining at the office to be sent to the Company's works, where they were deposited in confusion amongst the machinery. On the following day, August 4th, Mr. Watt handed in his resignation, which was immediately and unanimously accepted. Mr. Wright, having refused to obey instructions, was informed that his services as secretary would no longer be required. Mr. Samuel J. Boyce was then appointed secretary of the Company, and in compliance with Mr. Watt's request that the offices should be at once vacated, the registered offices were transferred to No. 2, Metal Exchange-buildings, Gracechurch-street, E.C. The Directors now feel that by the exercise of energy and patience the Company's affairs have been extricated from the confusion in which they found them, and they are enabled to lay before the shareholders a fairly accurate statement of the position of the Company. The Directors are also pleased to state that they have already effected a reduction in management expenses of over £1,000 a year. Upon the change of management, instructions were given to the Works Manager to stop all unnecessary and useless expenditure at the works, and to take the stock at cost price, and to give an approximate value of the plant and machinery. This has been completed, and the report of Messrs. Boyce and Ramsay is now in the hands of the Directors. By this report it will be seen that the assets were stated in the balance-sheet, at 31st December, 1887, at about £17,445 in excess of their value, and that the results of the trading have not been truly stated in the past. The Directors, after examination, have verified the statements contained in Messrs Boyce and Ramsay's report, and it is for the shareholders to look the facts fairly in the face and come to a speedy decision as to the future of the Company. The Directors have already made a claim upon Mr. Watt for the repayment of various sums to which they consider the Company are entitled. Notwithstanding the present unsatisfactory position of the Company, the Directors are strongly of opinion that, with honest and attentive management, a good and profitable business may be carried on. The Company possesses valuable patents, and good plant and machinery adapted to the requirements of the business, a state of things only to be attained by years of experience and the expenditure of a large capital. They also have a large and valuable stock. Installations have been erected in various parts of the country, and numerous applications are being made for estimates from all parts of the Kingdom, showing that the Company's system is appreciated. Under these circumstances, the Directors earnestly urge upon the shareholders the desirability of providing sufficient working capital for carrying on the business, as by that means alone can a new and prosperous business be developed. The Directors therefore recommend that the capital of the Company should be reduced by the cancellation of 2s. 6d. per share upon the existing 5s. shares, and that to provide working capital the 188,000 shares remaining unissued should be issued at 2s. 6d. each. With this object in view, the Directors have convened an extraordinary general meeting of the shareholders, to be held on Wednesday, the 3rd October, 1888, to which the necessary propositions will be submitted. They propose to issue the new shares of 2s. 6d. each immediately after the confirmation of the proposed resolutions, payable—sixpence on application, sixpence on allotment, and the remainder by instalments of sixpence each at intervals of three, six and nine months. It is hoped that as many shareholders as possible will attend the meeting, in order that they may have an opportunity of conferring personally with the Directors, but those who are unable to attend are invited to fill up and return the accompanying form of proxy and also the request for an allotment of the new shares.

TO THE EDITOR OF THE FINANCIAL NEWS.

SIR: You published in your issue of this morning, under this heading, a paragraph "Accountants Explain how the Results of Past Trading have not been Truly Stated." As we are the accountants referred to, will you allow us to say that the explanation you print as emanating from us is not accurate, and does not coincide in many ways with the report made by us to the directors? As you can only have been furnished with information by a shareholder, you no doubt have the means at your command for correcting the errors appearing in your report.—We are, Sir, yours, &c.,

BOYCE AND RAMSAY.

2, Metal Exchange-buildings, 95 and 96, Gracechurch-street, E.C., September 25, 1888.

SIR: The attention of our client, Mr. Hugh Watt, M.P., has been called to the article in your paper of this date, giving extracts from the statement of the position of the company's affairs issued to the shareholders by the directors, and he has requested us to state that such statement, as far as it relates to him, is altogether inaccurate. But as the matters in difference between our client and the company are about becoming the subject of proceedings in a court of law, we refrain from going into the same at present. Our client is, however, most desirous at once to contradict the statements made by the directors. We shall therefore be glad if you will kindly give insertion to this letter.—We are, Sir, yours, &c., MICHAEL ABRAHAMS, SONS AND CO.

London, September 25th, 1888.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended September 21, 1888, amounted to £4,956.

DIRECT SPANISH TELEGRAPH COMPANY.—The Board of this company have, upon the audited accounts for the half-year ended June 30 last being submitted to them, decided to recommend the payment of the dividend at the rate of 10 per cent. per annum on the Preference shares, and a dividend at the rate of 5 per cent. per annum upon the Ordinary shares, free of income-tax.

EASTERN TELEGRAPH COMPANY.—This company announce the payment on the 15th October next of a dividend of 3s. per share on the Preference shares of the company, less income-tax, for the quarter ending 30th September, and an interim dividend of 2s. 6d. per share on the Ordinary shares, free of income-tax, in respect of profits for the quarter ended 30th June last. The register of transfers will be closed from the 8th to 15th October, both days inclusive.

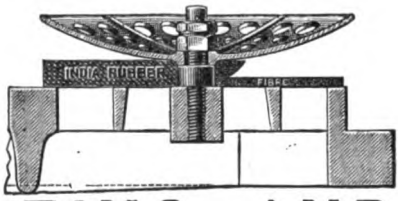
THE EASTERN EXTENSION, AUSTRALASIA AND CHINA TELEGRAPH COMPANY.—The accounts of this company for the half-year ended June 30th last show, subject to audit, a balance of profit of £79,165, after the payment of the interim dividend for the first quarter, and charging the cost of the completion of the Singapore-Saigon cable renewal, amounting to £15,401. The directors have declared a dividend for the quarter ended June 30th of 2s. 6d. per share, free of income-tax, payable on October 16th prox., and have decided to carry the balance of £47,903 forward to the next account.

TELEPHONE COMPANY OF AUSTRIA.—The directors of this company have declared an interim dividend at the rate of 6 per cent. per annum on the Preference shares of the company for the six months ending 30th instant.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended September 21st, 1888, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company (Limited), were £4,065.

NEW VALVE

No Rubber, Percha, or Leather.



One-half the price of Rubber or Metal.

FOR CIRCULATING AND AIR PUMPS.

Unaffected by any Lubricating Oils. Does not Expand in diameter. Feed Water may be worked at any temperature. Suitable for any shaped guards. Only one quality manufactured.

"12, John-street, Sunderland, 26th Sept., 1885.

"DEAR SIRS,—In reply to your letter of the 25th inst., the Valves I got from you have done their work well, and ARE AN UNQUALIFIED SUCCESS. I will continue to get them from you as required.—Yours faithfully, JAMES WESTOLL."

For further Testimony and Prices, apply to **MOSSES & MITCHELL, 68-71, Chiswell Street, London.**

The Right Hon. LORD SUDELEY, P.C., F.R.S.
LEOPOLD SALOMONS, Esq.
JOHN C. SALT, Esq.
C. A. WHITMORE, Esq., M.P.

Offices—**WINCHESTER HOUSE, OLD BROAD STREET. LONDON, E.C.**

The principal objects of the Corporation are :—

1. Performing the duties of Trustee, Executor and Administrator.
2. The Insurance of Bonds, Shares and all other Securities lodged with the Corporation against risks of all kinds.
3. The Issue of Warrants and Certificates against Securities deposited, and making and procuring advances on such Warrants.

The Office of Trustee or Executor is to private persons usually a thankless post, involving much anxiety, time and money, and frequently leads to serious actual loss; whilst death, illness and change of residence necessitate frequent fresh appointments, and consequent expense to the parties interested. The Corporation undertakes all the duties of Executor, Trustee or Administrator for reasonable remuneration proportioned to the work and responsibility in each case.

The Corporation insures existing Trustees and Executors against all risks attending those positions, where the business is conducted by the Solicitors to their Trusts under the supervision of the Corporation, it not being the desire of the Corporation to interfere in any way with the duties of the family solicitor.

The Corporation acts as Trustees for the Debenture Holders in Public Companies.

For terms, &c., application should be made to the General Manager at the Company's Office.

GEORGE PEARSON *General Manager and Secretary.*

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL SCIENCE, INDUSTRY AND ENGINEERING.

No. 542.—Vol. XXI. FRIDAY, OCTOBER 5, 1888. Price 4d.

NOTES.

During one of the discussions in Section A at the late meeting of the British Association it was recognised that the question of the magnetisation of steel by the oscillatory discharge of a Leyden jar required elucidation. We print this week, however, a letter addressed by Prof. Ewing to Dr. Oliver Lodge, in which the question receives a very simple and complete explanation. We may add that we have in our possession some MSS. of earlier date by Dr. J. Fleming, in which the same problem is considered, and practically the same conclusion is arrived at. This Paper we shall publish in due course.

Ever since the shareholders of the Maxim-Weston Electric Lighting Company received their dividends of 7½ and 5 per cent., in 1886 and 1887 respectively, we have felt curious to know how it was done. That an explanation would some day be given we were well assured, and at length our curiosity has been gratified. From the report of the accountants who have just concluded an examination of the Company's affairs on behalf of the newly elected Board, we gather that the process was substantially as follows: In 1885 a "reserve fund" amounting to £3,606 was created, apparently by adding together the items for premium on new shares issued and the balance left on the books after the reduction of the capital which had just been effected. In the following year this fund was entirely absorbed by the amounts which were written off from the various debts owing to the Company, no less than £2,074 being written off from the "agency" account alone. The "reserve fund" therefore disappeared from the balance-sheet of 1886, and being utilised for the reduction of book debts a large portion of the total revenue appeared as net profit, enabling a dividend of 7½ per cent. to be declared. In 1887 no provision whatever was made for loss on book debts, and nothing was written off the patent account, whilst, according to a subsequent valuation, the value of the stock, plant, furniture and fittings, &c., was over-estimated to the extent of about £8,700. Under these circumstances a dividend of 5 per cent. was declared. It must, of course, be recollected that this is to some extent an *ex parte* statement, and it is possible that the ex-directors may be able by-and-bye to put a different face upon the affair.

Unfortunately, however, the payment of a dividend—whether fairly earned or otherwise—is by no means the most serious grievance of which the shareholders complain. At the extraordinary general meeting which was held on Wednesday last the present chairman of the company laid before the shareholders a series of remarkable allegations reflecting upon the conduct of his predecessor. Amongst the least notable of these was the statement that, although Mr. Hugh Watt received a salary of £1,200 per annum as managing director—in addition to a commission of 5 per cent. on the sales—yet the amount of time and attention which he actually gave to the company's affairs was not sufficient to reduce the rate of remuneration below the handsome figure of £20 per hour. Altogether, it would be difficult to imagine a more utterly unsatisfactory state of things than that which has long existed, both as regards the external and (as it now seems) the internal affairs of this company. Its action in connection with the proposals for lighting the City called forth our most vigorous protests at the time; and this is not the only instance in which we have had reason to believe that its proceedings have been seriously detrimental to the interests of electric lighting.

As to the still more serious and explicit charges which the new Board has not hesitated to bring against Mr. Watt, this is not the proper time for us to comment on them. It is scarcely to be supposed that Mr. Watt will allow judgment to be delivered against him by default, and we therefore anticipate a searching investigation into the whole history of his connection with this unfortunate Company.

According to the *Indian Engineer*, Mr. W. F. Melhuish, of the Indian Telegraph Department, has effected an improvement in duplex working of some considerable value. In the ordinary methods of working duplex the capacity of the wire is only increased so long as no correction is required by either of the receiving clerks; but directly a word misses fire the remaining pair of signallers are reduced to enforced idleness whilst the correction is being made. The actual value of duplexing a line, therefore, depends very largely upon the skill and discipline of the staff. Mr. Melhuish's invention is intended to obviate this difficulty, and to enable either pair of clerks to send or receive at will. It seems by no means impossible that, with a reasonable amount of ingenuity, something of the kind may be accomplished; but we should prefer to hear a little more about the method employed before we express any decided opinion on the subject. The information at present given by our contemporary extends only to the fact that it involves "an additional instrument or two, and a rearrange-

Digitized by Google

ment of batteries." This is good, but perhaps not quite good enough.

We print elsewhere the clauses of a Bill which will be introduced in the next session of Parliament, and is entitled "An Act to Amend the Patents, Designs, and Trade Marks Act." The object aimed at is to secure the registration of patent agents, and to prevent any unauthorised person from habitually acting in that capacity; the Bill is not, however, intended to prevent any individual inventor from drawing his own specification. On the whole, we are scarcely inclined to agree with our contemporary the *Engineer*, which has entered a vigorous protest against its passage into law. Our contemporary draws a moving picture of the hardship which would be inflicted upon a "poor inventor" if he were debarred from obtaining the friendly assistance of some more experienced penman in drawing up his specification. This argument appears to us to be singularly weak. There is nothing in the Bill to prevent anyone on occasion from preparing another man's specification either gratuitously or otherwise. It is merely stipulated that nobody shall, in any sense of the term, "describe himself" as a patent agent unless duly registered by the Board of Trade. There can be very little doubt in the mind of anyone that under the present *régime* a considerable number of men do so describe themselves whose knowledge of patent law or of any technical subject is entirely inadequate to the duties which they assume. So long as anybody is entitled to take a room in Chancery-lane and stick up "Patent Agent" (or more often "Patent Office") over his doorway this will necessarily continue to be the case. For our own part, although we foresee some difficulty in its practical application, we are quite in sympathy with the Institute of Patent Agents in their desire to impart a sense of honour and dignity to their profession from which it is at present almost entirely excluded.

The subject is one which it is impossible to discuss in all its bearings within the limits of a note, but we may just indicate that our own feeling in the matter is that the work of the patent agent can only be done effectually by being specialised to a far greater extent than it is at present. We should like to see a considerable increase in the number of agents who devote their attention especially to a limited range of subjects. The services of an agent who can acquire and deserve a reputation for being a thorough master of the technical and patent office literature of any particular department will always be worth paying for. In our own profession there are already a limited number of agents who make electricity a speciality, and this we regard with satisfaction as a step in the right direction. Returning to the general question of registration, and judging from the correspondence which has appeared in the columns of our engineering comtemporary, it would seem that a strong feeling against the Bill exists in some quarters. Not much time is now left for the expression of public opinion, and if our readers hold any decided views for or against the measure we shall be very pleased to hear from them on the subject

It is certainly a very singular fact that up to the present time so very little use has been made of the electric motor on ship-board. Considering the fact that all steamships of any importance, whether in the navy or in the merchant service, are now invariably provided with an electric light equipment, and considering, moreover, that on board a modern man-of-war we sometimes meet with upwards of a score of separate steam-engines, it is simply astonishing that electric motors are not already in universal use. We publish elsewhere an extract from a very able Paper, written by Lieut. Murdock, of the United States Navy, in which this question is dealt with, and some further comment on the subject will also be found in our American Notes. We believe that in the English Navy certain experiments have already been tried in this direction, but with what result we do not know, though certainly little or nothing has yet been done. If the experiments were not considered a success we have no hesitation in saying that this must have been due to faulty design or manipulation, and we look forward with confidence to the superannuation of the majority of the supplementary steam-engines now employed, and to the advent of the electric-motor as an indispensable auxiliary for the distribution of motive-power on ship-board.

We learn with satisfaction that an opportunity will shortly be afforded of testing the practicability of the series system of electric traction in this country upon a working scale. The Series Traction Syndicate are now engaged upon the construction of a line at Gravesend some three miles in length, with which rapid progress is being made. The system adopted is, as regards its leading features, identical with that known in America under the name of Short-Nesmith, and which was described and illustrated in our issue of April 29, 1887, p. 549; but we understand that the Syndicate hold several other patents relating to the question of series traction, including the important telpherage patents of Fleeming Jenkin and Ayrton and Perry, and improvements in detail will no doubt have been effected. If the difficulty of the somewhat numerous contact points can be dealt with successfully, we feel confident that this system will have a future of great importance.

In our issue of September 14th we published an abstract of a Paper by Dr. Van der Weyde, containing a very severe attack upon Mr. Harold Brown in connection with his recent experiments on the effects of alternating and continuous currents on dogs. Our readers will, perhaps, recollect that the learned doctor was of opinion—for reasons which were duly set forth in the Paper—that the E.M.F. of the alternating current which killed the dogs could not have been much less than 80,000 volts, instead of 300 volts, as Mr. Brown supposed. He also accounted for Mr. Brown's error by the assertion that the voltmeter was connected in series with the ammeter. Our readers may easily have gathered, from the comments which we made at the time, that we did not attach a very high value to Dr. Van der Weyde's opinions, or to the calculations on which they were based; on the other hand, the positive statements as to the error in the connections seemed worthy of attention, more especially as the results of the experiments were of so

Digitized by Google

unexpected a character. In the current number of the New York *Electrical Review* we find, however, a letter from Mr. A. E. KENNELLY, which completely rehabilitates Mr. BROWN'S position, and in our estimation invests the experiments with an importance which they did not before possess. Mr. KENNELLY takes some trouble to show that Dr. WEYDE'S figures are fallacious, and that his ideas as to ammeters and voltmeters in general are erratic. With this, however, we need not concern ourselves further. As to the alleged mistakes in the E.M.F., it is sufficient to be assured that Mr. KENNELLY himself assumed the responsibility of measuring the voltage—a fact which had not before transpired.

MR. KENNELLY has also carried out a series of experiments of the same character at the Edison laboratory, with results which are briefly summarised as follows:—

> "For contacts of duration from 30 to 60 seconds, the lowest continuous-current voltage that has been fatal has been 276 in one case and 400 in another. The lowest alternating voltage that has been fatal in that time is 140 (applied after a continuous shock).
>
> "For contacts of between 15 and 30 seconds' duration, the lowest fatal alternating voltage has been 176. No continuous case furnished. For contacts of from 3 to 15 seconds' duration the lowest fatal continuous voltage has been 590. The lowest fatal alternating voltage 158.
>
> "For contacts of less than three seconds the lowest fatal continuous voltage has been 800. The lowest fatal alternating voltage 418.
>
> "It has also been observed that there is very much less struggling of the animal under the influence of an alternating current, even when not attended with fatal results, than appears with the direct current, and when the shock has not been fatal the effect of the alternating current has been to produce greater nervous depression than has been visible with the continuous current."

We therefore take it to have been conclusively proved that an alternating current is fatal *to a dog* at a very much lower potential than a continuous current. At the same time, we think that, with reference to human beings, the weight of evidence is at present at least slightly in favour of the reverse supposition.

Lighting of the Avenue Theatre.—The Avenue Theatre is now lit by electric light, over 1,000 lamps being employed.

Monte Carlo.—The *World* says that the electric light will supersede gas at Monte Carlo this winter, both in the public thoroughfares and inside the Casino.

City and Guilds of London Institute Old Students' Association.—The fourth annual dinner of the above association will be held at the Holborn Restaurant, on Saturday, October 13th, at 7 p.m.

Suakin.—The Eastern Telegraph Company's steamship "John Pender" has recently been rendering good service at Suakin by throwing the light of her electric projector on the nocturnal proceedings of the Arabs.

West Hartlepool.—Messrs. W. Gray and Co. have recently acquired a new ship building yard in West Hartlepool, having an area of about four acres. The yard is to be lighted by twenty-eight 2,000 candle-power Brush lamps.

Cowpen.—A special meeting of the Cowpen Local Board was held on Monday last to consider the tenders which have been sent in for lighting the district with electricity. We understand that it was decided to accept one of the tenders.

Wellington (New Zealand).—The City Council of Wellington have completed arrangements for lighting the city with the electric light, and a contract is to be signed shortly. It is expected that the greater portion of the city will be lit by November 30.

Hapton.—The streets of Hapton, near Burnley, have recently been experimentally lighted by 50 candle-power Edison-Swan incandescent lamps. The experiments, it is said, have been most successful, and arrangements are in progress with the local board with the view of making the system permanent.

Eastbourne.—The Eastbourne Electric Light Company has now offered to light the Esplanade for £32. 10s. per lamp per annum, but the Lighting Committee is still unable to see its way to pay more than £30. Now that the difference has been reduced to such moderate dimensions, it will be a great pity if the lighting is abandoned.

London Society for the Extension of University Teaching.—At the Chelsea Town Hall Mr. W. Lant Carpenter, B.A., B.Sc., will give ten lectures on "Electricity in the Service of Man," illustrated with experiments and lantern photographs, on Fridays, at 8 p.m., commencing October 12, 1888. Single tickets for the course 4s., tickets to admit three 10s. The inaugural lecture on Friday, Oct. 12, will be free; subject, "Electrical Energy and its Uses."

The Electro-Harmonic Society.—We are happy to announce that the concerts of this society (of which there were held four in the first and five in the second series) will this season be six in number, and will take place on the last Friday evening of the months, as follows:—October 26th, 1888, smoking concert; November 30th, 1888, ladies' night; January 25th, 1889, smoking concert; February 22nd, 1889, ladies' night; March 29th, 1889, smoking concert; April 26th, 1889, smoking concert.

Electrical Engineering Diploma.—From our advertisement columns last week it will have been observed that the Glasgow and West of Scotland Technical College grant an electrical engineering diploma. The opportunities of finding employment in the Glasgow engineering works whilst studying at the Technical College, or during holidays, were never better than they are at present, for the Clyde is busier in shipbuilding, &c., than it has been for years. The engineering classes commence this week.

Lambeth Vestry.—At the last meeting of this Vestry a letter was read from Messrs. Bircham and Co., solicitors to the Metropolitan Electric Supply Company, giving notice of the intention of the company to apply to the Board of Trade under the Electric Lighting Acts, 1882 and 1888, for a license to supply electricity for lighting and other purposes within the area over which the Vestry have jurisdiction, and asking for the consent of the Vestry to the application. The application was referred to the Electric Lighting Committee.

Metropolitan Board of Works.—At a meeting of the Metropolitan Board of Works on Friday last, a letter was received from Messrs. Bircham and Co., on behalf of the Metropolitan Electric Supply Company (Limited), stating that they intended to apply to the Board of Trade, under the Electric Lighting Acts, 1882 and 1888, for a license authorising the company to supply electricity for lighting and other purposes within the area described in a plan accompanying the letter. The letter was referred to the Works Committee.

The Anglo-American Brush Corporation at Bournemouth.—Energetic measures are being taken by the Anglo-American Brush Electric Light Corporation to establish a central station at Bournemouth for the early supply of electric light to the in-

Digitized by Google

habitants of that town, and we gather that the undertaking will be pushed forward as quickly as possible. We also understand that the Brush Corporation propose to establish central stations in various provincial towns where they have for some time past been pushing the interests of the electric light.

Barnet in Darkness Again—At 10 o'clock last Friday night the electric lamps at Barnet suddenly went out, and the streets were left in darkness, the only light to be seen being that coming from the windows of hotels and private houses. The night was very dark and somewhat foggy, and the inconvenience caused to pedestrians by the sudden deprivation of light was severely felt. The origin of the mishap was not known outside the electric light works, beyond the scanty information vouchsafed by one of the contractor's *employés* that something was wrong with the engine. It was not until midnight that the light was again available.

Electricity in Collieries.—At the twenty-first annual congress of the trades unions of the United Kingdom at Bradford, Mr. Beith, of Pontypridd, read a Paper on "Electrical Power, and its Application to the Coal Industries." Mr. Beith traced the history of the gradual growth of electric traction from the days of Jacobi to the present time, when 87 per cent. of the energy given to the dynamo is returnable at the motor. Mr. Beith was of opinion that the great efficiency of direct haulage electrical plant must eventually bring it to the front, and mentioned, as an instance, the successful application of electrical power to the pumping machinery erected by Messrs. Immisch at St. John's Colliery, Normanton.

The Royal Victoria Hall.—The artisan's classes at this institution reopened on Monday, October 1st, and comprise arithmetic, physiology, physiography, shorthand, chemistry, astronomy, English literature, mechanics, machine drawing, electricity, &c., many of the classes being in connection with the Science and Art Department. On Tuesday, October 2nd, after a lecture entitled "Science in the Saucepan," by Prof. Carlson Lambert, the certificates gained by the students last session were presented by Sir P. Magnus. The lecture arrangements for the rest of the month are as follows:—October 9th, "The Largest Bridge in the World," by Prof. Kennedy; October 16th, "Some Great Cities of the World," by Mr. A. H. Gilkes; October 23rd, Mr. W. Spralling; October 30th, "Colour Sense and Colour Blindness," by Dr. Collins.

A Submarine Torpedo Boat.—The Paris correspondent of the *Daily News* says that experiments are being made on the Seine, near Issy, with an electrical submarine torpedo boat made for the Minister of the Navy, and at his own expense. The boat is constructed of sheet iron, shaped like a cigar, having a length of 4·5 metres, and a diameter of 1·6 metres. Current is generated by Schanschieff's bisulphate of mercury battery. The motor is of the Edison type. The boat can be made to dive and to take an undulating course in the water. Large scissors project from the prow, which are intended to cut torpedo wires. Compressed oxygen is stored in tubes of peculiar construction, and in sufficient quantity to make it easy to keep the boat some time under water. This model has been adopted by the Russian Navy a short time after it had been tested at Cronstadt.

The Hanover-square School of Electrical Engineering.—At this school the following gentlemen recently obtained their certificates as the result of the examination conducted by Mr. H. R. Kempe, of the Engineer-in-Chief's Office, G.P.O.:—F. Thomson, 99 per cent. of full marks; E. M. Blakely, 97 per cent.; H. F. Laughton, 87 per cent.; W. N. Legge, 86 per cent.; W. W. H. D'Aeth, 85 per cent.; H. C. Hodges, 83 per cent.; F. A. Pocklington, 82 per cent. No certificate is granted for less than 70 per cent. of full marks, and the candidates had also to satisfy Mr. W. W. Beaumont as to their knowledge of steam engineering. The scheme of instruction of the advanced class has been re-organised under the auspices of the new senior instructor, Mr. Charles Capito, M.I.M.E., &c., with the view of meeting still more completely the requirements of the profession. Some of the above gentlemen have already obtained appointments.

St. George's, Hanover-square, Vestry.—At the last meeting of this Vestry, the Clerk submitted a letter from Messrs. Deacon, Gibson, and Medcalf, on behalf of the London Electric Supply Corporation, stating that they desired to apply to the Board of Trade for a license to authorise them to supply electricity in this parish, and submitting copy of the draft license. A letter was also submitted on behalf of the Metropolitan Electric Supply Company, stating that it is intended to apply to the Board of Trade for a license to supply electricity for lighting and other purposes within the parish, and submitting form of license. The Clerk remarked that the question of electric lighting had been before the Commissioners of Works. Mr. Southon said this was a question of such a large and delicate character that he did not think they were prepared to go into it at the present moment. He proposed that the receipt of the letter be acknowledged; it would bear further consideration. The proposal was adopted.

Birmingham.—According to the *Birmingham Daily Gazette* the scheme, promoted some little time ago by Messrs. Chamberlain and Hookham, of New Bartholomew-street, for supplying the electric current to large blocks of buildings in Birmingham, not only for lighting purposes but as a motive power for machinery, is now assuming a definite shape. The supply is offered on the following basis:—There will be no maximum charge, but the actual quantity of electricity supplied will be measured by meter and charged at the rate of 8d. per unit per quarter. Consumers can have their premises wired and their electroliers supplied by any firm they may select, or the company will themselves undertake the work. The incandescent lamps will be provided and maintained by the consumer. Messrs. Chamberlain and Hookham are prepared to sell or let on hire motors varying from one man-power to 15 horse-power, but the quarterly charge for driving these motors would depend entirely on the hours they are to be used and the power transmitted to them. A very respectable list has already been secured of tradesmen and others who have expressed their intention of using the electric light in some form or another on their premises.

The Registration of Patent Agents.—The following clauses are those in the Bill entitled, "An Act to Amend the Patents, Designs, and Trade Marks Act, 1889," which refer to the registration of patent agents:—(1) After the 1st day of July, 1889, a person shall not be entitled to describe himself as a patent agent, whether by advertisement, by description on his place of business, by any document issued by him, or otherwise, unless he is registered as a patent agent in pursuance of this Act. (2) The Board of Trade shall, as soon as may be after the passing of this Act, and may from time to time, make such general rules as are, in the opinion of the Board, required for giving effect to this section, and the provisions of Section 101 of the principal Act shall apply to all rules so made as if they were made in pursuance of that section. (3) Provided that every person who proves to the satisfaction of the Board of Trade that on the 1st day of July, 1888, he had for twelve months been *bonâ fide* practising in the United Kingdom as a patent agent shall be entitled to be registered as a patent agent in pursuance of this Act. (4) If any person knowingly describes

Digitized by Google

himself as a patent agent in contravention of this section, he shall be liable on summary conviction to a fine not exceeding £20. (5) In this section "patent agent" means exclusively an agent for obtaining patents in the United Kingdom.

St. Albans.—At the last meeting of the Town Council of St. Albans Councillor Westell moved for a committee to make inquiries as to the probable cost of lighting the city by electricity. Other corporations in various parts of the country had taken over the lighting powers, and had derived considerable profit from it; but in St. Albans one gas company had a monopoly. St. Albans would be in a unique position in regard to electric lighting, because the river could be used to generate the electricity, and there could be enough power derived from the water course to provide more electricity than the city would consume. If the Council took the matter up early they might be enabled to prevent the powers from getting into the hands of monopolists.—Councillor Slade seconded the resolution. He said that the same matter was considered by the Council a few years ago, but the electric light was then in its infancy and more expensive than now. They would now find it could be supplied more cheaply than gas. It would not be wise for a progressive city like St. Albans to be behindhand in this matter. If the electric light were found by the committee to be cheaper than gas, it would be the duty of the Council to introduce it for public lighting. The inquiries should not cost any money to the ratepayers.—Councillor Murray also supported the resolution, which was agreed to.

The Lighting of the Dartmouth Training Ships.—The electric light, recently introduced on Her Majesty's naval cadet training ship "Britannia," at Dartmouth, says the *Western Morning News*, gives much satisfaction. Replacing oil lamps, it is not only a more brilliant light, but it is much cleaner and more safe. Unpleasant odours are avoided, the light is steady, less labour is required, and there is likewise a saving effected as compared with the former method of illumination. There are throughout both the "Britannia" and "Hindostan" 460 incandescent lamps, each of 16 candle-power. The machinery is located in the after end of the "Hindostan." The dynamo is one of Siemens's latest pattern, giving 400 amperes at 80 volts at 400 revolutions. The dynamo is driven by one of Willans and Robinson's patent high-speed compound engines of 50 horse-power, the large boiler, one of the locomotive tubular type, being from the works of Messrs. Hornsby, Grantham. For the night lights (when the dynamo has ceased working) current is supplied through accumulators of Elwell and Parker's make. The room in which the accumulators are stored is well adapted for the purpose, being very airy and thoroughly ventilated. The whole of the circuits are under the control of the artificer in the dynamo room, where there are two switch-boards, with fusible cut-outs on each. It is intended to provide shortly a duplicate dynamo for use in the event of an emergency. To each cabin-lamp a switch is attached, so that the light can at any time be turned off independently of the others. The large cadets' dining room is lit with 33 lamps, and there is an average of five or six lights in the 17 study rooms. Captain Bedford, C.B., has shown great interest in the introduction of the electric light on the ship. The total cost of the installation has been upwards of £3,000.

Dublin.—A special meeting of the Dublin Municipal Council will be held in the Council Chamber on Monday, the 22nd October, at the hour of 1 o'clock in the afternoon, "to consider and do, or cause or direct all necessary acts to be done, upon or in relation to the after-mentioned business—namely, to consider, and, if deemed expedient, to adopt a resolution authorising an application by the corporation, as local authority for the City of Dublin, to the Board of Trade, for a provisional order to authorise the Corporation as such authority to supply electricity for any public or private purposes within the area of the City of Dublin."—The *Irish Times* says that the new station of the Alliance Gas Company for the purposes of electric lighting is now nearly completed, and will shortly be ready for work. The premises have been erected on a very suitable site in Hawkins-street, and are in every way adapted for their purpose, being lofty and roomy. A number of boilers have been placed in position, and the dynamos are being fixed. It is expected that the company will be able to supply their customers with the electric light from the new station in the course of a fortnight.—Referring to the same subject, Messrs. J. K. Fahie and Son, electrical engineers, write to the editor of the *Irish Times* as follows:—

"Sir: Referring to a paragraph in your issue of to-day under the above heading, as there appears to be some apprehension that the gas company have 'a concession' for supplying the electric light in the City of Dublin, will you kindly allow us to point out that there is no such thing as a concession for this purpose. The gas company enjoy no more privileges in this respect than ourselves or any other firm engaged in the electric light industry. More than this, under the Electric Light Act of 1882 the company dare not erect overhead or underground wires without the consent of the local authority, and seeing that the Municipal Council are at present seeking powers to deal generally with the lighting of the city by electricity, it is hardly likely that this consent will be easily obtained."

The Anglo-American Brush Company and the Lighting in the City.—The Anglo-American Brush Electric Light Corporation have resumed their negotiations with the Commissioners of Sewers with a view to the lighting of the City of London, and in connection therewith they have prepared for private circulation a memorandum setting forth the circumstances attending the past negotiations. In connection with the epidemic of crime which at present prevails, they remark that in the United States, where the electric light has been largely adopted for the streets, the police officers testify to its utility in the prevention of crime and the protection of life and property. On the general question of the development of electric industry they make this observation:—"Hitherto England has taken an important part in, and derived enormous benefits from, the industrial advance of other countries, but in regard to electric lighting the public at home have not only been deprived of the use of improved methods of lighting, but English manufacturers and contractors have on the Continent been forestalled by foreigners—not because they have lacked capacity to do the work, or enterprise or energy to initiate it, but because they have been unable to produce evidence that their systems have commanded support at home, where they should be better known. It was English people who carried out most of the important gasworks on the Continent; and they were able to do so because the gas industry had been fostered and encouraged at home. Electric lighting, on the other hand, which at best has an uphill battle to fight, has been hampered by the Legislature and discouraged by the municipalities. The Brush Corporation therefore speak in the interests of an industry which, under favourable conditions, promises to assume considerable dimensions, in urging on the Commissioners of Sewers of the City of London that this opportunity may not be lost of bringing to an issue the experiments and negotiations which that body so long ago initiated and have encouraged in the past, and of showing what can be done under methods approved and controlled by their own advisers."

NOTES ON THE REDUCTION OF BALLISTIC OBSERVATIONS TO ABSOLUTE MEASURE.

BY A. E. KENNELLY.

A ballistic galvanometer has to be employed in measurements of a magnetic field with the aid of an area-sweeping conductor, and in many cases where the quantity of electricity to be measured occupies a short but appreciable time in passing through the circuit, since it is essential that the whole period of passage be small compared with the period of vibration of the needle, or, in other words, that the whole electro-magnetic impulse be delivered to the needle before the latter has had time to sensibly alter its position.

We know that the total quantity of electricity, Q, passing, no matter how irregularly, during a small interval, through a ballistic mirror galvanometer, and producing a throw of d scale divisions from zero, is expressed to the first degree of approximation by the formula

$$Q = \frac{d}{2lg}\sqrt{\frac{IH}{m}} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where g is the galvanometer constant, or the number expressing the moment of the electro-magnetic couple set up on the needle by unit current strength in the coil.

H is the strength of the magnetic field in which the needle normally swings.

I is the needle system's moment of inertia.

l is the distance from the mirror to the scale centre, expressed in scale divisions.

and m is the needle's magnetic moment.

The angle of deflection is here assumed to be small, and the damping effect due to air friction and electro-magnetic induction is neglected.

As it would be difficult to calculate the needle's moment of inertia, I, even if its mass and form were known, since ballistic suspensions are generally built up in heterogeneous fashion, it is necessary to eliminate I by observing the mean period of the needle's vibration, the time of one semi-vibration (the time between any two immediately succeeding zero passages) being

$$T = \pi\sqrt{\frac{I}{mH}} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

These give us the equation

$$Q = \frac{dHT}{2lg\pi} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

Finally, we can eliminate the factor $\frac{H}{g}$ by passing a constant current of known strength, c, directly through the galvanometer, and noting the deflection d' as soon as it is steady, when we know that very approximately

$$\frac{H}{g} = \frac{2cl}{d'} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

and substituting in (3) we have equation (1) reduced to the form

$$Q = \frac{cdT}{\pi d'} \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

This calculation, which is in all essential particulars the one usually given in text-books, involves three measurements in addition to the observations of d itself, namely, cd' and T. The two latter cannot be regarded as constants, for they are often found to vary for the same galvanometer from hour to hour, and thus require for purposes of accuracy frequent redetermination, as any error made in determining these quantities enters by direct multiplication into the result. Under the most favourable conditions the formula will give results usually at least 3 per cent. in defect, owing to the reduction of the throw d by the disregarded damping.

The correction for this damping effect cannot be rigorously stated in finite terms, but can be found for any practically required degree of accuracy.

The rule for the first degree of correction, as usually recommended, is very simple. Let d'' be the most succeeding elongation of the image on the same side of the scale as d. Then, since the difference $d - d''$ is due to damping effect that has been operative over nearly four times the distance that existed between d and the original zero, increase d by $\frac{d-d''}{4}$.

This correction is always rather too small, especially with galvanometers with considerable damping, but when the latter is small for throws of 200 divisions or under the corrected value of d is usually within 1 per cent. of the truth.

To carry out the next degree of approximation, therefore, requires a fourth measurement, that of the decrement of the needle's vibrations, a quantity which for the same galvanometer and suspension is nearly constant. It is found that the rate of decrease in the elongations is always proportional to the elongation itself at the point considered; or, in other words, that the successive elongations on one side of the scale plotted as ordinates to abscissæ in time follow approximately a logarithmic curve. Obviously, if there were no damping, the image would oscillate continually between + true d and − true d on the scale. Supposing this to be possible, the observer would have in the path of the image before him almost the exact projection on the scale plane of an imaginary luminous satellite revolving in a circular orbit of radius d, with the scale zero as centre, and period 2 T; in other words, the image would execute a simple harmonic motion. Owing, however, to the damping effect, the imaginary satellite is always resisted by a force varying as the velocity, and attracted towards the scale zero with a force varying directly as the radius vector. Under these conditions, the satellite's orbit will no longer be a circle; but will approximate closely to an equi-angular or logarithmic spiral, that being the curve traced by a logarithmically decreasing radius vector revolving about a fixed centre with uniform angular velocity, and the actual path of the image is therefore approximately the orthogonal projection on the scale of the imaginary orbit executed as a contracting spiral, say, in the horizontal plane between the observer and mirror, round the scale zero, as origin with uniform angular velocity.

It follows that the ratios of any pairs of elongations separated by equal numbers will be equal. Thus, the ratios of the 1st and 3rd, 2nd and 4th, 7th and 9th, &c., elongations, are all equal. The following is a series of descending elongations observed with a ballistic galvanometer at the Edison Laboratory, which has a mean period of complete vibration, adjustable between 25 and 45 seconds, and a scale distance of 97·5 centimetres, or 1,510 scale divisions.

−		+	
		243	I.
II.	220·5		
		211	III.
IV.	191·7		
		183·6	V.
VI.	167		
		159·8	VII.
VIII.	145·7		
		138·3	IX.
X.	126·8		
		121	XI.
XII.	110·5		
		104·9	XIII.
XIV.	96·3		
		91·8	XV
XVI.	83·7		
		79·1	XVII.
XVIII.	73·6		
		69·5	XIX.

Thus, the ratio in this series of $\frac{I.}{IV.}$ is 1·268,

that of $\frac{III.}{VI.}$ is 1·263,

that of $\frac{V.}{VIII.}$ is 1·260.

Digitized by Google

The logarithm to the base ϵ of the ratio of any pair of consecutive elongations on opposite sides of the scale is, of course, constant, since the ratio is constant, and is called the Naperian logarithmic decrement, being generally represented by the symbol λ. Thus, λ is the $\log_\epsilon$ ratio $\frac{I.}{II.}$ or $\frac{II.}{III.}$, &c., and for the above series has a mean value of 0·0695. The ratio $\frac{\lambda}{\pi}$ is always the cotangent of the angle formed by the radius vector of the imaginary satellite and the geometrical tangent to its orbit at any point. Thus, $\frac{0·0695}{3·1416} = 0·02212$, the cotangent of 88° 44′, which is the angle between the radius vector and tangent for the imaginary orbit corresponding to the above series. This angle would, of course, be 90° in a circular orbit, so that the smaller we find λ the less does the spiral deviate from the circle and the less the damping effect on the needle.

It is evident that λ is the Naperian logarithm of the ratio of radii vectors in the imaginary orbit separated by an angular distance of π, also that 2λ is similarly the $\log_\epsilon$ ratio of radii vectors separated by 2π, or one complete revolution, and generally that radii vectors angularly distant $n\pi$ bear a ratio whose natural logarithm is $n\lambda$.

So that if D be the value of the throw d corrected for damping, then D must be the initial radius vector of the imaginary orbit, and since d coincides with the radius vector after the latter has described a right angle (approximately), the observed throw d will bear to the corrected throw D the ratio of radii vectors distant $\frac{\pi}{2}$; that is, the ratio whose natural logarithm is $\frac{\lambda}{2}$.

Thus
$$\log_\epsilon \frac{D}{d} = \frac{\lambda}{2} \quad . \quad . \quad . \quad . \quad . \quad . \quad (6)$$

or
$$D = d\epsilon^{\frac{\lambda}{2}} \quad . \quad . \quad . \quad . \quad . \quad . \quad (7)$$

expanding $\epsilon^{\frac{\lambda}{2}}$ by Maclaurin's theorem and rejecting all terms involving second or higher powers of λ, we have very nearly the relation
$$D = d\left(1 + \frac{\lambda}{2}\right) \quad . \quad . \quad . \quad . \quad . \quad (8)$$

Thus in the above series of elongations where $d = 243$ and $\lambda = 0·0695$

D would be $243\left(1 + \frac{0·0695}{2}\right) = 243 \times 1·0348 = 251·5$.

Equation (5) now takes the form
$$Q = \frac{c\,T\,d}{\pi a'}\left(1 + \frac{\lambda}{2}\right) \quad . \quad . \quad . \quad . \quad . \quad (9)$$

This correction is the one generally adopted in electromagnetic measurements, and is sufficiently accurate for almost all practical purposes. It is well to notice, however, that the value of D so obtained is only a close approximation, and not absolutely exact, for two reasons. Firstly because the whole theory of the equiangular spiral orbit assumes that the magnetic couple tending to bring the needle to rest varies directly as the angle of deflection, while we know that this force varies actually as the sine of that angle; hence the theory only applies rigorously to indefinitely small angles of throw. The error resulting from the discrepancy is, however, with a Thomson galvanometer, exceedingly small. Secondly, because the maximum elongation of the image on either side of the scale, owing to the deviation of the orbit from circularity, takes place before the radius vector of the imaginary satellite actually enters the plane of the scale. Thus the throw d is produced when the vectorial angle swept out is $\cot^{-1}\frac{\lambda}{\pi}$ in the above series; for example, when the radius vector had described 88° 4′, or was yet 1° 16′ from the scale plane.

Taking this latter consideration into account, the equation of correction becomes
$$Q = \frac{c\,T\,d\,e^{\frac{\lambda}{\pi}\tan^{-1}\pi}}{\pi a'}{}^{\lambda} \quad . \quad . \quad . \quad . \quad (10)$$

It is hardly ever necessary, however, to employ this formula.

To avoid the time and labour necessary for the determination of T and λ, which are required for the reduction of Q by this formula, two other methods of reduction have been published, and attributed to Sir William Thomson and Prof. Rowland respectively. Both these methods compare the throw d obtained from the unknown quantity Q with another throw, θ, obtained from a known quantity, q. Then, since both throws involve damping correction proportionately, this latter is entirely eliminated, and
$$Q = \frac{d\,q}{\theta} \quad . \quad . \quad . \quad . \quad . \quad . \quad (11)$$

The one method obtains the known quantity q from an induction coil of known constants, and by the interruption of a known current passing through its primary circuit. The other method obtains q from an earth inductor by revolving a coil of known constants in the earth's magnetic field H of known strength.

These methods, therefore, though rendering unnecessary the measurements of T and λ, still require the measurement of the known current in the one and of the known field H in the other, although, of course, those measurements may be made once only for many different measurements of Q.

There is, however, a third very simple and accurate method of obtaining q, which does not seem to have yet been published, and that is by means of a condenser of known capacity charged by a known electromotive force. A good standard condenser should be accurate within, say, 0·5%, and a Clark standard cell employed to charge it can, when duly corrected for temperature, be certainly depended upon to that degree of accuracy, so that if e be the electromotive force of the cell in volts, and k the capacity of the condenser in microfarads, the quantity of electricity q, in electro-magnetic units, obtained by the charge, will certainly be $10^{-7} e k$ under those conditions within 1 per cent.

With this condenser method, only the throw θ is required in order to obtain Q by direct proportion, and all measurements of magnetic fields by means of area sweeping conductors may thus be reduced to the simple relation
$$H = a\,d \quad . \quad . \quad . \quad . \quad . \quad . \quad (12)$$

where H is the field whose intensity is to be measured, d is the throw obtained by moving the conductor in that field, and a is a constant depending on the dimensions of the field-searching conductor, the resistance of the galvanometer and connections, the capacity of the condenser and the amount of the condenser throw, the complete formula being—
$$H = \frac{d\,e\,k\,r \times 10^2}{A\,\theta} \quad . \quad . \quad . \quad . \quad . \quad (13)$$

where r is the resistance of the field exploring circuit and A the effective area described by the field searcher, the other symbols having their above significations.

The condenser method furnishes also in itself a convenient means of determining λ when independently necessary. Let the discharge of the quantity q through the galvanometer produce a throw of θ divisions, as above.

Just as the image reaches the scale zero on its way to the next elongation on the opposite side, let the condenser be again discharged through the galvanometer. With a slowly moving needle this is not a difficult matter. Then, if there had been no damping the image would be brought instantly to rest at zero by this second discharge; owing, however, to the loss of momentum through damping, the impulse given by this discharge will more than neutralise the momentum of the needle, and will give it a slight recoil resulting in a small throw δ, say, on the same side as d. Then,
$$\lambda = \log_\epsilon \frac{d}{d + \delta} \quad . \quad . \quad . \quad . \quad . \quad (14)$$

Digitized by Google

For if ρ be the radius vector of the imaginary satellite at the commencement of its orbit, m its mass, and ω be its angular velocity, then the actual velocity of the satellite at starting would be $\rho\,\omega$ if the orbit were circular, but the orbit being spiral the initial velocity is $\frac{\rho\,\omega}{\sin\beta}$, where β is the angle $\cot^{-1}\frac{\lambda}{\pi}$ included between the radius vector and tangent. Consequently the initial momentum is $\frac{m\rho\,\omega}{\sin\beta}$.

When the image is next passing the scale zero the vectorial angle is π and the radius vector is $\rho e^{-\lambda}$, so that the momentum retained by the satellite is $\frac{m\rho\,\omega e^{-\lambda}}{\sin\beta}$.

The momentum retained by the satellite after the second discharge at this point will be the difference of these two momenta or the momentum lost by damping.

Thus, if ρ_1 be the initial radius vector of the new orbit after the second discharge, then

$$\frac{m\rho_1\omega}{\sin\beta}=\frac{m\rho\,\omega}{\sin\beta}(1-e^{-\lambda}), \quad . \quad . \quad . \quad (15)$$

whence

$$\lambda=\log_\epsilon\left(\frac{\rho}{\rho-\rho_1}\right); \quad . \quad . \quad . \quad . \quad (16)$$

but $\rho=d\,e^{\frac{\lambda}{2}}$ approximately,

and $\rho_1=\delta\,e^{\frac{\lambda}{2}}$;

so that

$$\lambda=\log_\epsilon\left(\frac{d}{d-\delta}\right). \quad . \quad . \quad . \quad . \quad . \quad (17)$$

For example, the throw from a condenser charged by a standard cell gave with the above-mentioned galvanometer a throw, d, of 243 divisions, and a recoil, δ, after the second discharge of 18·0; so that λ from these observations would be

$$\log_\epsilon\frac{243}{243-18\cdot0}=\log_\epsilon 1\cdot080=0\cdot0769.$$

A more elaborate and much more accurate method for determining λ by means of a series of similar recoil throws is given by Clerk Maxwell.

HERTZ'S RESEARCHES ON ELECTRICAL OSCILLATIONS.

BY G. W. DE TUNZELMANN, B.SC.

(*Continued from page 665.*)

Dr. Hertz was at first inclined to suppose that as the micrometer circuit was only broken by the extremely short air space limited by the maximum sparking distance under the conditions of the experiment, it might therefore be treated as a closed circuit, and only the total induction considered. The ordinary methods of electro-dynamics give the means of completely determining the total inductive effect of a current element on a closed circuit, and would, therefore, in this case have sufficed for the investigation of the phenomena observed. He found, however, that the treatment of the micrometer circuit as a closed circuit led to incorrect results, so that it, as well as the primary, had to be treated as an open circuit, and, therefore, a knowledge of the total induction was insufficient, and it became necessary to consider the value both of the E.M.F. induction and of the electrostatic E M.F. due to the charged extremities of the exciting circuit at each point of the micrometer circuit.

The investigations to which these considerations led are described by Dr. Hertz in a Paper "On the Action of a Rectilinear Electrical Oscillation upon a Circuit in its Vicinity," published in Wiedemann's *Annalen*, Vol. XXXIV., p. 155, 1888.

In what follows, the exciting circuit will be spoken of as the primary, and the micrometer circuit as the secondary. Hertz points out that the reason that the electrostatic effect cannot be neglected is to be found in the extreme rapidity with which the electrostatic forces change their sign. If the electrostatic alternations in the primary were comparatively slow they might attain a very high intensity without giving rise to a spark in the secondary, since the electrostatic distribution on the secondary would vary so as to remain in equilibrium with the external E.M.F. This, however, is impossible, because the variations in direction follow each other too rapidly for the distribution to follow them.

In the present investigations the primary circuit consisted of a straight copper wire 5 millimetres in diameter, carrying at its extremities hollow zinc spheres 30 centimetres in diameter. The centres of the spheres were one metre apart, and at the middle of the wire was an air space $\frac{3}{4}$ centimetre in length. The wire was placed in a horizontal position, and the observations were all made at points near to the horizontal plane through it, which, however, did not, of course affect their generality, as the same effects would necessarily be produced in any plane through the horizontal wire. The secondary circuit consisted of a circle of 35 centimetres radius of copper wire 2 millimetres in diameter, the circle being broken by an air space capable of variation by means of a micrometer screw.

The circular form was selected for the secondary circuit because the former investigations had shown that the sparking distance was not the same at all points of the secondary, even when the conductor as a whole remained unchanged in position, and with a circular circuit it was easier to bring the air space to any part than if any other form had been used. To attain this object the circle was made movable about an axis passing through its centre perpendicular to its plane.

The circuits of the dimensions stated were very nearly in unison, and they were further adjusted by means of little strips of metal soldered to the extremities, and varied in length until the maximum sparking distance was obtained.

We shall follow Dr. Hertz in first considering the subject theoretically, and then examining how far the experimental results are in accordance with the theoretical conclusions. It will be assumed that the E.M.F. at every point is a simple harmonic function of the time, but that it does not undergo reversal in direction, and it will further be assumed that the oscillations are at any given moment everywhere in the same phase. This will certainly be the case in the immediate neighbourhood of the primary, and for the present we shall confine our attention to such points. Let s be the distance of a point, measured along the circuit from the air space of the secondary, and F the component E M.F. at that point along the circular arc $d\,s$. Then F is a function of s, which assumes its original value after passing once round the circle of circumference S. It may, therefore, be expanded in the form

$$F=A+B\cos\frac{2\pi s}{S}+\ldots\ldots+B'\sin\frac{2\pi s}{S}+\ldots\ldots$$

The higher terms of the series may be neglected, as the only result of so doing will be that the approximate theory will give an absolute disappearance of sparks where really the disappearance is not quite complete, and indeed the experiments are not delicate enough to enable us to compare their results with theory beyond a first approximation.

The force A acts in the same direction, and is of constant amount at all points of the circle, and therefore it must be independent of the electrostatic E.M.F., as the integral of the latter round the circle is zero. A, then, represents the total E.M.F. of induction, which is measured by the rate of variation of the number of magnetic lines of force which pass through the circle. If the electro-magnetic field containing the circle is assumed to be uniform, A will therefore be proportional to the component of the magnetic induction perpendicular to the plane of the secondary. It will therefore vanish when the direction of the magnetic induction lies in the plane of the secondary. A will consist of an oscillation, the intensity of which is independent of the position of the air space in the circle, and the corresponding sparking distance will be called α.

The term $B'\sin\frac{2\pi s}{S}$ can have no effect in exciting the

Digitized by Google

fundamental vibration of the secondary, since it is symmetrical on opposite sides of the air space.

The term $B \cos \frac{2\pi s}{S}$ will give a force acting in the same direction in the two quadrants opposed to the air space, and will excite the fundamental vibration. In the two quadrants adjacent to the air space it will give a force in the opposite direction, but its effect will be less than that of the former one. For the current is zero at the extremities of the circuit, and therefore the electricity cannot move so freely as near the centre. This corresponds to the fact that if a string fastened at each end has its central portion and ends acted on respectively by oppositely directed forces, its motion will be that due to the force at the central portion, which will excite the fundamental vibration if its oscillations are in unison with the latter. The intensity of the vibration will be proportional to B. Let E be the total E.M.F. in the uniform field of the secondary, ϕ the angle between its direction and the plane of the latter, and θ the angle which its projection on this plane makes with the radius drawn to the air space. Then we shall have approximately

$$F = E \cos \phi \sin \left(\frac{2\pi s}{S} - \theta \right),$$

and, therefore, $B = -E \cos \phi \sin \theta$.

B, therefore, is a function simply of the total E.M.F. due both to the electrostatic and electro-dynamic actions. It will vanish when $\phi = 90°$—that is to say, when the total E.M.F. is perpendicular to the plane of the circle, whatever be the position of the air space on the circle. B will also vanish when $\theta = 0$—that is to say, when the projection of the E.M.F. on the plane of the circle coincides with the radius through the air space. If the position of the air space on the circle is varied, the angle θ will vary, and, therefore, also the intensity of the vibration and the sparking distance. The sparking distance corresponding to the second term of the expansion for F can, therefore, be represented approximately by a formula of the form $\beta \sin \theta$.

Now the oscillations giving rise to sparks of lengths α and $\beta \sin \theta$ respectively are in the same phase. The resulting oscillations will therefore be in the same phase, and their amplitudes must be added together. The sparking distance being approximately proportional to the maximum total amplitude may therefore also be obtained by adding the sparking distances due to the two oscillations respectively. The sparking distance will therefore be given as a function of the position of the air space on the secondary circuit by the expression $\alpha + \beta \sin \theta$. Since the direction of the oscillation in the air space does not come into consideration we are concerned only with the absolute value of this expression, and not with its sign. The determination of the absolute values of the quantities α and β would involve elaborate theoretical investigations, and is, moreover, unnecessary for the explanation of the experimental results.

Experiments with the Secondary Circuit in a Vertical Plane.—When the circle forming the secondary circuit was placed with its plane vertical, anywhere in the neighbourhood of the primary, the following results were obtained:—

The sparks disappeared for two positions of the air space, separated by 180°, namely, those in which it lay in the horizontal plane through the primary; but in every other position sparks of greater or less length were observed.

From this it followed that the value of α must have been constantly zero, and that θ was zero when the air space was in the horizontal plane through the primary.

The electro-magnetic lines of force must therefore have been perpendicular to this horizontal plane, and therefore consisted of circles with their centres on the primary, while the electrostatic lines of force must have been entirely in the horizontal plane, and therefore this system of lines of force consisted of curves lying in planes passing through the primary. Both of these results are in agreement with theory.

When the air space was at its greatest distance from the plane the sparking distance attained a maximum value of from 2 to 3 millimetres. The sparks were shown to be due to the fundamental vibration, by slightly varying the secondary, so as to throw it out of unison with the primary, when the sparking distance was diminished, which would not have been the case if the sparks had been due to overtones. Moreover, the sparks disappeared when the secondary was cut at its points of intersection with the horizontal plane through the primary, though these would be nodal points for the first overtone.

When the air space was kept at its greatest possible distance from the horizontal plane through the primary, and turned about a vertical axis, the sparking distance attained two maxima at the points for which $\phi = 0$, and almost disappeared at the points for which $\phi = 90°$.

The lower half of Fig. 8 shows the different positions of minimum sparking. A A′ is the primary conductor, and the lines *m n* represent the projections of the secondary circuit on the horizontal plane. The arrows perpendicular to these give the direction of the resultant lines of force. As this did not anywhere vanish in passing from the sphere A to the sphere A′, it could not change its sign.

The diagram brings out the two following points:—

(1) The distribution of the resultant E.M.F. in the vicinity of the rectilinear vibration is very similar to that of the electrostatic E.M.F. due to the action of its two extremities. It should be specially noted that near the centre of the primary the direction is that of the electrostatic E M.F., showing that it is more powerful than the electrodynamic, as required by theory.

(2) The lines of force deviate more rapidly from the line A A′ than the electrostatic lines, though this is not so evident

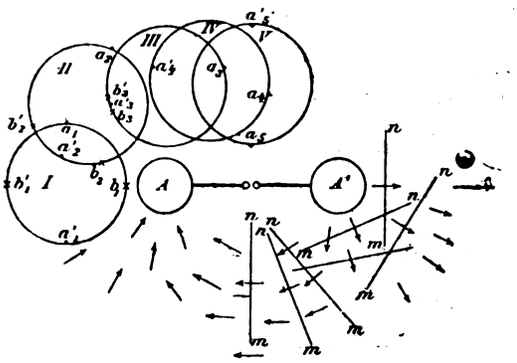

Fig. 8.

on the reduced scale of the diagram as in the author's original drawings on a much larger scale.

It is due to the components of the electrostatic E.M.F. parallel to A A′ being weakened by the E.M.F. of induction, while the perpendicular components remain unaffected.

Experiments with the Secondary Circuit in a Horizontal Plane.—The results obtained when the plane of the secondary was horizontal can best be explained by reference to the upper half of the diagram in Fig. 8.

In the position I., with the centre of the circle in the line A A′ produced, the sparks disappeared when the air space occupied either of the positions b_1 or b'_1, while two equal maxima of the sparking distance were obtained at a_1 and a'_1, the length of the spark in these positions being 2·5 millimetres. Both these results are in accordance with theory.

In the position II. the circle is cut by the electro-magnetic lines of force, and, therefore, α does not vanish. It will, however, be small, and we should expect that the expression $\alpha + \beta \sin \theta$ would have two unequal maxima $\beta + \alpha$ and $\beta - \alpha$, both for $\theta = 90°$, and having the line joining them perpendicular to the resultant E.M.F., and between these two maxima we should expect two points of no sparking near to the smaller maximum. This was confirmed by the observations.

The maximum sparking distances were 3·5 millimetres at a_2 and 2 millimetres at a'_2. Now with the air space at a_2, the sphere A being positive, the resultant E.M.F. in the opposite portion of the circle will repel positive electricity from A, and therefore tend to make it flow round the circle clockwise. Between the two spheres the electrostatic E M.F. acts from A

Digitized by Google

towards A′, and the opposite E.M.F. of induction in the neighbourhood of the primary acts from A′ to A, parallel to the former, and acting more strongly on the nearer than on the further portion of the secondary, tends to cause a current in the same direction as that due to the former, namely, in a clockwise direction. Thus the resultant E.M.F. is the sum of the two as required by theory, and in the same way it is easily seen that when the air space is at a'_2, the resultant E.M.F. is equal to their difference.

As the position III. is gradually approached, the maximum disappears, and the single maximum sparking distance a_3 was found to be 4 millimetres in length, having opposite to it a point of disappearance a'_3. In this case clearly $\alpha = \beta$, and the sparking distance is given by the expression $\alpha(1 + \sin\theta)$. The line $a_3 a'_3$ is again perpendicular to the resultant E.M.F.

As the circle approaches further towards the centre of A A′ α will become greater than β, and the expression $\alpha + \beta \sin\theta$ will not vanish for any value of θ, but will have a maximum $\alpha + \beta$ and a minimum $\alpha - \beta$, and in the experiments it was found that the sparks never entirely disappeared, but varied between a maximum and a minimum, as indicated by theory.

In the position IV. a maximum sparking distance of 5·5 millimetres was observed at a_4 and a minimum of 1·5 millimetre at a'_4.

In the position V. there was a maximum sparking distance of 6 millimetres at a_5 and a minimum of 2·5 millimetres at a'_5. In these experiments the air space should be screened off from the primary in the latter positions as well as in the earlier ones, in which it is unavoidable, as otherwise the results would not be comparable.

In passing from the position III. to the position V. the line $a\,a'$ rapidly turned from its position of parallelism to the primary circuit into a position perpendicular to it. In the latter positions the sparking was essentially due to the inductive action, and therefore the author was justified, in the experiments described in my previous Papers, in assuming the effect in these positions to be due to induction.

Even in these positions, however, the sparking is not totally independent of electrostatic action, except when the air space is half way between the maximum and minimum positions, and, therefore, $\beta \sin\theta = 0$.

(To be continued.)

THE USE OF ELECTRIC MOTORS ON SHIPBOARD.*

BY LIEUT. J. B. MURDOCK, U.S.N.

The use of electric motors is extending very rapidly ashore, and naturally raises the question whether there is a field for them on shipboard. The transmission of energy by electricity possesses two general advantages over any other system—in being more economical when energy is to be transmitted to a distance, or when it is to be subdivided into a number of paths. The former has no application on shipboard, where distances are short, but the latter seems to meet many of the conditions for the modern navy.

A good dynamo will place 90 per cent. of the mechanical energy it receives in the form of available electrical energy in its external circuits. If, now, a good motor be placed in this circuit 90 per cent. of this electrical energy, or about 80 per cent. of the work of the engine, can be obtained as mechanical work. The loss in transmission is 20 per cent., and the cost of dynamo and motor renders such a system uneconomical in comparison with the simple one of placing a steam engine where the work is to be done. If, however, the power is required in twenty places instead of in one, the question becomes radically different, and this is the one inviting our attention.

In the new cruisers one of the first impressions received is that of complexity and confusion arising from the number of small engines scattered over the vessels. Nor is the feeling dispelled by a closer examination, for the ship is found to be a labyrinth of steam, exhaust, and circulating pipes, complex in arrangement, and requiring constant care and attention to keep in order. Joints and valves leak, steam condenses, and water freezes, totally disabling some part of the mechanism. If injuries occur, repairs are difficult and frequently impossible with the ship's resources, and an important engine may be disabled for months, or until the arrival of the vessel in port. A still more important objection to this complicated system of steam circulation in men-of-war is found in its liability to injury in action, and the danger to the crew which such injury might bring about. A single pipe cut by shot might disable a very important part of the ship's offensive apparatus, and pipes so injured are difficult to repair, and require time which could not be spared. The escape of steam in such a case would inevitably interfere with the fighting of the ship, and might cause loss of life or even a panic in the crew. If, therefore, it is necessary to use so many auxiliary motors, is steam the best vehicle for the transmission of power?

The electric motor is for equal power smaller than almost any steam engine, is more efficient, involves less waste in transmission, and has small mains, which are therefore less liable to injury, and admit of rapid repair of injuries. With the low potential used on shipboard there is, moreover, no danger to the *personnel*, and a broken main could be stopped without the delay of turning off the current. Every objection against the indiscriminate use of steam engines is removed by the use of the electric motor. A motor is, moreover, portable, and power may thus be quickly obtained in any place in the ship where the motor may be fastened down.

On grounds of utility, therefore, the motor appears to possess decided advantages. These appear to exist equally in economy. Small engines are notoriously uneconomical as compared with large ones. Small motors and dynamos are less so. By concentrating the whole auxiliary power of the ship in the dynamo room, large, economical compound condensing engines may be used in driving high-efficiency dynamos, and the power thus obtained distributed through large mains to the motors with very slight loss. The question of economy therefore rests upon the amount of subdivision, and is apparently in favour of the electric motor under just the circumstances in which distribution by steam becomes complex, and the loss due to using a number of uneconomical engines forms a large total aggregate. The question of economy of coal is one of the most important to be faced, and becomes paramount in a ship, which, without plenty of coal in her bunkers, is a mere helpless steel box, drifting at sea. Is it not advisable to seriously consider the saving and general advantages to be obtained by the high economy of large engines of the best type, and the high efficiency of well-designed dynamos and motors, in place of the notorious wastefulness, heat, dirt, and noise of small auxiliary engines?

In order to carry out such a plan it is only necessary to connect the motors to the incandescent-light mains. It will be necessary to closely analyse the demands for power, and to place in the dynamo room a sufficient number of dynamos to supply the maximum required to be used at any time. The paramount consideration should be to have a reserve in action, and it is probable that more power will be needed then, through the use of gun-carriage and other motors and search-lights, than will be saved by the diminished use of incandescent lights. The dynamo room in this case becomes a central station for light and power, and valuable information may be derived from the experience of central stations ashore. It seems to be settled now in ordinary practice that, in cases where the load varies largely, it is in the long run more economical to use several engines of medium size, throwing in one after the other as the demand increases, rather than to employ one or two large engines which must generally be operated in partial load.

The objection to such a system is, that although the danger in action is not diffused over the whole ship it is concentrated in one place, and any injury there would cripple the ship. This is merely placing the dynamos in the same category as the engines and boilers, and, like them, the dynamo room must have all protection that can be given it. It should always be below the protective deck, when there is one, and in other cases below the water line. The mains should consist of several parts in parallel, connected together by copper wire spans at intervals. Each main becomes then a net work of conductors, and although this entails greater first cost, it reduces loss in transmission to a negligible quantity and guarantees safety and durability. The distribution should be made as much as possible below the protective deck, branch mains being generally vertical. Every circuit necessary in action should be thoroughly accessible for repairs, while at the same time receiving all possible protection. The highest insulation is of course demanded.

The simplicity of such a system is in marked contrast with that of steam distribution. All incandescent lights, search lights, and motors are connected in parallel, and any one may be put in or out of action by the movement of a single switch.

Apart from all advantages of distribution, the electric motor is the most efficient, compact, noiseless and simple vehicle for the transmission of energy that is known. If well made, it requires only ordinary care and attention to be always ready for use. Its principal danger on shipboard is from salt water, but with proper care this is small.

Nothing like a complete presentation of so wide a subject can be given within the limits of a single article, but the foregoing may call attention to some of the necessities of our service, and also to some fields in which experimental work may well be carried on.

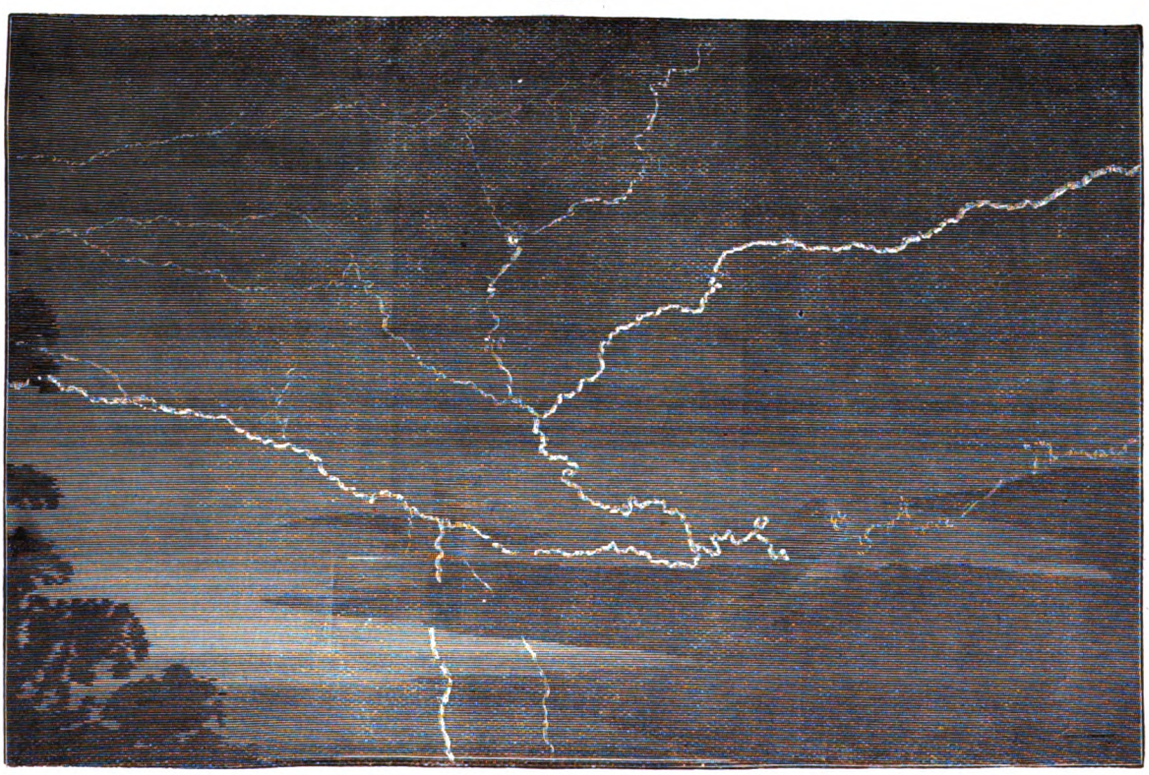
PHOTOGRAPHS OF LIGHTNING EXHIBITED AT THE MEETING OF THE BRITISH ASSOCIATION.

FIG. 1.—This figure shows the apparent duplication of flashes, probably from internal reflection from back of glass plate. Also the ribbon-like form of one of the flashes. Taken on board H.M.S. "Neptune," November 14, 1884, 6:30 p.m., between Madeira and Gibraltar.

FIG. 2.—This figure shows three flashes nearly parallel; also one *dark* flash. Taken August 17, 1887, in London.

FIG. 3.—This figure shows the meandering type of flash, also the tendency to form brighter spots in certain portions of the flash. Observe, too, that the flash is slightly ribboned at the edges only, where the definition is less good than in the centre. Taken May 26, 1886, 10:30 p.m., near Tours.



The above engravings are taken from photographs exhibited by the Hon. R. Abercromby during the discussion on Lightning Conductors at the meeting of the British Association. These photographs are amongst those obtained by the Royal Meteorological Society in response to their recent app Unfortunately, some of the finer details are inevitably lost in the process of engraving on wood.

The Electrician.

Published every Friday. Price Fourpence; Post Free, Fourpence Halfpenny.
Editorial and Publishing Offices
No. 1, SALISBURY COURT, FLEET STREET, LONDON, E.C.
Telephone No. 8714.

All Communications to be addressed to "The Electrician," 1, Salisbury-court, Fleet-street, London, E.C. Cheques and Money Orders should be made payable to "The Electrician."

All letters intended for insertion in "The Electrician," or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.

"The Electrician" is published every Friday morning, in time for the morning mails. Subscribers should receive their copies by the first post on Friday morning.

"The Electrician" is on sale at the railway bookstalls throughout the United Kingdom on Friday morning, and can be obtained at all Booksellers and Newsvendors; or direct from the office as above.

SPECIAL NOTICE.

Owing to the increase in the number of pages of "The Electrician," in order to partly cover the increased postage, we have been compelled to revise the rates for Foreign Subscriptions, which are now as follows:—

	3 months.	6 months.	12 months.
For Foreign Parts and Colonies:—	s. d.	s. d.	s. d.
Within Postal Union	6 6	... 12 6	... 24 0
„ Aden, Borneo, Ceylon, China, India, Japan, Java, Labuan, Mozambique, New Caledonia, Persia, Philippine Islands, Siam, Transvaal, and Zanzibar	7 6	... 14 6	... 28 0
The rates for the United Kingdom remain as follows:—	5 0	... 10 0	... 19 6

TO ADVERTISERS.

"The Electrician" *offers exceptional advantages to Advertisers.* **It has the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application to this office.

Trade Advertisements *intended for the current issue must be handed in not later than First Post on Thursday morning.*

Small Prepaid Advertisements *(for Rates see page XI.) are accepted up to 4 p.m. on Thursday.*

TECHNICAL PRINTING.

"The Electrician" Printing and Publishing Company (Limited) *beg to inform Electricians and Electric Light Engineers that they make a specialty of Technical Printing, and have a Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electrical Catalogues and Electro-Technical Literature generally.*

The Electricians' Directory.

Royal 8vo. Cloth Boards, 3s. 6d. Boards, 3s.

At the end of December in each year is issued The Electricians' Directory and Handbook. *The Directory was established in 1883, and has now attained considerable proportions. Every care is taken to make the names and addresses of all persons engaged in the Electrical Industries absolutely accurate. Useful Tables and Electrical Formulæ are given, together with popularly-written Biographical Notices of the leading Electricians, accompanied in many cases by Portraits.*

THE DIRECTORY FOR 1889 IS IN PREPARATION.

THE SOCIETY OF ARTS MOTOR TRIALS.

In the month of December, 1886, the Council of the Society of Arts announced that they were prepared to conduct a series of competitive trials of prime motors "suitable for electric light installations," and that they would award two Gold and four Silver Medals. The motors were to be divided into two classes, A and B, and one gold and two silver medals were to be awarded in each class. In Class A were to be included those motors "in which the working agent is also produced," the steam-engines being further classified into condensing and non-condensing types, and the gas motors into coal gas, water gas, petroleum vapour, and liquid petroleum engines. In Class B were to be included those motors "to which the working agent must be supplied," including steam engines without boilers, gas and water engines. Each class was again subdivided into two groups, one for engines developing under 10 horse-power and the other for engines developing from 10 to 20 horse-power; and it was further announced that no competition would be held unless at least ten motors were entered. The conditions laid down for the trials were in the main identical with those adopted by the Royal Agricultural Society. The experiments were originally intended to have been carried out in or about May or June, 1887. In the month of January, however, a revised set of regulations was issued by the Council with the object of including engines deriving power from the combustion of any kind of hydro-carbon, and also air engines, and the trials were at the same time postponed for twelve months until May of the present year.

Digitized by Google

In making these proposals the Council of the Society of Arts were of course actuated by the best possible intentions, and it is impossible to overlook the fact that their willingness to undertake so serious an expenditure of time, labour, and money, on behalf of electrical engineering, entitles them to the gratitude of every member of the profession. But although we have previously taken occasion to express our appreciation of this well-meant scheme, yet at the same time—and so long ago as July of last year—we gave expression to some foreboding that its success would not be commensurate with the importance of the question or with the dignity of its sponsors. We most sincerely regret to find that our lugubrious anticipations have proved only too correct, for notwithstanding a still further postponement of the trials—which in fact are scarcely now complete—the entries have been extremely meagre in number, being confined to *one* steam engine and *three* gas engines.

The want of alacrity of the engine makers in entering upon a competition of this character is not difficult to understand. From a commercial point of view it is obvious that an average firm has more to lose than to gain by taking a part in the game, and the smaller the number of competitors the more will the triumph of the successful rival be minimised. But apart from general considerations it is evident that in this particular case there are difficulties of a special kind which render the selection of the most suitable motor for electric lighting purposes a task of more than usually difficult, if not an altogether impossible character. In our own opinion—an opinion which we endeavoured to force upon the attention of the Council whilst there was still time for reconsideration—the scheme was doomed to failure if only on account of the lack of any definite indication as to the *kind* of electric light installations for which the engines were to be supposed to be adapted. That any one engine could be pronounced the most suitable for any and every species of installation is absurd on the face of it. As a matter of fact, there is probably not a single fairly good type of engine in existence which is not somewhere or other in use at the present moment for electric lighting. We do not argue from this that every known type of engine may be advantageously employed in some phase or other of the electric lighting industry; but the consideration is one which certainly tends to emphasise the fact that the conditions under which dynamos have to be supplied with motive power are by no means of a uniform character. It is true that regularity of speed is the one distinctive feature which is demanded of every motor used for electric lighting, but this speed may be high, low, or moderate; it may be required to be absolutely constant, or to be capable of automatic variation within a certain range. Again, if the engine be large, we look to economy of working as of the first degree of importance, and we can, if necessary, correct speed variations by means of an electric governor or otherwise; but if the engine be small, it is seldom desirable to do this, and the question of economy is to some extent subordinated to absolute steadiness of running. Central station lighting, domestic lighting, factory lighting, ship lighting, constant current and constant potential distribution, distribution with or without batteries, and so on, each demand that the question of engine power shall be considered from a special standpoint, and we repeat that it is impossible to select any motor which, without qualification, can be asserted to be the best for electric lighting purposes in general. It may be said, and probably with some degree of accuracy, that the Society of Arts never intended to place their *imprimatur* upon any one motor as the best for all round purposes, and that this is proved by the classification which they have so carefully set forth. But, unfortunately, this classification, elaborate as it is, does not take any account whatever of the different requirements of the various types of installations to which we have referred; and therefore any motor which obtained the gold medal in Sections A or B goes forth to the world as the most "suitable for electric lighting installations."

It is, of course, true that any adequate extension of the scheme in the direction indicated would have immensely increased both the difficulty and the cost of the undertaking, and in fact it would probably have proved impracticable.

That the affair should terminate, however inevitable this may have been, in something very like a *fiasco*, is the more to be regretted since the Commission appointed by the Society to carry out the tests is exceptionally strong, and the equipment at their disposal is probably of unequalled excellence. The *personnel* consists of Prof. KENNEDY, F.R.S., Dr. J. HOPKINSON, F.R.S., and Mr. BEAUCHAMP TOWER. The motors upon which the trials have just been carried out are one Davey Paxman engine (of the same type as that which last year gained the prize at the Royal Agricultural Society's trials at Newcastle), one "Otto" gas engine, one "Griffin" gas engine, and an Atkinson cycle gas engine. The trial, therefore, resolves itself into a contest between these three gas engines, and regarded from this standpoint the result will still possess considerable interest and importance to electrical engineers. The points of merit considered of the greatest importance are the following:—

a. Regularity of speed as to revolutions per minute under varying loads.

b. Regularity of speed during the various parts of one revolution.

c. Power of automatically varying speed to suit arc lights.

d. Noiselessness.

e. First cost.

f. Cost of running.

g. Cost of maintenance.

Special meters were provided to measure the consumption of gas with exceptional accuracy. Each engine undergoes three tests:—(1) a continuous run of six hours at full power; (2) a run of three hours at half power; (3) a run of one half hour unloaded. The brake power and the indicated power are both obtained; also the quantity of cooling water employed and its rise in temperature. The time required to start the engine is also ascertained. The tests have been carried out under conditions which leave no room for doubt that the final results will possess the highest attainable degree of accuracy, but some time will necessarily elapse before their publication, and, as we have said, the whole thing resolves itself into a competition between three of the leading gas-engine makers.

ON THE C.-G.-S., AND PRACTICAL UNITS OF MEASUREMENT.*

BY W. H. PREECE, F.R.S.

In the C.-G.-S. system, which may now be considered to be in universal use, the quantity of heat which will raise one gramme of pure water one degree centigrade from the standard temperature, 4°, is the C.-G.-S. thermal unit, and is frequently called the *calorie*; but the term calorie is just as frequently applied to the kilogramme water degree. Its mechanical equivalent is 42,000,000 ergs.

* Paper read before the British Association meeting (Section A) at Bath, September, 1888.

Digitized by Google

Since heat is a generic term applied to that form of work which is expended on any substance when its temperature is raised, it seems desirable that the thermal unit and the unit of work should be more closely allied.

The *watt* has been universally accepted as the unit of power; it is the unit rate of doing work. It is 10^7 ergs done per second.

Now, Sir W. Siemens at Southampton, 1883, proposed to call 10^7 ergs a *joule*. Hence, a watt or the work done by a coulomb or by an ampere flowing through one ohm for one second is a joule per second, and there would be 4·2 joules in one calorie.*

Thus, ·2381 gramme of water raised one degree, or one gramme of water raised ·2381°, would equal one joule.

We cannot, unfortunately, avoid the use of a coefficient. The arbitrary character of the degrees of temperature prevents this, but the relations between the quantities are very simple.

One joule = 10^7 ergs = ·24 calorie.

One watt = one joule per second = ·24 calorie per second.

One calorie = 4·2 joules = 42,000,000 ergs.

One British thermal unit (pound-water degree F.) = 1,058, joules = 252 calories.

Let us take a glow lamp having the following elements:—

	C.-G.-S. units.	Practical units.
E.M.F.	$= 100 \times 10^8$	100 volts.
R.	$= 200 \times 10^9$	200 ohms.
C.	$= \cdot5 \times 10^{-1}$	·5 ampere.
E.C.	$= 50 \times 10^7$	50 watts.
Candle-power		20 candles.

$$H = \frac{C^2 R}{J} = \frac{\cdot0025 \times 200 \times 10^9}{4\cdot2 \times 10^7} = 12 \text{ calories.}$$

Thus, 50 watts develop 12 calories per sec, 4·2 watts develop 1 calorie, 1 calorie per sec. develops 1·7 candle.

It is quite clear that the acceptance of the joule will facilitate many calculations, and prevent much confusion. While on this question, it is well to point out the extreme inconvenience that is rapidly increasing owing to the incessant necessity for using C.-G.-S. units in magnetic questions, through our having the ampere and the C.-G.-S. unit current different. This is the consequence of having accepted the volt as equal to 10^8 instead of 10^9 C.-G.-S. units.

The result is that the ampere is one tenth of the C.-G.-S. unit current.

The only reason ever given in favour of the accepted volt is that it is very nearly the electromotive force of a Daniell's cell. This was a good reason twenty-five years ago when telegraphy was the principal practical application of electricity; but now, when we are rapidly extending the applications of electricity in all directions, when we are using higher multiples of volts every year, the time has come when we should seriously consider the advisability of making the volt 10^9 instead of 10^8 C.-G.-S. units of *electromotive force*, and so make the ampere and the C.-G.-S. unit of current the same.

Again, it is perfectly clear that 106 centimetres of mercury at O°C. 1 square millimetre in section is only a very rough approximation to the true ohm, and that 106·3 would be a much closer approximation, and be very nearly the truth. The roughness of the approximation of the legal ohm has prevented its general acceptance, and there will be no universal acceptonce of one and the same unit of resistance until we agree on the value of the true ohm.

The legal ohm was accepted in 1883 provisionally for 10 years.

There will be a congress of electricians in Paris next year, and if we English electricians proceed there, armed with the opinion of the British Association Committee that 106·3 C.M. in their opinion more nearly represents the true ohm, and that the volt should be made equal to 10^9 C.-G.-S. units of electromotive force, it would have very great weight in the final determination.

It is most desirable also that we establish and name unit magnetic field, but whether this is to be based on the C.-G.-S. units or on the practical units must remain open for consideration and discussion.

There is one other point to which I wish to direct the attention of the committee; it is the value of the standard of pure copper.

We have hitherto accepted implicitly Matthiessen's standard. According to his experiments the specific resistance of a cubic centimetre of pure copper at 0°C. is 1,642 C.-G.-S. units; but this is known to be about 3 per cent. wrong, and it is most desirable that experiments should be made to determine the proper figure. The resources of the Cavendish laboratory, where so much good work has been done, might be devoted to this desirable work.

I recommend (1) that the practical unit of work 10^7 ergs be called the *Joule*; (2) that experiments be made to determine the specific resistance of pure copper.

THE SPECIFIC RESISTANCE OF PURE COPPER.*

BY WALTER T. GLOVER.

The introduction of the electric light, whilst effecting many improvements in electrical manufactures, is in one essential particularly aided in developing an improvement which had already commenced, and which had been principally initiated and carried on by the development and extension of submarine telegraphy. The increased length of submarine cables, drawing attention to the necessity of decreased resistance in the conductor employed, naturally brought with it as the result of most careful testing, a more perfect system of smelting, and the production of a quality of copper of greatly increased purity, as this necessity became apparent and was insisted on. Whilst the original cables submerged in 1853-4 between England and Holland had a conductor consisting of solid copper wire, with a conductivity of about 50 per cent. of pure copper, the latest form of submarine cables now possess a conductor equal to and exceeding 96 per cent. of pure copper.

The special attention given to the electrical quantities of the copper wire used for telegraphic and telephonic external work has tended in the same direction of obtaining a material of greater electrical efficiency, and lastly the electric light has still further added a strong stimulus to the smelter and to the wire manufacturer to produce a metal of the best possible conductivity. It can be well understood of what great importance a difference of two or three per cent. of conductivity of an electric light cable would make in the economical working of an installation. An increase in the resistance of an electric circuit of two or three per cent. may practically be assumed to mean a corresponding increase in the cost of the production of the motive power, and an increased item of the general expenditure for maintenance.

The lowness of the conductivity of the copper conductor must be met by the increased cost of construction by employment of a larger conductor, or by the increased cost of maintenance. These results have, however, been avoided by the great improvements in manufacture, whereby a material is now produced of a much higher specific conductivity than was formerly thought possible for ordinary commercial use.

This result has produced an apparent anomaly, for it is now not unfrequently the case that "hanks" of copper wire are manufactured which, on undergoing careful tests for conductivity at the works where they are to be used, are actually found to possess a *higher conductivity* than that assigned to absolute pure copper of the same gauge.

Numerous instances of this fact were given by Mr. Willoughby Smith in a communication addressed by him to the Society of Telegraph Engineers and Electricians some time back, in which some samples came out 4 per cent. in excess of the standard of pure copper.

If these were isolated cases it would not be immaterial to suppose that some error had occurred in the tests; but similar observations have so often been noticed that one is inevitably led to the conclusion that the standard usually accepted as that represented by pure copper must be an erroneous one, and one which should require recalibration.

* The Committee decided to call the C.-G.-S. thermal unit a "therm," to avoid the confusion arising from the use of the calorie.

* Paper read before the British Association meeti (Section A), at Bath, September, 1888.

Digitized by Google

A reference to various text-books, tables, &c., all show that whilst a certain amount of difference exists in the various standards given, as the base of the tables, there is a general unanimity in describing the standard as obtained from determinations by Dr. Matthiesen. The experimental investigations by Dr. Matthiesen into the specific conductivity of the various metals were carried out more than 15 years ago, and it is evident that the quality or purity of the metal experimented with at that time was, as regards copper, different from the quality or the purity which can be obtained at the present time. The table produced by my firm, and which has been found everywhere a most useful help in electrical calculations and observations, is based upon one of Dr. Matthiesen's tests, but owing to the present quality of copper produced it represents more nearly commercial copper than that which is considered as absolutely pure copper. The question of the wire gauge having now been definitely settled in favour of the Board of Trade Standard Wire Gauge, I feel that the British Association for the Advancement of Science may with the greatest advantage to both the scientific and commercial worlds, advance a step further in this direction by instructing their Committee on Electrical Standards to at once commence a series of definite experiments to determine what is the specific resistance of pure copper. We shall have the greatest satisfaction, being large manufacturers of every variety of copper conductors for electrical purposes, in supplying the committee with all their requirements so far as this metal is concerned, and as the experimental investigation must of necessity be carried out at some considerable expense, and not being aware of how far the finances of the Association will enable them to place a grant at the disposal of the committee, we wish to mark our sense of the great scientific and commercial importance of this undertaking by contributing towards the determination of an authorised standard of the "specific resistance of pure copper."

On the final determination of this standard we would pre-prepare suitable tables, based on the British Standard Gauge, which should be available for all branches of the profession for reference and calculations.

COMPARISON OF GASSNER'S DRY CELLS WITH LECLANCHE'S.*

BY WM. LANT CARPENTER, B.A., B.SC.

Shortly after their recent introduction into England two of Gassner's dry cells—a round and a flat form—were brought to the Hanover-square School of Electrical Engineering, with a request that they should be carefully tested and compared, under varying conditions, with the No. 2 size Leclanché cell. The E.M.F.'s were taken by Law's condenser method, and the internal resistances were measured by Kempe's method, the shunt employed being 1 ohm. The results for the round Gassner cell were respectively 1·317 volt and 0·205 ohm, and for the flat form 1·52 volt and 0·7 ohm. No attempt was made to determine the composition of the contents of the cell, which consisted mainly of a yellow, opaque, somewhat stiff, jelly, remarkably constant under varying conditions of atmospheric temperature and humidity; hence the cells could be placed in any desired position (on their side, for example), a great convenience where space is limited.

The flat form and a No. 2 Leclanché were each circuited through 10 ohms, and the fall in potential difference observed at frequent intervals for three hours. The curve representing the rate and amount of fall of the dry cell was much more regular, and showed a total fall somewhat less than that of the Leclanché. Both cells, after six days' interval, were short-circuited through 2 ohms for 2 minutes, and their recovery from polarisation observed at frequent intervals for 65 minutes. This caused a fall of 0·21 volt in the dry cell, and of 0·552 volt in the Leclanché. The recovery curves showed that while the flat cell recovered 85 per cent. of this loss in 6½ minutes, and nearly the whole of the remainder in the succeeding 10 minutes, the Leclanché required 18 minutes to recover the same proportion of its loss, and 30 minutes to arrive at the same E.M.F. as the dry cell. The latter, however, scarcely altered appreciably afterwards, while the Leclanché continued to recover slowly for some hours.

The two dry cells and two No. 2 Leclanché cells were then short-circuited through one ohm for one minute, and frequent throws of the galvanometer were taken to determine the respective rates of recovery from polarisation. The results were very similar; both dry cells recovered the greater part of their lost E.M.F. in seven minutes, and the subsequent recovery was very slow, while the two Leclanché cells required at least double the time to recover in the same proportion.

The resistance of a ringing bell, determined by the reproduced deflection method, was ascertained to be 20 ohms. The same four cells were then circuited through 20 ohms for 168 hours each, and observations of their potential differences were made, with the annexed results.

Four cells, circuited through 20 ohms.

90 8	1·30	1·23
114 0	1 33	1·24
117 0	1·34	1·25

Considering the whole of these results, it appears that the round form of Gassner's dry cell polarises less than a No. 2 Leclanché, and is also of considerably lower internal resistance (the average value being about 0·25 ohm); further, that although the dry cell takes somewhat longer to completely recover its E.M.F. when the circuit is opened, the rate of recovery is more rapid than that of the Leclanché for the first five or ten minutes. The flat form of dry cell appears to behave in most cases not quite so well as a No. 2 Leclanché, the internal resistance being about the same—0·6 ohm. I should add, in conclusion, that the measurements here described were made under the superintendence of Mr. E. C. Rimington.

ELECTRICITY AS APPLIED TO MINING.*

BY FRANK BRAIN, M.E.

This is a Paper, from the mining engineer's standpoint, briefly sketching the known applications of electricity to mine working up to the present time. The writer regrets there is little to add to what has already been made public. He cannot but express surprise that a power which it is apparent has now passed the range of experiment, and is developing itself economically and efficiently, should not have been made greater use of than appears to have been the case hitherto.

The recommendations of the Mines Commission, and the passing of the more stringent Coal Mines Act of 1887, both have stimulated mine managers to inquire into and recognise the advantages of electricity for blasting and lighting.

By means of a small hand magneto battery and electric fuses all the shot firing in most of the fiery collieries is now done, the explosive used being one of the many lately introduced, which, fired by an electric detonator, gives off no flame. Dynamo machines at many pits are used for lighting the surface and main roadways of the colliery, and this current has been also used for the purpose of shot firing, notably, at Ynyshir Colliery, Rhondda Valley, South Wales. All the shots are fired in this way simultaneously, with every man out of the pit, thus putting loss of life beyond possibility.

This adaptation, it should be said, however, is protected by a patent. The adoption of the electric lamp in place of the well-known safety lamp is now very strongly advocated. There are several in the field, notably the "Swan" and "Pitkin" secondary batteries, and the "Schanschieff," a primary battery.

The South Wales Institute of Engineers (who have referred the matter to a Special Committee), with other kindred societies, have lately had these and other lamps put before them, and several colliery engineers are practically testing them.

One, Mr. G. W. Wilkinson, of Risca, has in use daily several hundreds, and so satisfied is he with their results that he has ordered a further number for other of his collieries.

The lighting of the main roadways by electricity is common in many mines.

Mr. Sopwith, of the Cannock Chase Collieries, who it will be remembered read a Paper in connection with the 1886 meeting of the British Association on the subject, informs the writer his plant, which has since been extended, continues working well. He has lately introduced large accumulator cells to supply twelve volt lamps in various parts of the colliery workings, where moisture and a very bad roof had to be contended with. He found there was no difficulty with the "leads," and the result was in every way satisfactory.

The applications of electricity to transmission of power are confined to a few collieries; so far as the writer knows, in Great Britain to three only, viz, Trafalgar Colliery, Forest of Dean; St. John's Colliery, Normanton; and Allerton Main Colliery, Leeds.

At Trafalgar what was a very small pumping plant started in December, 1882, developed in May, 1887, into three sets of plant doing the greater part of the underground pumping of the colliery.

As the writer has been directly concerned in the working of this plant a brief description of the last installation may be interesting.

The pump, a double-throw 9in. plunger, with 10in. stroke, is fixed 2,200 yards from the generator and 1,650 yards from the bottom of the pit-shaft. The pipe main is 7in., and at a maximum speed of 25 strokes the pump lifts 120 gallons per minute 300 feet high. It is geared 6 to 1, the small pinion being driven by a belt from the motor (an Elwell-Parker). Current is conveyed to the motor by a conductor of 19 No. 16 wires, insulated and carried on earthenware insulators. An old 4in. iron-wire rope serves for the return current. The current is 43 amperes, and the E.M.F. 320.

The cost of engine and electric plant was £644. The weekly cost of maintenance, allowing 15 per cent. for interest and depreciation on plant, £7. 17s., or ·002 of a penny per horse-power per hour, and the economy effected about £500 per annum. The power lost and useful effect in the different stages is as follows:—

INDICATED H.P. OF STEAM ENGINE, 29·49.

Received by	Loss in	Useful effects.
H.P.		
Generator 23 00	Steam engine..22 per cent.	78 per cent.
Cables 18 44	Generator.....20 ,,	80 ,,
Motor..... 14 99	Cables .....20 ,,	80 ,,
Pump..... 11·99	Motor .....20 ,,	80 ,,
Water 10 36	Pump .....14 ,,	86 ,,

The efficiency obtained throughout is only 35 per cent., but it will be noticed the engine, which is an old one, loses 6·49 horse-power, or 22 per cent. alone. This plant has worked daily since May, 1887, without interruption, and is giving every satisfaction.

At St. John's Colliery, Normanton, 39 gallons per minute are raised 530ft., equal to 6·3 horse-power work done. This is with an old girder engine, which indicates 14·2 horse-power. The efficiency, therefore, is 44·4 per cent.

* A Paper read before the British Association meeting (Section G) at Bath, September, 1888.

Digitized by Google

This plant commenced working in the latter part of 1887. In the early part of this year (1888) so satisfied were the owners of the colliery with its working, that they laid down what is at present the largest electrical pumping plant in England. 120 gallons per minute are raised 900ft., equal to 33 horse-power nearly. The engine has not been indicated, which is to be regretted; but there is an output of 53 horse-power from the generator, so that the efficiency, comparing the actual work done with the output of the dynamo, is about 62 per cent. The current averages 66 amperes with an electromotive force of 600 volts. Immisch motors are used here. These extensions speak for themselves.

At Allerton Main Colliery very small quantities of water are being dealt with at inaccessible points, the power being taken to the motors in secondary batteries charged at the surface and conveyed in the colliery tubs.

Mr. Blackburn, the manager of these collieries, has also in work a coal-cutting machine. The motor is carried upon the bed-plate of the machine, a rotary motion being transmitted to the shaft carrying the cutter bar through gearing. The current is conveyed to the coal face from the dynamo machine placed on surface by flexible cable.

On the Continent we have underground haulage at Zaukerode Colliery in Saxony, which has been successfully and economically working since 1882. The distance from the dynamo—a Siemens and Halske—to the working level is 300 yards, and the total length of the line is 700 yards. The current is carried by well-insulated conductors to angle irons, which run along the roof of the roadway, and from which the current is taken to the motor carried upon the locomotive. A full train is 15 tubs, each containing 10 cwt., and the locomotive weighs 30 cwt. The speed varies from five to seven miles per hour. The total cost of plant was about £800, and the cost of working about three farthings per ton.

At Paulus and Hohenzollern Colliery, in Upper Silesia, a similar plant has been working since 1884. The distance from the dynamo to the working level is 250 yards, and the length of the line 820 yards. The current is conveyed as at Zaukerode. The full train is 16 tubs, each containing 10 cwt., and the locomotive weighs 42 cwt. The cost is about one halfpenny per ton, or one-half cheaper than horse transport. A similar arrangement is also working in the salt mines of New Stassfurt and at Salzberg works. At New Stassfurt tail rope haulage has been applied.

In Australasia the writer can only trace one application, and that is at the Phœnix Gold Mines, Skipper's Creek, New Zealand. Here two Brush dynamos, driven by two Pelton water wheels, generate about 52 horse-power. A No. 8 B.W.G. copper wire, on telegraph poles, conveys the current over a mountain 800ft. high, a distance of some three miles, to a Victoria motor, which drives 20 stamp-heads (each of 8cwt.), at the rate of 70 blows per minute, and it is said to be powerful enough to drive thirty heads. The loss in transmission is stated to be about 3 horse-power only.

In America the use of electric motors is much more extended than with us. The electric light companies hire them out for varied purposes, their large central lighting stations enabling them to do this to great advantage. Horses on street tramways are being fast replaced by the electric locomotive. For example, in one city alone, Richmond, Va., with grades of 3 to 10 per cent., 200 cars driven by Sprague motors on the overhead conductor system are running daily, carrying some 80,000 passengers per week. It is stated the economy as compared with horses is 25 per cent. on gross receipts. It is but lately attention has been turned to mine work, but now that they have commenced with the push and spirit of enterprise which is a distinguishing feature with American engineers, we find them making great progress.

At Silver City, Idaho, a Sprague motor is driving a 50-stamp mill four miles away from the generator. The latter, which gives off 75 horse-power, is driven by a turbine. It is stated by the manager of this mine that he saves in the haulage of his ore alone $90 per day.

At Veteran Tunnel, Aspen, Colorado, two sets of rope haulage drums are working with 10 horse-power Sprague motors, and a third is being erected.

These draw six trams at the rate of 500 feet per minute up a three-per-cent. grade.

The Lykins Valley Coal Company, at the Short Mountain Colliery, Pa., in the autumn of 1887 started an electric locomotive, which has since continued doing good work. The motor, a 25 horse-power Schlesinger, is connected to the locomotive wheels by chain gearing, and after six months' running the teeth of the pinion show but a wear of $\frac{1}{64}$th of an inch. It receives the current through a side conductor from a 50 horse-power generator. The length of the track is 6,300 feet, and it is hauling daily, at a speed of from six to eight miles per hour, some 500 tons per day. The time taken to make an all-round trip is about 14 minutes, as compared with 50 minutes when mule power was employed. The most stupendous set of electric mining plant in existence, so far as the writer knows, is now working at Big Bend Tunnel Camp, Butte County, California. A tunnel, 16ft. by 12ft. and $2\frac{1}{3}$ miles long, is cut from the Feather River through the mountain. A permanent dam is built across the river just below the head of the tunnel, by which the river is diverted from its channel and made to flow through the tunnel, thus drying up the bed of the river. A canal two miles long is constructed from the tail end of the tunnel, by which a fall of 300ft. is obtained. Here powerful Pelton waterwheels are fixed driving the dynamos (Edison's).

The working electromotive force is 1,000 volts, the conductors are double metallic, and extend a distance of 18 miles, delivering electricity at 14 different points in the circuit where power is required for winding, pumping, &c. Some 10 to 20 Sprague motors, varying from 5 to 50 horse-power, are worked by branch conductors from these various stations. The potential at the motors varies from 500 to 700 volts. It is apparent where water-power can be thus applied that the saving, when compared with the use of fuel, is very considerable, especially so in metal or diamond mining districts, where coal is expensive. The ease with which any power can be conveyed over hill and dale and into the intricacies of the mine—these are factors of no mean importance. It will be seen by this review of the more important applications of electricity to mining at present in existence how very little progress, comparatively speaking, has been made in this respect; and yet it is proving in every instance where it has been adopted a commercial success, and its application has invariably been extended. No doubt want of familiarity deters some engineers. They look upon electricity as a new idea, a something which cannot be explained, and as not to be relied upon when compared with steam, compressed air, water under pressure, and other well-known applications of power. The drawbacks and shortcomings of these are admitted, but yet they are preferred because of their certainty of action and known properties. Many look upon electricity as yet in a transition stage, but it is not so. The efficiency of the machines is now so great, the price so moderate, and men of such high standing and repute are now engaged in their development that there need be no fear or hesitancy. Electricity has passed beyond the range of theory and experiment. It is now a power in the world, and that power will increase mightily. The writer will be amply repaid if by the perusal of this *résumé* any of his fellows are induced to take up the matter for themselves. He is satisfied that under many conditions common in mine working electricity can and will be applied successfully and economically.

ELECTRO-CALORIMETRY.*

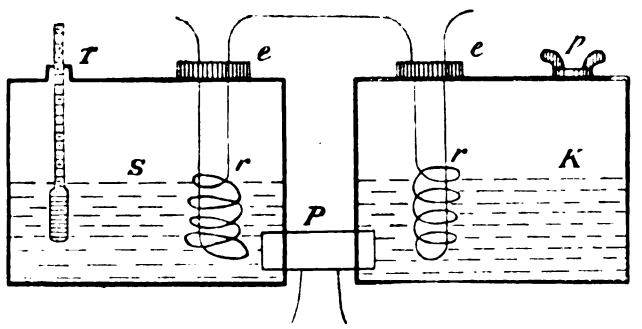
BY WILLIAM STROUD, D.SC., B.A., AND W. W. HALDANE GEE, B.SC.

Experiments have been continued, both at Owens College and the Yorkshire College, with the electrical method of measuring the specific heats of liquids, described at the B.A. Meeting at Manchester. The apparatus now adopted is shown in the figure. The calorimeters K and S are employed. They

* Abstract of a Paper read before the British Association meeting at Bath (Section A), September, 1888.

Digitized by Google

are cylindrical vessels of thin hard-rolled sheet brass. In each is a resistance coil, *r r*, of insulated platinised wire, fitted in the vessels by means of screw plugs, *e e*, of ebonite. The calorimeter S, called the standard, contains a thermometer, T, whilst K is the working vessel, provided with a screw plug, *p*, for the admission of a pipette, used in changing the quantity of liquid. Connecting S and K is a thermopile, P, made of iron and German silver wire All the fittings are by screws, with leather washers, or by India-rubber tubing, so that leakage and evaporation are entirely avoided. Instead of the compli cated methods formerly adopted for agitating the contents of the calorimeters the very simple and exceedingly effective one of shaking the vessels themselves has been employed. For this purpose the calorimeters are enclosed within a suitable box, so as to be easily rocked or shaken.



The authors discuss fully the ways of adjusting the rates of rise of temperature when electrically heated, so that these rates may be made as nearly as possible equal. This may be effected by shunting one of the coils or by adjusting the amount of liquids in the calorimeters. The latter method is found the best. For the elimination of small errors, methods analogous to those adopted in accurate weighings may be employed. Either a method of reversal or a method of substitution may be followed. The latter, by far the more preferable method of the two, is conducted as follows :—Equal quantities of water of mass *m* are at first placed in both calorimeters. After adjustment to equal temperatures the current is passed through the coils, thereby imparting to the calorimeters nearly equal quantities of heat. The difference of temperature $d\theta$ at the end of the period of heating is observed by the thermopile, and the total rise of temperature σ is also noted in the thermometers. Next the water in K is replaced by the liquid *m*, whose specific heat *d* is desired. This liquid should be approximately equal in thermal value to the water previously in K. A second electrical heating now enables the correspondiug quantities $d\theta'$, $d'\theta$, to be ascertained. It can then be shown that the formula $\sigma = \frac{m}{m_1}\left(1 + \frac{d\theta}{\theta} - \frac{d\theta'}{\theta'}\right)$ is applicable. There is no correction for cooling, for the capacities of the vessel, or for inequality in resistance of the coils. Since $d\theta/\theta + d\theta'/\theta'$ may be small, the method is not dependent for its accuracy on thermometers, and hence a much higher degree of accuracy is attainable than is possible by the older methods.

LETTERS FOR LEARNERS AND UN-PROFESSIONAL READERS.

BY H. D. WILKINSON.

Section II.—Electro-Magnetic Fields.

(Continued from page 629.)

130. *Intensity of Magnetisation.*—An important branch of research tending to further the improvement of electrical apparatus and machines as well as to offer one of the most interesting fields for experimental investigation is that in which the relation between magnetising force and the resulting magnetism in different metals is studied. We shall refer later to some of the work which has been accomplished in this direction, but must first concern ourselves with the necessary fundamental bases on which comparisons can be effected in the degree or extent or quantity of magnetism acquired by masses of iron or steel, differing in dimensions and shape, when subjected to the action of magnetic fields of given intensity.

The two fund mental bases of comparison may be stated as:

1. The magnetic moment acquired per unit volume of metal, and termed the "Intensity of Magnetisation" (denoted by the letter I).

2. The number of lines of force per square centimetre of sectional area, forced through the mass of the metal, and called the "Magnetic Induction" denoted by the letter B). These two quantities were written in old English letters ℑ and 𝔅 by Prof. Clerk Maxwell, and the student will find them frequently written so in writings on the subject.

We shall now consider the first of these means of comparison. The conception of the idea of "intensity of magnetisation" is essentially one in which the strength of pole or amount of "free magnetism" is thought of. That is to say, the extent of the magnetism in the mass is expressed or thought of with regard to the force of attraction or repulsion that can be exerted by its poles externally. The "action at a distance," or force exerted by a given pole strength, has been discussed already (para. 108), and it can be easily understood that we may have a number of bars of iron, of very different sizes, all of which exert the same external force, *i.e.*, have equal pole strengths, but in which the magnetism is distributed in very different proportions; or again, magnetised bars of similar size may have very different pole strengths. To effect comparisons, then, between the densities of magnetism—if one may so use the term—acquired by different bars, the pole strength is regarded as so much "free magnetism" distributed uniformly over the ends (shaded portions Fig. 110), and a comparison

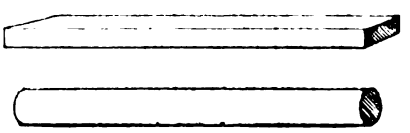


Fig. 110.

can then be made by finding for each bar what amount of free magnetism, or pole strength, exists at its ends *per square centimetre of sectional area.* This is termed the "intensity of magnetisation," or sometimes simply "magnetisation," and is obviously the same as magnetic moment per cubic centimetre. Take a bar 10 centimetres long and 2 square centimetres sectional area. If its pole strength is 1,000 C.-G.-S. units, the intensity of magnetisation is found by

$$\frac{\text{pole strength}}{\text{sectional area}} = \frac{1000}{2} = 500 \text{ C.-G.-S. units};$$

that is, for every square centimetre of end area there are 500 units of pole strength. It is evident that if we multiply both numerator and denominator of the above by the length, we have

$$\frac{\text{magnetic moment}}{\text{volume}},$$

which is, therefore, the same thing, and has the same value, and gives us the usual definition for the intensity of magnetisation, viz., the magnetic moment per unit volume (per cubic centimetre on the C.-G.-S. system). Obviously this is the more generalising definition, as it covers irregularity of sectional area. As an example of the comparison of magnets of the same size but of different pole strengths by their intensities of magnetisation we may take the two magnets already mentioned (para. 125, examples 3 and 4), which were found to have pole strengths of 554 and 527 C.G.S. units respectively. They were flat bars, measuring at the end 2·8 centimetres by 1·3 centimetre, and therefore of $2{\cdot}8 \times 1{\cdot}3 = 3{\cdot}64$ square centimetres sectional area, uniform throughout. Their intensities of magnetisation were therefore

$$\frac{554}{3{\cdot}64} = 152 \text{ C.-G.-S. units}$$

and

$$\frac{527}{3{\cdot}64} = 145 \quad \text{" "}$$

Digitized by Google

The intensity of magnetisation reached when soft iron is subjected to powerful electro-magnetic fields may be very much higher than the above, even to values nine or ten times as high, although the above are average intensities ordinarily met with in new steel *permanent* magnets.

To further illustrate this method of comparison the following measurements taken with wrought and cast-iron bars are cited. A constant difference of potential of 42 volts was kept at the terminals of the magnetising coil (Fig. 111), which was

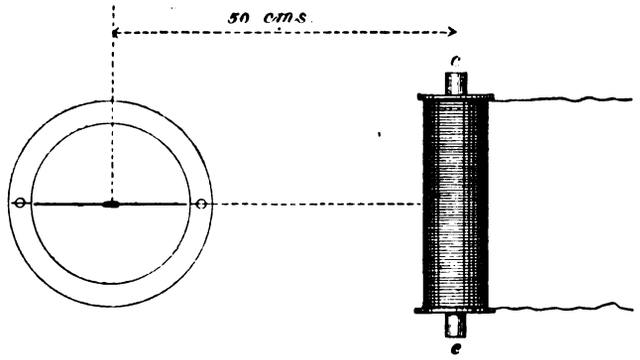

FIG. 111.

one of those previously described (para. 129, Fig. 109), the current, and therefore the magnetising force, being twice as much as that previously given for the two coils together under the same potential difference, viz.,

$$670 \times 2 = 1340 \text{ ampere-turns, approximately.}$$

We shall show in the next section on the magnetic fields of coils without cores, or solenoids, that the magnetising force expressed in C.-G.-S. units (lines of force per square centimetre) at the central cross section of a long solenoid of length l centimetres, and excited by a current C, in C.-G.-S. measure is equal to

$$\frac{4\pi C n}{l} \text{ C.-G.-S. units intensity of field,}$$

the length of the solenoid being great compared to its diameter, and forming a long narrow coil. We anticipate, however, for the purpose of showing the relation between ampere-turns and C.-G.-S. units of magnetising force. The C.-G.-S. unit is equal to 10 amperes, so that if x ampere-turns are equal to one C.-G.-S. unit we have

$$\frac{\text{ampere-turns}}{x} = \text{field in C.-G.-S. units,}$$

and therefore

$$\frac{10\,C n}{x} = \frac{4\pi C n}{l}$$

(C being in C.-G.-S. units on both sides of the equation),

whence

$$x = \frac{10\,l}{4\pi} = \frac{l}{1{\cdot}257},$$

and therefore

$$\text{field in C.-G.-S. units} = \frac{\text{ampere-turns}}{\text{length of coil (centimetres)}} \times 1{\cdot}257.$$

In the above example, therefore, which is a coil 18·5 centimetres in length, instead of 1,340 ampere-turns of magnetising force, we may put it

$$\frac{1340 \times 1{\cdot}257}{18{\cdot}5} = 91 \text{ C.-G.-S. units.}$$

The magnetising force is usually denoted by the letter H, or in Maxwell's notation by its old English form 𝔄.

It will be noticed that the electromagnet is placed, as previously described, for measuring the moment by the first method of Gauss (para. 125), the distance of its centre from that of the magnetometer needle being 50 centimetres. First of all, before putting any core in the coil, its own field with the current on was measured. This deflected the magnetometer 11 divisions, and therefore in the measurements of the moments of the cores this deflection was deducted from the readings. Three cylindrical cores similar to C C, Fig. 111, but of different dimensions, were tried, with the following results :—

Cores.	Length in cms. (l).	Diam. in cms (d).	Magnetometer deflection.	Moment in C.-G.-S. units (M).	Intensity of Magnetisation (I).
I. Wrought Iron	30·7	2·3	420	106,300	833
II. Ditto	25·9	1·9	280	67,210	881
III. Cast Iron ...	30·8	2·3	280	69,350	541

Here the dimensions of core differ, and therefore the magnetometer readings and calculated moments offer no basis of comparison as to the density of free magnetism acquired by each. This is seen notably in the last two cores, where the deflections are equal, and the moments not very widely different ; but the intensity of magnetisation, which forms the basis of comparison, shows one little more than half the other.

It may be of assistance to the student to see one of these examples worked out. Take the first :—

$$\tan \alpha = 4\,20 - {\cdot}11 = 4{\cdot}09$$

$$\text{Earth's field (H)} = {\cdot}18$$

$$r^3 = (50^2 + 15{\cdot}35^2)^{\frac{3}{2}}$$

and (*see* para. 125)

$$\text{Moment} = r^3 \text{H} \tan \alpha = 106{,}300 \text{ C.-G.-S. units,}$$

$$\text{sectional area} = \frac{\pi d^2}{4} = \frac{3{\cdot}1416 \times 2{\cdot}3^2}{4} = 4{\cdot}147 \text{ square cms.}$$

volume = area × length = 4·147 × 30·7 = 127·3 cubic centimetres, and Intensity of magnetisation

$$\text{I} = \frac{\text{moment}}{\text{volume}} = \frac{106{,}300}{127{\cdot}3} = 833 \text{ C.-G.-S. units.}$$

The low magnetisations obtained for the above-mentioned magnetising force are most probably due to the estimation of the number of turns of wire in the bobbin (para. 129) being too high. It was not wound specially for the purpose, and the exact length of wire and number of turns were not known. Further, no mechanical stress or blows were given to the iron while under the magnetising field, which would have increased the magnetisation acquired.

When the core is not of uniform sectional area, if its volume cannot readily be computed by direct measurement it may be determined for a large core by immersing it in water, and measuring the volume of water thereby displaced. Or, again, for a small core, such as a piece of iron wire, it may be found by weighing in air and then in water, the ratio of the weight in air to the loss of weight in water being the specific gravity, and, in the C.-G.-S. system the weight of 1 cubic centimetre of water at 4 degrees C. being 1 gramme, we have

$$\text{volume in cubic centimetres} = \frac{\text{weight (in air) in grammes}}{\text{specific gravity}}.$$

Substituting for specific gravity, we have

volume in cubic centimetres = loss of weight in water (in grammes).

The determination of the intensity of magnetisation is not confined to methods like the above, which have for their *modus operandi* the measurement of the external field of force of the magnetised bar, but may be calculated from the value of the magnetic induction B when that has been determined by a different method (presently to be detailed) and the magnetising force can be accurately computed.

The importance of the subject of electro-magnetism as regards our knowledge of iron and steel in various stages of magnetisation, may be conceived when it is borne in mind that most of the men whose names are most honoured amongst us, as much in some for their high scientific attainments as in others for their practical experience, insight, and intuition, have given to this field of research their careful thought and investigation, and that what we know and make use of to-day is the result of incessant experimental investigation extending over, in many cases, years of patient toil. It will be the aim of the writer to point out some of the most salient results arrived at, and to endeavour to render clear to the student the terms used in connection with this subject.

(To be continued.)

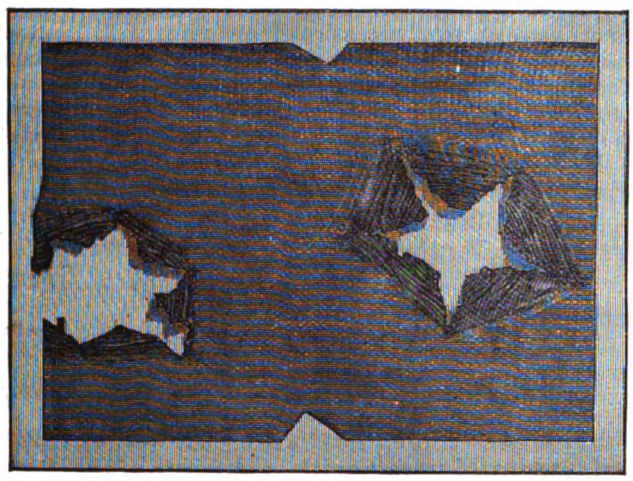
A DAMAGED LIGHTNING PROTECTOR.

The accompanying figure, taken from *La Lumière Electrique*, is a full-size representation of the sheet of paraffined paper which is placed between the line and earth plates in lightning guards of the gutta-percha sheet pattern. During the storms of July last the paper of the lightning guard at the Gréasque (Bouches-du-Rhône) office was perforated as shown. The perforations were nearly 30mm. across, one being very much like



a star-fish, while the other was not so well defined. On the plates there were blackened facsimiles of the rents, and in the centre of each black stain there was a bright spot formed by a drop of melted metal. Under normal conditions the paper is pierced only by one or two holes, such as would be made by a pin, these holes being surrounded by a black or a red aureola about 3mm. or 5mm. in diameter.

ELECTRIC TRACTION IN PARIS.

The following is a brief account of the electric tramway constructed at Paris by MM. Philippart Frères, and which runs between the Place de l'Étoile and the Porte Maillot :—

The current is furnished by a battery of 144 special twin-plate Faure-Sellon-Volckmar accumulators, having a capacity of 150 ampere-hours, with a 25-ampere discharge. Taking the mean useful voltage per cell at 1·8 volt, the total capacity of the battery is 37,000 watt-hours, or 50 horse-power-hours—that is to say, 40 horse-power-hours are practically available, permitting a 6-hour service without recharging. The accumulators are placed in the four recesses formed by the corners of the car, the 36 cells in each group being arranged in three tiers. This vertical disposition has several drawbacks : it adds to the length of the car, renders the inspection and manipulation of the cells very difficult, and dangerously raises the centre of gravity. In the new cars the cells will probably be

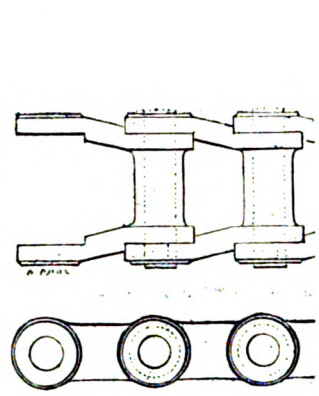


Fig. 2.

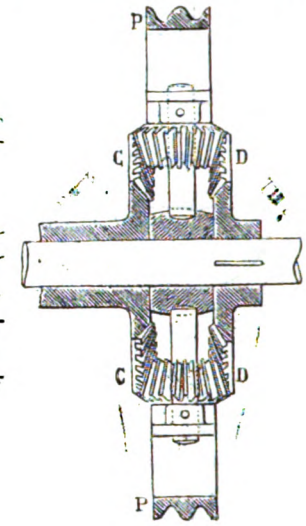

Fig. 3.

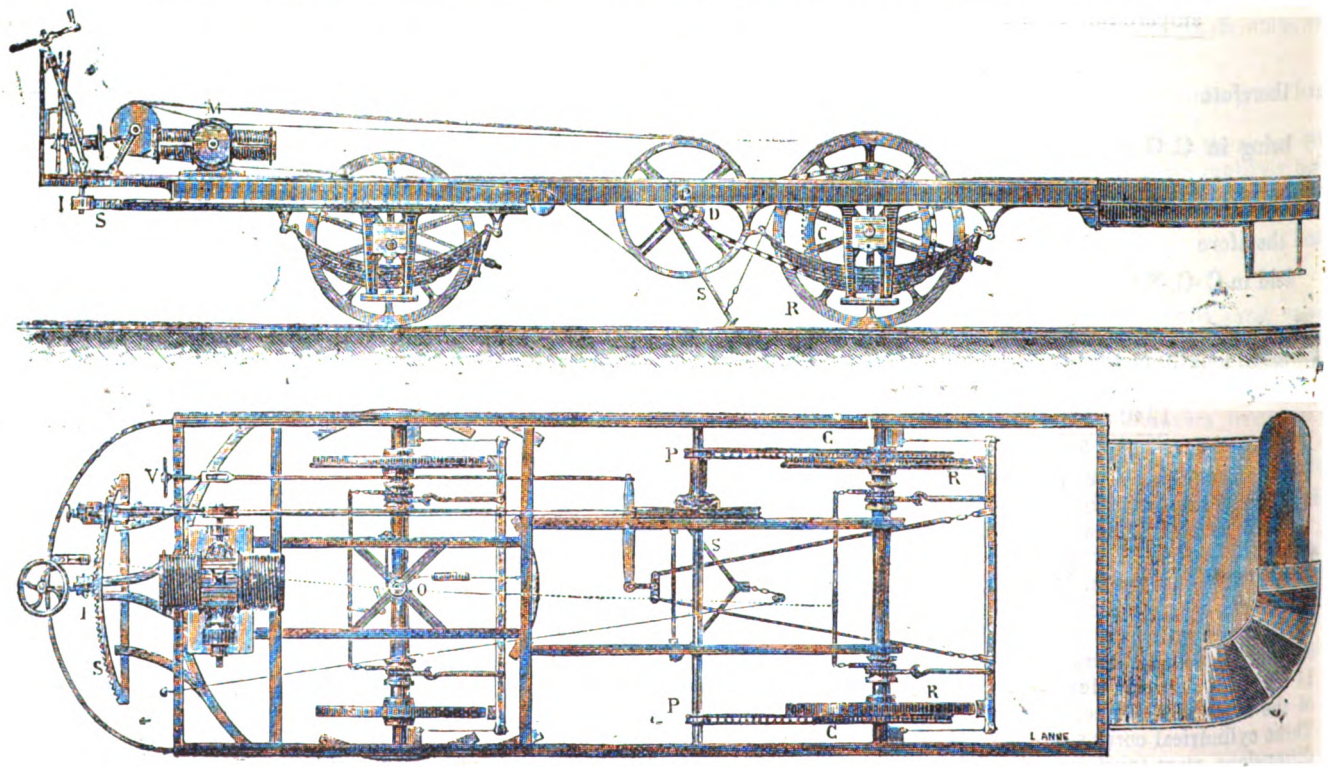
arranged in two rows under the seats. The total weight of a car with 50 passengers is about 9 tons.

Car	3·5 tons.
Accumulators	1·5 ,,
Machinery	·75 ,,
Passengers	3·5 ,,
Total	9·25 tons.

The electric motor M (Fig. 1) is a dynamo machine of the well-known Siemens type, running at from 1,000 to 1,200 revolutions per minute. This machine drives a countershaft, P, by means of a Raffard coupling. The motion of the pulley on the shaft P is transmitted to the driving wheels R by means of two Gall chains C C (shown in full in Fig. 2). The two wheels R are independent, each being driven by a special pinion, P. When running on the straight,



Electric Traction in Paris.—Fig. 1.

Digitized by Google

the two pinions P, and the two wheels R, which they actuate, run at the same speed, but when going round curves, owing to the differential arrangement shown in Fig. 3, the two angle wheels, C and D, can revolve at different speeds. The turning of curves is also greatly facilitated by the rotation of the front wheels round a vertical axis, O, a movement which is governed by the wheel V, the pinion I and the sector S. Thanks to these devices curves of the smallest radius are easily turned.

For purposes of alteration of speed and starting, the accumulators are divided into four groups. On starting the four groups are in parallel, and there is an available E.M.F. of about 70 volts. When running at full speed all the cells are in series. The sections can also be grouped by the turning of a lever, two in series and two in parallel, as well as three in series and the fourth section in parallel with these. The car is of course lighted by electricity, six 10 candle-power incandescent lamps being run off the accumulators.

THE TELEPHONE EXCHANGE OF NEW YORK CITY.*

BY F. F. SHERWOOD.

The Metropolitan Telephone and Telegraph Company has 7,300 subscribers, operated by eleven exchanges, which are furnished with the following systems:—John, Thirty-ninth, and Harlem Exchanges, Western Electric Multiple; Pearl, New, Nassau, Murray, and Twenty-first-street Exchanges use the Chinnock system; Spring-street the improved Chinnock system, adapted by Mr. Jos. P. Davis, formerly general manager of the company; Fulton and Beaver-street Exchanges use the Law system.

John-street Exchange has 799 subscribers, and 40 trunks distributed among them. Thirty-ninth-street Exchange has 1,108 subscribers and 39 trunks, and Harlem has 374 subscribers but no trunks, terminating outside of the trunk sections. The reason that we have trunks at the two former exchanges among the subscribers is to connect the system with points not accessible or convenient to reach with trunk-calling wires.

To operate the boards during the busiest hours requires the following number of operators:—John-street, 14 operators, 57 subscribers per operator; Thirty-ninth-street, 21 operators, 52 subscribers per operator; Harlem, 6 operators, 62 subscribers per operator. But counting the trunk wires according to the business done over the average subscriber's wire, will be equal to adding 73 subscribers to John-street and 70 to Thirty-ninth-street, thus increasing the average at John to 62 and at Thirty-ninth to 56. The reason we have a greater average at John and Harlem is that they are situated in the centre of the business district, while Thirty-ninth-street, being a manufacturing district, a larger portion of the business is trunk.

We are using what we term trunk calling wires between the various exchanges, one terminating at John-street and the other at Thirty-ninth-street, for calling all trunk connections to the exchanges named.

There is an average of 3,000 connections per day called over each of these wires, and as each connection is ordered off again, the number of orders is increased to 6,000. All this work is done by two operators at each of these exchanges, and could be done by one if the whole section of the board was within her reach. We divide the trunks, one half being used for receiving and the other half for sending. Those we receive on are not multiple through the board, but end in cords, and stand open at all times except when in use. When a number is called on any given trunk, the connection is immediately made, and is ready for ringing, this being done by the office calling, as we make the office where the call originates responsible for the connection. If the number called is busy, we throw battery on the trunk, dropping the annunciator as a signal. We find this system very advantageous, as there is no delay in calling or clearing trunk connections, and the service is made prompt, as shown by ten trunk connections made and conversation started with subscribers in six and one-half minutes.

At the exchanges which have the Chinnock system, each operator at the cases answers 100 subscribers and completes all local connections, using a local calling wire and a set of local trunks which connect all the cases together. The calls for trunk connections are written on slips of paper, and passed to the operators who control the trunks to the various exchanges. Ten trunk connections were made and conversation started through this system in twelve and one-half minutes.

The Fulton and Beaver-street Exchanges have, together, 410 subscribers, and are operated by nine operators and one chief operator. All local connections are completed by the operator who receives the call over the calling wire, and trunk connections are completed by the operator at the exchange for which the subscriber calls. The Law operator simply connects the subscriber's wire with the trunk wire, and rings down the annunciator, when the operator answers and ascertains from the subscriber the number wanted. The trunk connections made through the Law system were completed and conversations started in four and one-quarter minutes, ten local connections in two and three-quarter minutes.

The number of trunk wires connecting the exchanges in New York City is 532, and average 60 connections per day, and, as this average could be increased to 70 per day, the number of subscribers could be increased 600 without increasing the trunk facilities. To other exchanges we have 187 trunks, and with those the service is quite satisfactory, and especially so with the new Brooklyn Exchange of the New York and New Jersey Telephone Company, as the service is prompt and satisfactory in every particular.

By the consolidation of the seven exchanges in the new exchange at 18, Cortlandt-street, 206 trunks which connect those exchanges will be abolished, and the number of trunks to all other exchanges may be reduced, for the total number divided among the seven exchanges will not be required when they are all accessible to an operator in the new exchange.

The new switch-board at 18, Cortlandt-street, will soon be completed, and the consolidation of the seven exchanges made. It is wired for 5,100 subscribers' and 900 trunk wires. The subscribers' operators will attend to 50 or 75 wires, according to the business done at different sections of the board. Trunk calling circuits to the other exchanges will be in operation, each receiving trunk operator attending to 50 wires. The local battery of each operator's outfit will be two cells of storage battery, one to be in use during the day, and the other at night. The one in use during the day will be charged at night from the main storage battery, and the night battery will be charged from a dynamo during the day. All wires will approach the exchange through the underground system, the underground cables terminating in the cellar. From there they will be carried to the distributing board in the exchange by 334 conductor cables.

The consolidation of the several exchanges will be beneficial in many respects. The service will be improved, the great value of "sent" trunk business will be reduced from 20,000 to 8,000 connections, and the running expenses of the exchanges will be reduced about $2,700 per month.

1,527 miles of wires are now underground, and 2,784 separate wires are altogether or in part so working, most of which give general satisfaction. The underground facilities are rapidly increasing. 18 miles of 102 conductor cable running from 18, Cortlandt-street to various points are now completed, and will be used when the exchanges are consolidated. Eight and three-quarter miles of the same cable will soon be run for trunks from 18, Cortlandt-street to the other exchanges, thereby making the trunk service from this exchange entirely underground, and doing away with the delays and expense of crossed and broken trunks, and will do away with the danger of crosses with wires carrying a heavy current, which proved so costly in connection with the burning of the Thirty-ninth-street Exchange, on which a few remarks may be of interest.

On May 23 the Thirty-ninth-street Exchange was set on fire by a cross with a wire carrying a heavy current, and one and one-half sections of the board was burned out. The work of restoring the Western Electrical Multiple Board after it has been burned and saturated with water can only be appreciated by those who have had it to do. In order to straighten out the wires it was necessary to make 1,260,000 tests, to splice 9,600 broken wires, to replace 16 cables which were destroyed from the switch-board to the cupola, and dry out the saturated portion of the board. The work of getting the lines in complete working order was delayed by the accumulation of line trouble while the troublemen were working in the exchange, but the switch-board and all the lines were in complete order two weeks from the date of the fire.

* Paper read before the Telephone Convention in New York.

UNIVERSITY COLLEGE, LONDON: THE SCIENCE SYLLABUS.

We have received a copy of the syllabus of University College, from which we extract the following information relating to the electrical work in the Faculty of Science. Throughout the session Dr. A. H. Fison lectures to a junior class on "Experimental Physics," the following being the syllabus of the lectures on "Electricity and Magnetism:"—

MAGNETISM.—Characteristic properties of magnets. Magnetic substances; properties of iron and steel. Magnetic induction. Methods of magnetisation. Law of magnetic attraction and repulsion. Comparison of magnetic moments. Terrestrial magnetism.

Digitized by Google

ELECTRICITY.—(*a*) *Statical.* Conditions under which electrical effects are produced. Positive and negative electricity. Conduction and insulation. Law of electrical force. Induction; potential; capacity. Disruptive discharge.

(*b*) *Dynamical.* Conditions for the production of continuous electric currents. Galvanic and thermo-electric batteries. Electromotive force; strength of current; resistance. Heating and chemical effects of currents. Mutual forces between currents and magnets, and between currents and currents. Magneto-electric and volta-electric induction.

Prof. Carey Foster, F.R.S., and Dr. Fison also lecture to the Senior class on the same subjects.

The lectures in this class include the elementary mathematical theories of the chief branches of physics, and the discussion of the methods employed and results obtained in the quantitative study of physical phenomena.

The syllabus includes the following:—

MAGNETISM.—Quantitative study of magnetic phenomena.

ELECTRICITY.—Methods of measuring the most important electrical magnitudes, as Quantity, Potential Capacity, Specific Inductive Capacity; Electromotive Force, Strength of Current, Resistance; Coefficients of Induction—and discussion of their mutual relations.

In the department of Electrical Technology, lectures are delivered by Prof. J. A. Fleming, M.A., D.Sc. This course is intended as a supplement to the courses of physics and engineering, to provide for engineering students and others instruction in the subject of applied electricity, a department of technology of rapidly increasing importance. The lectures will be supplemented by visits to various practical works under the guidance of the Professor. The course will consist of about twenty-one lectures, and be arranged as follows:—

First Term.—Faraday's researches on electro-dynamic induction. The theory of electro-magnetic induction. The theory of the dynamo and of dynamo-electric machinery generally. Production of electric currents for purposes of electric lighting and locomotion. Direct and alternate current machines. Designing of dynamos for various purposes. Ship lighting. Isolated lighting. Central station lighting.

Second Term.—Distribution of electricity. Systems of underground and overhead conductors. Distribution by secondary generators. Arc and incandescent lamps. Electrical measurements. Electric photometry. Electric meters. Dynamo-electric motors. Transmission of power. Electric cars.

Third Term.—Primary and secondary batteries. Electrical distribution by accumulators. Electro-deposition of metals. Electro-fusion and metallurgy. Telephones and telegraphs. Electric bells, and recent applications of electricity.

The electro-technical laboratory is provided with a gas engine, dynamo, secondary batteries, and appliances for testing arc and incandescent lamps, and carrying out other practical electrical work. Students who have attended the lecture course, or who have obtained some preliminary acquaintance with the subject, can thus receive practical instruction in the various testing operations requisite in electrical engineering, and take part in the management of the electric lighting plant. The course comprises the testing of arc and glow lamps, measurements of various kinds, the calibration of electrical instruments, and the testing of electrical materials.

BOOKS, &c., RECEIVED.

"Bell's Asbestos Company's New Catalogue and Price List."

"Naval Reserves, Training, and Matériel." (Published by the Office of Naval Intelligence, Washington, June, 1888.)

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *September 22nd*, 1888.

Our Navy department has just issued a Red Book on Naval Reserves, training and material, which contains much matter of interest to electricians and electrical engineers. As you are doubtless aware, one of the means hit upon for spending the large surplus revenue of the country has been the rebuilding and reorganisation of the United States Navy, and it was about time that the work was taken in hand. Several new ships have recently been launched, and several others are in course of construction or are soon to be put in hand. Under these circumstances, it was eminently desirable that all the latest information from abroad as to the best forms of equipment, &c., should be obtained. This volume, which is No. 7 of the Annual General Information Series, is the result of inquiries in certain special fields, and it is a valuable contribution to the science of naval warfare. The part most interesting to electricians is comprised in Chapter V., specially prepared by Lieutenant J. B. Murdock, and dealing exclusively with the application of electricity on shipboard. The chapter discusses various ways in which electricity may be utilised in the reconstructed navy, and naturally abundant reference is made to English practice in this respect, the ships cited being the "Benbow," "Hero," "Camperdown," "Howe," and "Archer." Lieutenant Murdock calls attention to the various good points required in a ship electric lighting plant, such as compactness, simplicity, and efficiency, and under these various heads he has much to say that is interesting. He pronounces in favour of a slow-speed, compound dynamo, directly coupled to its engine. Such plants, he remarks, are almost universal in European navies, and seem better adapted by strength, simplicity, compactness, and general utility, to the conditions of naval use than anything else yet devised. He adds, however, that no American firm has as yet constructed slow-speed dynamos for the trade, although a few have been made for special purposes at a heavy expense. He furnishes a suggestive table to illustrate the difference at present existing between American and European dynamos on the basis of watt output per pound of dynamo. It is noticeable that although there are several European machines running at the rate of over 350 to 550 revolutions, there is not a single good American machine below 550. The American machine of lowest speed, the Bradley, has a speed of 550 revolutions, weighs 1,025lb., and gives the high output of 9·75 watts per pound. This is equalled in one case throughout the entire series, namely, by the Victoria H 3 machine, which, at a speed of 350 revolutions, and a weight of 3,700lb., gives 9·7 watts per pound. The Bradley is a multipolar machine. Coming to the question of engines, Lieut. Murdock bestows special commendation on the Westinghouse, as the best of the class of high-speed, double cylinder, single acting engines for all work where durability of plant is combined with lightness and economy of floor-space. Lieut. Murdock's chapter is also devoted to a consideration of the various problems connected with electric light wiring on shipboard, signalling, torpedo service, the use of storage batteries, and the use of electric motors. He is quite enthusiastic in regard to the excellent qualities of motors. In our own cruisers, he says, the first impression one receives is that of unnecessary complexity and confusion due to the large number of small engines distributed all over the vessels. The result of this use of steam is that the ship is a labyrinth of steam, exhaust and circulating pipes, which are always getting out of order, and which require constant care. Over and against the disadvantages of the use of steam he sets the many excellent qualities of the electric motor. He notes that for equal power the electric motor is smaller than almost any steam engine, is more efficient, involves less waste in transmission, has smaller mains, which are by no means liable to injury, and admits of very rapid repairs. In short, he holds the electric motor to be the most efficient, compact, noiseless, and simple vehicle for the transmission of energy that is known, and such being the case it is in its most rightful sphere on board ship. In this connection it may be mentioned that our new man-of-war "Chicago" is to have one of its 8in. guns operated by electric motor, and if this proves satisfactory, the use of motors will certainly be extended to others of the new vessels.

Some little while ago I sent you a few details as to the Craig Automatic Telegraph System which has been put on exhibition at the National Capitol. I said at the time that there would probably be some effort made to induce Congress to buy this system, as the nucleus of a Government telegraph service. Senator Blair has now taken the first step in this direction, by offering a resolution which provides for an examination of the system. He explained that if it was all that was claimed for

Digitized by Google

it, his idea was that it should be secured for the benefit of the people. He characterised the Western Union Company as a gigantic monopoly, owning practically every useful telegraph invention, and almost every telegraph line in the country. Against such a monopoly no redress was to be had, and the only hope, outside of the purchase of the Western Union plant at an extravagant valuation, lay in the introduction of such a system as the Craig, which could supplant the other at a comparatively slight expense. I do not think that Mr. Blair's ideas are likely to make any considerable impression on his colleagues or the country at large. In fact, most Americans, even those in favour of protection, would rather see free trade resorted to, even if a reduction of the surplus follow, than agree to such a remarkable method of using the surplus to put the Government into competition with private enterprise, and against property and capital which it has covenanted to protect. The Western Union Company is not an institution which is altogether lovely and of good repute; in fact, it has a reputation, in many circles, for ways that are dark and tricks that are mean, but it is yet to be shown that either the electrical profession or the public at large would prefer a Government monopoly of the telegraph, with all its new elements of political bribery, jobbery, intrigue, and corruption. As far as we are informed in this country, the Government telegraphs in England are admirably managed, and by clean-handed and able administrators; and yet such figures as are obtainable here show that the system barely meets its working expenses, failing altogether to pay any return on the investment which the country made in its purchase.

A good deal of interest is being manifested here in the subject of electric boats, and I should not be at all surprised to see a number of such craft afloat in our waters next spring. Attention has just been called to a novel electrical boat, which has been running very successfully this summer in Pennsylvania. She is in the form of a catamaran, and is equipped with storage batteries charged from the lighting plant of the yacht of her owner. She is very steady in water, and offers little resistance in motion, so that a small charge and a small motor are sufficient to propel her some distance at the rate of four miles an hour. The only trouble that hinders the introduction of electric boats is the want of charging stations, otherwise they would be found everywhere; but now that so many hotels at our seaside and other resorts are putting in electric light plants, this difficulty will be overcome.

Electric railways are still on the boom, and there is no hint from any quarter as to the time when they will cease to be so. The Sprague Company has just been calling attention, with not unjustifiable pride, to the fact that, although it was not turning a single wheel last February, it now has about a dozen roads running, and has just closed its 26th contract. The various contracts it has must certainly reach a total of not less than one or two million dollars. The Thomson-Houston Company also report themselves very busy with a score of roads in operation, and others building in New England, the south and the west. The Julien Company has just started off the first of its ten storage cars built for Mr. Vanderbilt's Fourth Avenue road in this city. These cars are 18ft. long, and are superb in all their fittings and appointments. The large windows are of bevelled plate glass, all the panels of the doors and the sides are of elaborate carved wood, and the cushions and curtains are such as one expects to find only in a Pullman palace car. In fact, the cars are altogether suggestive of first-class railway travelling, and the main criticism offered on them by electrical engineers, I am told, is that they are unnecessarily heavy for street railway work. Still, amidst so much that is flimsy and shoddy in construction, they err in the right direction, and I have no doubt that the succeeding cars, as they are put into service, will be lighter, though not less luxurious, it being understood to be Mr. Vanderbilt's intention to have the service on this line as pleasant and comfortable as it can possibly be made. The results obtained on the Fourth Avenue road are being watched by the citizens generally with the greatest interest, and one hears very little but good wishes on every hand for the success of the enterprise.

Electrical journalism, like everything else connected with electricity in this country, continues to show signs of development. The last evidence of growth is the issuance, in Kansas City, of a new journal called *The Electro Mechanic*. This makes the second electrical publication in the West. The *Mechanic* is a monthly of 20 pages, and devotes special attention to the commercial side of electricity. The appearance of this paper impresses very forcibly on the mind the wonderful growth of Kansas City, which a few years ago was no larger than a fair-sized village, but is now in wealth, population and commerce on terms of rivalry even with Chicago. It has an extraordinarily large number of telephone subscribers, is a large receiving and distributing point for telegraphs, and has a remarkably fine electric light service. The arc lighting there has been done with the Thomson-Houston system by Mr. E. R Weeks, vice-president of the National Light Association, and one of the most thorough and efficient men in the profession. At the present time Mr. Weeks is busy over the construction of a large incandescent plant which is to supply Kansas City with some 30,000 lights, and upon which $150,000 or $200,000 will be spent at the outset. It must, by the way, be noted as somewhat significant of the strength of the arguments still made for the continuous current that the Edison system should have been adopted for very large central stations, not only in Kansas City, but in Minneapolis, one of the leading North-West cities.

The Keely motor once more fills the public eye, and empties the pockets of its shareholders. There is now a quarrel amongst some of those interested as to whether Mr. Keely shall or shall not divulge his secret. The case came up in Philadelphia last week, where a gentleman owning about half the Keely stock went into court to get a writ of attachment for Keely's arrest, on the ground that the inventor had not obeyed the order of the court made on the 7th April, to the effect that he must show the principle of his machine within thirty days. The court declined to grant a writ, and has ordered that experts shall meet at Keely's workshop and report as to what they see or can find out. The way in which this matter drags along is truly absurd. It will be remembered that one of Keely's latest dodges was to claim that he had some electrical features of importance embodied in his apparatus; but all the electricians who have had an opportunity of examining the machine characterise the whole business as a rank swindle. Most people have been of that opinion for a long time, and the course of events only strengthens the general conviction on the subject.

CORRESPONDENCE.

MAGNETISATION OF STEEL BY LEYDEN JAR DISCHARGE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Can you insert the enclosed important letter from Prof. Ewing in this week's issue?

I feel sure he has hit on the solution of the difficulty. I had temporarily forgotten the fact, but now remember that the oscillations of a spark were actually observed by Feddersen to be of gradually lengthening period, and in connection with this important suggestion of Prof. Ewing's the accompanying portion of a Paper of mine in the *Philosophical Magazine* for November, 1867, may be of sufficient interest to quote:—

"*Note added October* 14, 1876.

"Since the above was in print I have seen a paper of Sir William Thomson's in the *Philosophical Magazine* for June, 1853, 'On Transient Electric Currents,' from which I gather that Weber had already applied his electrodynamometer to the investigation of transient currents—in which, moreover, I find that Thomson predicted the experiment of Dr. Feddersen, mentioned above (§ 3 and footnote, p. 355), almost exactly, and calculated the value of every oscillation in a discharge. It is also shown that all the oscillations ought to occur at equal intervals of time, whatever be the resistance ρ of the discharging circuit, provided only that it remains constant The interval is not, indeed, the simple harmonic semiperiod

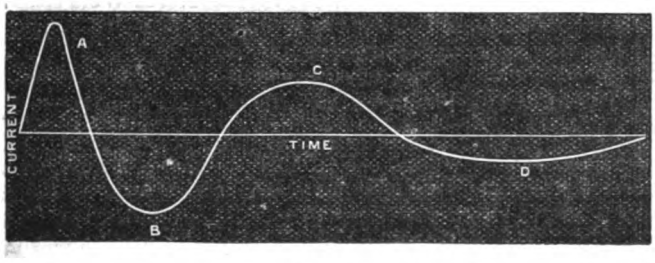
Digitized by Google

$\frac{\pi}{\sqrt{(n\kappa)}}$, but it is $\frac{A\pi}{\sqrt{(A n \kappa - \frac{1}{4}\rho^2)}}$, A being a constant which I do not yet understand, but which Thomson calls 'the electrodynamic capacity of the discharger.' I imagine, therefore, that the increasing intervals actually observed were due to the resistance of the air, across which the discharge took place, increasing as the strength and heat of the successive sparks diminished."

The constant "A" which I mention as then not understanding is now very familiar to everybody as the coefficient of self-induction L.—Yours, &c., OLIVER J. LODGE.

Victoria College, Liverpool, October 2, 1888.

"DEAR LODGE: I see in the report of the lightning rod discussion (which I was very sorry not to be able to attend) that you referred to the difficulty there is in seeing how an oscillatory current can leave permanent magnetic effects in an iron conductor or in neighbouring iron, and Lord Rayleigh spoke of experiments showing that when a Leyden jar is discharged through a helix with a steel bar inside the bar may be magnetised *in cylindrical layers* with opposite directions of magnetisation at different distances from the surface. Does not this suggest oscillations in which the period lengthens while the amplitude decays?



"Current A is so transient that its effects are extremely superficial. The inner layers are protected by induced currents in the iron (as Lord Rayleigh remarked), but it magnetises the surface layer strongly. Current B is not strong enough to reverse the effect of A on the outermost layer, but it is slow enough to magnetise a layer that lies a little nearer the axis. C, again, is too weak to reverse the effect of B, but its effects reach deeper still, and so on.—Yours, &c.,

"J. A. EWING.

"University College, Dundee, September 29, 1888."

LIGHTNING CONDUCTORS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I demur to Prof. Oliver Lodge's second statement made in the Practical camp, viz., "Leyden jar discharges have nothing oscillatory or alternating about them, or at least the existence of such alternations is an unproved assumption."

I do not deny the existence of oscillations in a Leyden jar discharge. Under certain circumstances they must occur; but I question whether these circumstances ever can occur in a lightning flash, or that it is proved that when they do occur in a Leyden jar they are of the very great frequency assumed in the Theoretical camp. I admit also oscillations in a lightning flash, but of small frequency, such as can be distinguished by a wagging head, and not such as would be due to the presence of that which has been defined by a waggish head to be "impudence."

When Prof. Lodge wrote the following sentence, "Electric charges splash about in a struck mass of metal, as does the sea during an earthquake or when a mountain top drops into it," I wish he had added "and as does a theorist when he takes a header into a bath of cold practice."—Yours, &c.,

W. H. PREECE.

THE FINSBURY TECHNICAL COLLEGE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Referring to your note as to the probable placing of restrictions upon the entries to the evening classes in the various electrical subjects at the Finsbury Technical College, will you allow me to allay your apprehensions by informing you that nothing is further from our intentions than to impose an examination on paper as a test of admission. What we shall be driven to do if the present influx of students continues, will be to restrict admissions to the following classes of persons: (*a*) Those who are actually employed in the electrical industries; (*b*) those who have already attended some systematic course at such institutions as the Birkbeck, the City of London College, or the various Polytechnic Institutions, and now desire to go on to our more practical and more specialised work. If we do not so restrict our unmbers we fear that the laboratories will be overcrowded with mere amateurs and hunters after examination prizes. I may add that in the present session these restrictions are not likely to be applied to the laboratory class for practical electro plating and typing, in which the entries as yet are few.—Yours, &c.,

October 1st, 1888. SILVANUS P. THOMPSON.

THE ANGLO-AMERICAN TELEGRAPH COMPANY'S 1869 CABLE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I beg to inform you that the cable laid in 1869, which was broken at 135 miles from St. Pierre, in shallow water, on the 23rd ult., was successfully repaired on the 30th by the company's s.s. Minia.

A statement having appeared in many of the London papers to the effect that an entirely new cable could have been laid for the amount which has been expended in its repair and renewal, I should be much obliged if you will kindly correct this statement by publishing the following facts:—

The money expended in the repair and renewal of the Brest-St. Pierre cable laid in 1869 (during nineteen years) does not amount to *one-third* of the capital necessary to lay a new cable, even at the present low prices, and that more than *two-thirds* of the entire cable has never been disturbed since the day it was laid.—Yours, &c.,

H. WEAVER, Managing Director.

1st October, 1888.

THE MAXIM-WESTON ELECTRIC COMPANY.

CIRCULAR ISSUED BY MR. WATT.

Mr. Hugh Watt, M.P., has issued a circular to the shareholders of the Maxim-Weston Electric Company (Limited), in which he says:—

"Gentlemen: Having been identified with the Maxim-Weston Electric Company (Limited) for nearly five years, I cannot allow the misstatements made by the present Board to pass unnoticed. I would also take the opportunity of explaining my reasons for having filed a petition to wind up the Company.

"At the first meeting of the new Directors, which I attended, notwithstanding the amicable arrangement whereby I agreed not to oppose the appointment of the persons in question, provided they were acceptable to a general meeting, no sooner had I entered the room than a hostile demonstration was made by several of these persons. Mr. John Marks proposed as chairman Mr. Louis Swaby, who in turn proposed Mr. John Marks. I protested on the grounds that I had been appointed Chairman by the shareholders more than four years ago, and that my position had been recognised by the persons present so late as a few days previously at a general meeting of the shareholders. I maintained that an appointment of the shareholders could not be set aside by any committee or Board of Directors; but as they insisted upon appointing Mr. John Marks I tendered my protest and withdrew.

"I was in attendance at every Board meeting subsequently held, but owing to my being unable to induce the Board to listen to my statements or to consider the urgent financial requirements of the Company, and owing also to the violent scenes which took place at every Board meeting, I found it impossible to co-operate, much as I desired it, with my new colleagues. At five p.m. on or about August 1, after I had left for the day, Mr. Louis Swaby removed from the registered offices the minute books, the cash books, and ledgers of the Company. This was reported to me next morning, when I stated that, being unable to exhibit to shareholders, in terms of the Act, the books of the Company, I would be no party to the other books or papers remaining at my address. I consequently instructed the secretary to take to the works in a cab all the more important books, and I asked Mr. Gribble to get a van and remove to the works every book and paper belonging to the Company. The secretary was instructed by me to request Mr. Tough to place the more important

Digitized by Google

books under lock and key, while Mr. Gribble was instructed to accompany the van and deposit the other books and papers according to the works manager's instructions. A large number of the papers taken by Mr. Gribble consisted of old 'Electric Light and Power Generator Company' wages sheets, and other papers of no value, but I cannot believe that this person, who was for nearly seven years in my employ, and is now the chief clerk to the Company, engaged by the present secretary, could have been guilty of what is insinuated in the Directors' report to have been done by my instructions. The statement with regard to payment of the staff is incorrect, as the total sum I received was only about £2 per week in excess of transfer fees.

"I repeat that throughout I told the Directors that every information in my possession, or that of the staff, was at their disposal, and I reiterated this on August 4 to Messrs. Marks, Couchman, Hildyard, and Swaby. I was, however, unable to give all the information I desired, not only as an official of the Company for five years, but as then the largest shareholder in the Company, and having a large number of friends deeply interested; for, I regret to say, as pointed out by letter to Mr. John Marks, dated August 4, the present Directors declined to listen to me, and, as stated in that letter, 'In view of the unseemly scenes which again took place yesterday, and the violent and improper language used at the Board meeting,' I sent in my formal resignation 'as Chairman of the Company, and also as a Director from to-day.'

"As I have already stated, my Chairmanship had been disputed as far back as July 19, and I had not been allowed to act as Chairman.

"A similar letter to this, complaining of the conduct of the Directors, was sent to me by Messrs. Nash, Field, and Withers, who were appointed solicitors to the Company by the new Board, without either my knowledge or consent. That firm was employed by the new Directors to ascertain the validity of their election as Directors, and right to act without a confirmatory meeting, and the occasion on which they state they were refused admittance was by an arrangement with that firm, who gave an undertaking that the new Directors would not attempt to act in such capacity until the opinion of counsel had been ascertained as to the validity or otherwise of their election.

"I deny absolutely that the books or affairs of the Company were in any confusion other than that created by the committee and afterwards the new Board, who were in the habit of sitting from about 11 a.m. till 6 p.m., rummaging over and leaving in the utmost confusion the entire books of the Company, and doing everything and saying everything but attending to the affairs of the Company.

"One of the first acts of the new Board was to dismiss nearly the entire staff at the Company's works, which had been carefully collected by me over a period of years, and was, without exception, the most efficient electrical staff in London. I am not disposed to trouble the shareholders with contradicting in detail the statements contained in the Directors' report, or in the circular addressed to them by Messrs. Boyce and Ramsay. The statements with regard to the balance-sheet of 1887 are, in fact, those, only varying in detail, given by me at the ordinary general meeting of the Company held in March last. It will be in the recollection of shareholders that after the most exhaustive explanation at a meeting of nearly three hours' duration, the report and accounts were unanimously passed. If the Directors were conversant with the Articles of Association, they would find that it is not now competent, under Clause 95, to reopen the balance-sheet in question, except as regards any error discovered within three months after passing of the accounts. Waiving the question of three months, no error has been discovered to date.

"I should wish to know how it is, in detailing the expenditure upon the Watt plant, that Messrs. Boyce and Ramsay have omitted to state that a very large amount of Watt plant has been manufactured, largely exceeding in value the expenses detailed, notwithstanding the fact that the patterns and expenses consequent on making the first machines are largely in excess of the subsequent expenditure necessary for their manufacture. The new Directors will, perhaps, be surprised to learn that when I took office the plant was then valued at about £23,000, and that upon a revaluation made at that time by a competent firm it was estimated that it would realise £3,000, and that about two-thirds of it was sold, realising only about £1,800.

"I think the Directors might have saved themselves a vast deal of trouble; but I cannot forget that they have now been in office nearly three months, and have literally and absolutely nothing to show for that period, and I therefore sympathise with them in placing before the shareholders a confusing mass of figures, so as not to appear at the meeting they have convened entirely empty-handed.

"I am informed that the Directors earnestly urged the re-valuer of the stock—the same person who originally valued it—to put everything down at the very lowest figure. If it is a question of auction value, the revaluation is as valueless as the original valuation. The principle upon which I proceeded in originally valuing the old stock was in taking over the sound machines at the lowest price at which I could purchase them, and the price at which the machines were valued at December 31st, 1887, was a little less than the price at which they could then be obtained; the exact figures at which the goods purchased by me were obtained; and a valuation similar to that at which the old plant was taken over from the original management. I maintain that the new valuation, therefore, is misleading and incorrect. I do not think the shareholders will thank the new Directors for cutting down the value of their assets from 5s. per share to 2s. 6d., merely to suit their financial exigencies in providing fresh capital. . . .

"I wish to know if the new direction, who have been nearly three months in office, have introduced business of £5 value to the Company, and whether orders that have been received have not been entirely from connections established by me?

"I wish to know whether the new Directors have mortgaged the plant of the Company for an advance of £1,000, and whether a large portion of this sum has been disbursed in fees to Mr. Louis Swaby and themselves, notwithstanding their protestations to the contrary when taking office?

"I wish to know whether they have voted themselves £100 in payment of the expenses of the committee? which, if done, is *ultra vires*.

"I wish to know if Mr. John Marks proposed and Mr. Couchman seconded the appointment of Mr. Louis Swaby as Managing Director; and whether Mr Swaby voted for himself, being opposed by Messrs. Klenck and Hildyard?

"I wish to know whether the same gentleman proposed and Mr. Swaby again supported his own appointment to proceed to America to examine the different electrical systems there, and report in the interests of the Company?

"I wish to know whether the moment the American Company knew that I had ceased to be a Director of the Company they withdrew the long credit granted to me for plant supplied and available to almost any amount?

"I wish to know whether any firm have agreed to supply the Company with goods to any value upon terms of credit?

"With regard to my account with the Company, since March last, and during all the time that the committee were, according to my judgment, doing their best to wreck the Company, I was lending the Company, from time to time, large sums of money to prevent writs being served, and to enable operations to continue. Upon the new Directors taking office I urged upon them the desirability of a subscription among the Board for the purposes of the Company; but, as I have already said, they declined to listen to me. Notwithstanding the fact that the Company was owing me a large sum of money, I was prepared to advance to the Company £1,000 provided the other Directors subscribed £500 each. I made a similar proposal to the committee in April last. . . .

"But for the appointment of the committee in March last I would have been able to obtain a payment of, say, £4,000 to £5,000 from outstanding debtors with regard to whom trifling disputes had arisen, some of which had been already settled, and others were on the point of a settlement, when a committee was appointed of comparatively unknown men.

"In conclusion, I would recommend the shareholders to leave those who have taken upon themselves the reins of office to subscribe, as I did in 1883, the capital necessary to carry on and extend the business; but as I have no hope that such will be the case, I have, in the interests of myself, as a large creditor and shareholder, filed a petition, believing that the only outlet from the present deadlock and a further squandering of the assets of the Company is by liquidation and reconstruction under the auspices of men of social, commercial, and financial position. I may add that my petition is supported by other creditors, and, provided you approve of the course which I have taken, I shall be glad if you will intimate to me in writing that you do so, which will no doubt strengthen my hands in the quickest mode available for getting rid of the present Board, and placing the Company at an early date in the position it occupied before the present Board took office."

COMPANIES' MEETINGS & REPORTS.

The Direct Spanish Telegraph Company (Limited).

The thirtieth ordinary general meeting of this Company was held on Tuesday, 2nd inst., at Winchester House, Old Broad-street, Sir James Anderson in the chair.

Mr. CH. GERHARDI (the Manager) read the notice convening the meeting, and the report of the Directors was taken as read.

The CHAIRMAN said: When I last had the pleasure of addressing you I held out the hope that we should reach a dividend of 5 per cent. I am to-day in a position to say that we have reached that point. It has been customary with us at these meetings to tell you what we have done since the date of this report—that is, during the three months beyond the period which the report deals with. The traffic has increased—we have carried 2,000 more messages in the three months than in the corresponding three months of 1887—yet we have not earned as much money. This arises from two causes, the first being that the practice of inditing messages in code has increased, and telegrams are thus made shorter. The other reason is that the extra European traffic which we carry over our cables has slightly decreased, in consequence of the raising of the tariff on the American cables since the 1st of September last. I do not despair of being able to keep up our dividend of 5 per cent., and I should not be surprised if we made more; but at present we are not making more. The traffic, however, is sound, and derived from commercial sources, and there is nothing political or spasmodic about it. There are a few relatively small items in the accounts which I will explain. The first is for a new cable house at Barcelona and for protection of cable amounting to £194, half of which has been charged to the present account. There is, as you know, an International Exhibition at Barcelona this year. It has not done us any good telegraphically; on the contrary, we have had to spend something in protecting our cables with buoys to keep them clear of the men-of-war which on the occasion of the opening of this Exhibition anchored near the cable. In this matter we were assisted very frankly and very kindly by the Minister of Marine of Spain, and every possible assistance was given us by the local naval authorities; therefore, our cables sustained no damage. With regard to the cable house, the temporary hut which was erected in 1874 required renewing, and as the land on which it stood was within the Exhibition grounds, we decided to erect a new and suitable cable house before the opening of the Exhibition; and, in consequence, we hope to get, and we

Digitized by Google

have a positive promise that we shall get, the ground which the cable house and shore-end occupy free of rent, so that we are so far fortunate. The other item I may mention is one of £28 "special allowance." This was for medical and other expenses incurred by one of our superintendents who had been called up to London to explain some matters, and who was taken very seriously ill whilst here. Another amount is that of £55. 6s. 8d. for inspection of foreign stations. Our manager, Mr. Gerhardi, went to Bilbao, Madrid, Barcelona and Marseilles to see how all was going on, and to improve some working arrangements with the Spanish and French Governments. You will observe by the report and accounts that the traffic receipts for the half-year show an increase of £851 over the corresponding period of 1887, and I may add that in order to get that increased traffic we had to spend £260 more than we did in the corresponding half-year of 1887. I have really, gentlemen, very little to say. Everything is going on well, your cables are in good order, and your traffic is steadily growing. The first six months of the year to which the report refers are those during which there is the least traffic, so that we are justified in expecting that we shall get a larger increase still in the second half of the year ending on 31st December next. I shall be glad answer any question that any shareholder may have to put.

No one having put any question to the chair, the first resolution, proposed by the CHAIRMAN and seconded by Mr. ETLINGER—

"*That the report and accounts now presented be and are hereby received and adopted,*"

was carried unanimously.

The second resolution, proposed by the CHAIRMAN, and seconded by Mr. ETLINGER—

"*That the dividend at the rate of 10 per cent. per annum, less income-tax, on the Preference Shares, and a dividend at the rate of 5 per cent. per annum, free of income-tax, on the Ordinary Shares, both for the half-year ended 30th June, 1888, be and are hereby declared,*"

was also carried unanimously.

A vote of thanks to the Chairman and Directors, moved by Mr. LEWIS WELLS and seconded by Mr. DAVID LOWE, was carried *nem. con.*, and the CHAIRMAN having thanked the shareholders, the proceedings terminated.

Maxim-Weston Electric Company (Limited).

An extraordinary general meeting of the shareholders was held at the City Terminus Hotel, Cannon-street, on Wednesday, Mr. John Marks, the Chairman of the Board, presiding.

Mr. SAMUEL J. BOYCE (the Secretary) read the notice convening the meeting. The report of the Directors was taken as read.

The CHAIRMAN: The duty now devolves upon me, gentlemen, of moving the adoption of the resolution that has been read by the Secretary, and which is contained in the notice convening this meeting. But before doing that it will be, perhaps, as well for us to retrace our steps a little, and devote a few minutes to a consideration of the causes which have led us to the necessity of asking you to consent to a reduction of capital. You will recollect, gentlemen, that in March last the late Board called the annual general meeting of the shareholders, and Mr. Watt, the then Managing Director of the Company, having moved that the report and the accounts should be adopted, Mr. Swaby, the only then remaining Director with Mr. Watt, moved the rejection of the report and accounts, on the ground that they were altogether untrue. That led up to some discussion, and Mr. Watt, I think you will bear in mind, made some very grave charges against Mr. Swaby at that meeting, which it is very satisfactory to us to know have been refuted in the Law Courts since. As a sort of compromise, a committee was appointed to inquire into the affairs of the Company, and to report to the shareholders at a subsequent meeting. That committee did their work as well as they could under the circumstances and with the limited power with which they were invested. The result of their investigation was that they reported to the shareholders that the balance-sheet presented by Mr. Watt was an untrue one, and they recommended the shareholders to appoint additional Directors to act with Mr. Watt in carrying on the affairs of the Company in future. At a subsequent meeting, at which Mr. Watt presided, five gentlemen were named as new Directors, and the names were supported from the chair and carried unanimously. That was on July 19th. The new Directors at once set themselves to work, and on that very day two of our number called at the office and requested the secretary to call a Board meeting for the following day. Mr. Watt had, however, to preside at a meeting of the New Chili Company, I believe, on the following day, and it was arranged that the Board meeting should take place two days later—on the 21st July, two days after the election of the new Directors. At that Board meeting Mr. Watt was not present. The Directors asked the secretary to produce the books and documents belonging to the Company, but he replied that they were locked up in the safe, and that the key of the safe was in Mr. Watt's possession. We were unable, therefore, to transact any business whatever at that meeting, but we did the best we could under the circumstances. We instructed the secretary to have returns prepared of the *employés* at the works and the clerks in the offices, with their respective salaries. At that meeting, when we asked the secretary what he had to report, he said that a cheque for £724 had been received from the Peel Mills Company. The cash-book was not locked up in the safe, so we looked to see if the cheque was entered up. It was entered up, but there was no entry in the bank-book of the cheque having been paid into the account of the Company.

A SHAREHOLDER: When was that?

The CHAIRMAN: At the first board meeting, on July 21st.

The SHAREHOLDER: When was the cheque received?

The CHAIRMAN: Some days previously. Upon asking the reason why the cheque had not been paid in, the Secretary informed us that he had endorsed the cheque, and entered it, and that Mr. Watt had then paid it into his private account, saying that the Company were indebted to him, which they were. Mr. Watt retained the cheque, and paid into the Company's account a cheque for £74, retaining £650 against what he claimed as being due to him from the Company (shame). At the following meeting, on July 27th, Mr. Watt was present; but, notwithstanding that he had presided at the meeting at which the new Directors, whom he supported, were elected, he positively refused to let us have access to the minute book and the other documents of the Company, and which were absolutely necessary for the purpose of carrying on the business of the Company, and the ground upon which his refusal was based was that he questioned the validity of our election, and that until he had taken a legal opinion on that point he refused to give us any assistance whatever in carrying on your business. We, however, took the opinion of Mr. Emden, through our solicitors, Messrs. Nashville and Withers, and that was that we were legally appointed Directors of the Company, and had a right to carry on the business of the Company on behalf of the shareholders (cheers). The Chairman went on to refer to the steps which led up to the resignation of Mr. Hugh Watt, and said that Mr. Watt caused all the books and papers to be removed to the works, except the transfer book, which was retained "so as not to cause inconvenience to members of the Stock Exchange." This was in August, but certificates sent in for transfer as far back as March last were in the office then (shame). The then Secretary absolutely refused to carry out the instructions of the Board. He was therefore peremptorily dismissed (hear, hear). The Chairman continued: Then came the question of the clerks. Upon inquiring of the clerks whether they were the servants of the Company they said they were not—they were the servants of Messrs. Hugh Watt and Co. We asked the clerks what salaries they were receiving, and upon their telling us we turned to the books and found that the amounts were paid by this Company. The whole staff of clerks paid by the Company were clerks of Messrs. Hugh Watt and Co. They were doing the clerical work of the Maxim-Weston Company, the Yuruari Mining Company, the New Chili Mining Company, and the Port Darwin Company, and there was a shorthand clerk doing Mr. Watt's correspondence with his constituents in Glasgow (laughter). These were all being paid out of the coffers of this Company. I think the other companies I have named must get their work done very cheaply.

Mr. KLENCK: Query, is it done cheaply?

The CHAIRMAN: We do not know that. On Aug. 3rd, the day before his resignation, Mr. Watt called in a firm of engineers in the City, took them to the works and sold them some movable plant and stock for a sum of £175, and two engines alone, part of this property, had cost the Company between £300 and £400, and the very morning of the day on which he resigns he collected the money and paid it into his own private account (shame). Let us now refer to Messrs. Boyce and Ramsay's investigation of the books. You will remember that in the annual balance sheet the profit on the year's trading was put down at £1,555. As to how Mr. Watt dealt with some of these items I have the particulars before me. First, as to the Palace Hotel, Birkdale, a question was asked about the debtors at the meeting in March last, and Mr. Watt said that the whole of these debts were "good and recoverable." I am quoting his own words. The Palace Hotel, Birkdale, was indebted to the Company in the sum of £2,750 for plant supplied. That Company went into liquidation on the 30th of November, 1887—that is to say, a full month before the balance sheet was made up, and about four months previous to Mr. Watt's statement that all the debts were good and recoverable. I say on the 30th November, 1887, that Company went into liquidation; we took back our lighting plant in discharge of our debt of £2,725, and Mr. Watt told you in March last that the debts were good and recoverable, knowing that this Company, owing £2,700, was in liquidation. Messrs. Lewis and Co., of Manchester, by our books, were owing £1,265, for which they never paid a penny piece, and in June of this year the plant was returned to the Company, and we sustained a loss of something like £700. The plant, stated in our books as being supplied at a cost of £200 to the people owning the shop in Victoria street, also showed a loss. There is in the books a profit on the transaction of £104, and a few weeks after the goods had been supplied they were sent back to us and taken back into stock, and this is treated as a regular sale at a profit of £104, on which Mr. Watt takes his commission. And this is the manner in which the profit on the year's working has been made up.

Mr. NEWTON: When the goods were sent back were they taken as a purchase?

The CHAIRMAN: No, sir, they were not. The plant was put in the books as being supplied at a cost to the purchaser of £200; that was put back into stock and is still there, and has never been paid for. It has been put there merely as a kind of show, and it has been looked upon, I suppose, as a very good advertisement; but to write that up as plant supplied and to put it in the balance-sheet, I call it scandalous. That is how the profit of £1,550 has been made up. Plant to the value of £5,000 or £6,000 has been consigned to various parties abroad, to some people in the Mauritius and in various parts of the colony. That has been written in the books as if it were an actual sale. A profit amounting to upwards of £2,000 is assumed to have been made, and upon this £2,000 of course Mr. Watt has taken his commission, likewise bear in mind; and when we come to correspond with those gentlemen in the Mauritius, they inform us they have sold between £500 and £600, and they will be very pleased to return the remainder. That is to say, £5,500 was sent, £500 has been sold, and they will be very pleased to return the remaining plant to the value of £5,000. It would not then, it would not now, absolutely pay the cost of sending it over; and this is what Mr. Watt treats as a *bonâ fide* sale according to your books, and upon

Digitized by Google

which he takes his commission as Managing Director. I could go on *ad infinitum* with similar instances, but I think I have now shown you sufficiently how Mr. Watt has made up his accounts, and how it is that he has credited you with a profit of £1,555 on your last year's trading.

A SHAREHOLDER: You have other instances?

The CHAIRMAN: I am sorry to say we have. With regard to the profit and loss account, I do not know that I can add anything to what the accountants have mentioned in their report; it merely goes to show how in this particular instance, as in others, to use a homely expression, Mr. Watt has cooked the accounts of the Company, and beyond that I cannot say anything to you. Now, gentlemen, I think I have said sufficient to show you the manner in which Mr. Watt has mismanaged the Company, and for which he was paid the large salary of £1,200 a-year and 5 per cent. commission. I think it would be a matter of surprise if this Company was in any different position under such management than it is. It would be simply short of a miracle if in the hands of such a manager the Company should go on in a successful course. So much for the past. Now for the present. Let us turn to the Directors' report. You will find the Directors say in one paragraph of the report that the Company possess valuable patents and good plant and machinery adapted to the requirements of the business, a state of things only to be obtained by years of experience and the expenditure of large capital. They also have a large and valuable stock. Well, gentlemen, we consider that after writing off the amounts recommended by the accountants, after reducing the value of the patents—after considerably reducing the value of the patents—that the present assets of the Company represent about 2s. 6d. per share; we therefore propose to start *de novo* with the reduction of the capital from 5s. to 2s. 6d., and we ask you shareholders to take up the unissued shares, amounting to 188,000, at 2s. 6d. The Board are prepared to do their share in taking up these shares, and we have applications from gentlemen who are unable to attend this meeting to the extent of some thousands of the new shares. Now, gentlemen, we know perfectly well that we labour under this disadvantage, that you can purchase these shares in the market at less than 2s. 6d.; but we feel confident, as stated in the report, that notwithstanding the unsatisfactory position of the Company, with honest and attentive management a good and profitable business may be carried on, and therefore we strongly recommend you to fall into the scheme and reduce the capital to 2s. 6d., and take up these unissued shares, because we feel confident, with a capital of £23,500, which it will give us as a working capital, the present shares, which can be bought at considerably less, will be brought up to fully 2s. 6d., and the time will very soon arrive, if you fall into our scheme, that they cannot be bought on the market at that. What are the prospects of the Company in regard to electric lighting? I dare say you, in common with myself, have read the address delivered by Mr. Preece, the celebrated electrician, at the British Association's recent meeting at Bath. Therein he says that the time has now come when there never has been such a prospect for electric lighting companies as there is at the present time; the disadvantages under which they have laboured on account of past legislation have been removed, and he says altogether he thinks the present is a most propitious opportunity for electric lighting. I am happy to say he refers, though not by name, to the Maxim-Weston. He does not name the Company; but he refers to the installation at the central Post Office Savings Bank, which he eulogises in the highest possible manner.

A SHAREHOLDER: Is it going on?

The CHAIRMAN: We believe thoroughly well.

The SHAREHOLDER: Is it on the Watt patent?

The CHAIRMAN: Oh, dear, no; it is on the Maxim-Weston scheme. Well, gentlemen, we have had before us many schemes, and we have given careful attention to the whole of them; but the scheme which we feel is best to recommend to you is that of which we have given you notice, and which will be moved to-day. The only alternative scheme that presents itself is to fall into Mr. Watt's views and to wind up. There is no help for it. If you do not take up the unissued shares there is no help for it but to wind up, and, as you are all aware, Mr. Watt has a petition on the file which comes on for hearing next Wednesday. I have no doubt whatever we shall successfully resist his motion to wind up. Should you not fall into our views and pass this resolution to-day and take up these shares, there is no help for it but to wind up, and in that case we might as well let Mr. Watt deal with the thing, and there will be very little left for the shareholders. The Chairman then proceeded to deal with the circular issued that morning by Mr. Watt, reading the various paragraphs through and commenting upon them *en passant*. He said that it was perfectly true that he (the Chairman) had proposed Mr. Swaby's election as Chairman—for this reason, that Mr. Swaby was the only old Director remaining except Mr. Watt, and it was believed to be in the interests of the Company that Mr. Swaby should be elected. Mr. Swaby declined to act as Chairman, and proposed that himself (Mr. Marks) should occupy that position, and that was carried unanimously. It was not correct to say that Mr. Watt attended every Board meeting. He did not attend the first meeting, and he was not present for more than five minutes at any subsequent Board meeting. As to the violent scenes, they were wholly on the part of Mr. Watt. The books and papers referred to where thrown amongst the machinery (shame). On August 7th, Mr. Watt was most gracious, and told the Board that he would assist the Company all he could, and would never dream of taking an action against the Company. The shareholders had seen how these promises had been carried out. As to Mr. Watt's statement that he had not been allowed to act as Chairman, that was correct, because the new Board elected their own Chairman, as they were fully entitled to do by the Articles of Association. It was quite true that the staff had been reduced, but not in the indiscriminate manner that Mr. Watt would have them believe. The whole list was gone through with the works manager, and all the men indispensable to the proper carrying on of the business had been retained. Mr. Watt (continued the Chairman) omitted to state that all the Watt plant manufactured had been included in the stock sheets. He was happy to say that the new Directors had done some business, very nearly, if not quite, equal to what had been done by Mr. Watt in the preceding six months. The new valuation had been made fairly and honestly (cheers). As to the fresh capital, he would be very sorry if the shareholders did not fall in with the views of the Board, for they believed the Company would be made successful by adopting them; but it was a matter of indifference to the Board whether their recommendations were accepted or not. As to the questions asked by Mr. Watt, the Board had made a claim against Mr. Watt for certain sums—that, in fact, he was the Company's debtor instead of its creditor. The Directors had not arrogated anything to themselves. They were appointed by the shareholders, and they were ready to vacate their seats whenever the shareholders wished it. As to the auditor, Mr. Dever, who was present, was a gentleman of the highest position, and was incapable of covering up anything which the shareholders should know. Mr. Dever wrote a report upon the 1886 accounts, which Mr. Watt did not read to the meeting. As to their refusal to register the transfer of Mr. Watt's shares, that was because Mr. Watt, as they contended, was in the Company's debt, and they had a lien on the shares of holders in default (cheers). When the new Board took office there was the magnificent balance of £3 at the bank, and the new Board had made themselves personally liable for an overdraft of £1,000 with which to carry on the business, taking a debenture from the Company for the amount; but neither the Board nor the committee had ever received a farthing for their services, except Mr. Swaby, to whom a certain amount legally and properly due had been paid (cheers). The parent Maxim-Weston Company had, through their representative here, made inquiries about the Company, and he believed they would assist it; but they would not do so while Mr. Watt was at the head of affairs. Improvements had been made in the original patents, and these would be available for this Company. It was proposed that the works manager and one of the Directors should go to America on the business of the Company, but at present no selection had been made pend-

ing the result of Mr. Watt's petition to wind up the Company and the probability of additional capital being provided. Mr. Watt had, it was true, lent the Company money, but he had charged 10 per cent. for it; whereas the bank had lent the Board £1,000 at 5 per cent. Mr. Watt spoke of his five years' connection with the Company, but it would have been to the advantage of the shareholders if that connection had ceased some years ago (cheers). After strongly recommending the scheme proposed in the report of the Directors as the only one by which the Company could be saved from utter ruin, the Chairman concluded by moving the following resolution :—

"*That the capital of the Company be reduced from £125,000, divided into 500,000 shares of 5s. each, to £62,500, divided into 500,000 shares of 2s. 6d. each, and that such reduction be effected by cancelling capital which has been lost or is unrepresented by available assets to the extent of 2s. 6d. per share upon each of the 312,000 shares which have been issued and are now outstanding, and by reducing the nominal amount of all the shares in the Company's capital from 5s. to 2s. 6d. per share.*"

Mr. J. M. KLENCK seconded the resolution.

Mr. HIRSCH thought the shareholders ought to congratulate themselves on the fact that at last they had a Board of Directors who were trying to do the best they could for the interests of the Company. As to Mr. Watt's circular, there were many statements in that which the shareholders themselves knew to be incorrect, and he thought the Chairman had dealt with that effusion in a very able manner. The shareholders ought undoubtedly to strengthen the hands of the Board in taking proceedings against Mr. Watt for the amount due by him to the Company; and with regard to the recommendation of the Board as to the finding of further capital, it was clear that if the money was not found the Company would have to be wound up.

Mr. EMPSON asked what was the position of the Company with regard to the Watt patent, which Mr. Watt claimed for his own, although this Company had been charged with the expense of bringing it out. He also asked whether the Directors had considered the advisability of instituting proceedings against Mr. Watt.

Mr. JOHN NEWTON said it seemed to him that Mr. Watt's circular was part and parcel of the petition which was to be heard next Wednesday, and unless the shareholders strengthened the hands of the Directors at that meeting, there was the possibility that the petition would be granted. If it were properly opposed by a resolution of the shareholders it would probably be dismissed, or at least adjourned. The statements made by Mr. Watt were simply intended to damage the credit of the Company. Mr. Newton confirmed the Chairman's statement as to the violent behaviour of Mr. Watt at the Board meetings which he attended, and said he thought the other companies attended to in Mr. Watt's office might be fairly asked whether they paid anything towards the salaries of the clerks paid by this Company.

Mr. DEVER (of Messrs. Deloitte, Dever, Griffiths and Co.) said that certain facts with respect to the accounts of 1886 were referred to by him in a letter accompanying the balance-sheet. This letter, however, Mr. Watt did not read, and the shareholders were left in the dark. That meeting he (Mr. Dever) did not attend; but finding that his letter had not been read, he addressed another communication to the shareholders, concerning the 1887 accounts, and the reading of that document at the meeting in March last led up to the appointment of the committee (cheers). The item of patents had actually been increased from £32,829 to £40,737 during 1887, instead of being written down.

Mr. GRIFFITH said the first question to be decided was whether the Company was to continue, or be wound up, and he thought they should distinctly make up their minds on that point (cries of "Vote").

The resolution proposed by the Chairman was then put and carried unanimously.

Mr. HIRSCH then proposed

"*That the Directors of this Company be, and are, hereby authorised to oppose Mr. Hugh Watt's petition for winding up this Company.*"

And, secondly,

"*That the Directors of this Company be, and are, hereby authorised to take immediate legal steps against Mr. Hugh Watt for the purpose of recovering such sum or sums as are due by him, the said Mr. Hugh Watt, to the Company.*"

Mr. EMPSON seconded the proposition.

Mr. LEE did not think the resolution could be legally passed, but he was quite sure the Directors would do everything necessary to protect the interests of the shareholders.

The CHAIRMAN pointed out that the resolution, though not legally binding, would strengthen the hands of the Board in opposing Mr. Watt's petition for the compulsory winding up of the Company.

Mr. GRIFFITH, while agreeing with the proposal to resist the petition for winding up, contended that the difficulties of the Company were due mainly to their having at the start paid the American Company large sums for patents which had proved to be useless. They had consequently had to pay thousands more for doubtful improvements, and yet they were told to expect assistance from the parent Company, which, instead of helping its child, had been living on it. He thought the suggestion that legal proceedings should be taken against Mr. Watt showed more feeling than judgment. What ought to be done was to see whether the claims could not be compromised (no, no).

After some further conversation the proposition to oppose the winding-up petition was carried *nem. dis.*

The second proposition led to considerable discussion, at the conclusion of which

Mr. J. M. KLENCK, one of the newly-elected Directors, said it would be well to repeat briefly how matters stood. Mr. Watt had put a petition on the file claiming £754, but the Company had a claim against Mr. Watt for £2,113, independently of other sums which might be found to be due to the Company. Mr. Watt had also petitioned for a rectification of the register; but the Directors would certainly oppose this, as while a shareholder was in debt to a company the Directors had a lien upon the shares of the debtor. He thought, therefore, that the resolution would strengthen the hands of the Board (hear, hear). The point of the whole thing, however, was—Were the shareholders going to find the money? (cries of "Yes"). In that case the Company would be able to do a good and profitable business. There could be no doubt that the electric light was to be the light of the future now that the restrictions imposed by the Board of Trade had been removed and the light had been perfected. The Directors, therefore, with confidence asked the shareholders to entrust them with the means of putting the Company in a sound position, for they thoroughly believed that with the small amount of capital asked

for—under £24,000—the undertaking would be made commercially successful (cheers).

Mr. Hirsch's second proposition was then put and carried with two dissentients.

Mr. HILYARD, in reply to a question, said that, so far as the Board had been able to ascertain, Mr. Watt had spent about sixty hours at the factory during 1887; his pay had therefore been at the rate of about £20 an hour (laughter).

The meeting having lasted nearly two hours and a-half, then closed with a vote of thanks to the Chairman and Directors.

Eastern Extension Australasia and China Telegraph Company (Limited).

Report and accounts of the Directors for the half-year ended 30th June, 1888, to be submitted to the thirtieth ordinary general meeting to be held at Winchester House, 50, Old Broad-street, London, E.C., on Wednesday, 10th October, at 2 o'clock.

2. The gross receipts, including Government subsidies, have amounted during that period to £239,926. 0s. 5d., against £219,201. 4s. 8d. for the corresponding half-year of 1887.

3. The working and other expenses, including £22,112. 6s. 4d. for cost of repairs to cables and expenses of ships, absorb £69,297. 10s. 11d., against £76,241. 3s. 6d. for the corresponding period of 1887, leaving a balance of £170,628. 9s. 6d. From this is deducted £3,229. 0s. 5d. for income-tax, and £41,595 for interest on debentures and contributions to sinking funds, leaving £125,804. 9s. 1d. as the net profit for the half-year, against which the balance of cost of the Singapore-Saigon Renewal, amounting to £15,401. 5s. 0d., has been charged, leaving an available balance of £110,403. 4s. 1d.

4. One quarterly interim dividend of 1¼ per cent. amounting to £31,250 has been paid during the half-year, and another of like amount will be distributed on the 16th instant, leaving £47,903. 4s. 1d. to be carried forward.

5. Numerous small repairs have been effected by the Company's maintenance ships during the half-year under review, but no interruptions of a serious nature occurred until the 30th June, when both the Java-Australian cables were suddenly and simultaneously interrupted in deep water about 220 miles from Banjoewangie. The Company's s.s. "Recorder" was immediately dispatched from Singapore to effect repairs, and special steamers were chartered by the Company and the South Australian Government to carry telegrams between Java and Australia during the interruption. At first some difficulty was experienced by the s.s. "Recorder" owing to the prevalence of bad weather and the ends of the cables being deeply buried, but communication was successfully restored on the 13th July, and the second cable was also repaired on the 6th August, when it was found that the interruptions had been caused by volcanic action.

6. In consequence of the serious inconvenience to the telegraphing community, occasioned by the unfortunate interruptions above referred to, and in order to avert a recurrence as far as possible, your Directors immediately decided to lay an additional cable from Banjoewangie to Western Australia, to connect with the land lines of that colony, avoiding, as far as practicable, the volcanic region. This line will give the Colonies the advantage of a third cable to Java and an alternative land system *vid* Perth and Eucla to the existing overland line between Port Darwin and Adelaide. The announcement appears to have given much satisfaction in the Colonies and elsewhere.

A contract has been entered into with the Telegraph Construction and Maintenance Company for manufacturing and laying this cable, which is expected to be in working order early next year.

NEW COMPANIES REGISTERED.

MEDICAL AND SCIENTIFIC APPARATUS COMPANY (LIMITED).—This company was registered on the 25th September, with a capital of £1,000 in £1 shares, to acquire the provisional protection and subsequent patent rights of T. P. C. Crampton for improvements in chemical thermometers, applicable also to other thermometers, and to carry on business as electricians and electro depositors. The subscribers are:—

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended September 28th, 1888, amounted to £4,788.

DIRECT SPANISH TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the month of September, 1888, amounted to £1,888, against £1,996 in the corresponding period of last year.

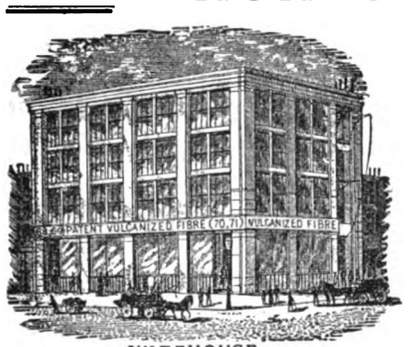
EASTERN TELEGRAPH COMPANY.—The traffic receipts of this line for the month of September, 1888, amounted to £49,273, and to £46,081 in the corresponding period last year.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended September 28th, 1888, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company (Limited), were £3,947.

WEST COAST OF AMERICA TELEGRAPH COMPANY.—The traffic receipts of this company for the month ended September 30th, 1888, amounted to £4,875.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The estimated receipts of this company for the half month ended September 30th, 1888, were £2,034, as compared with £2,388 in the corresponding period of 1887.

THE NON-CONDUCTOR OF ELECTRICITY.

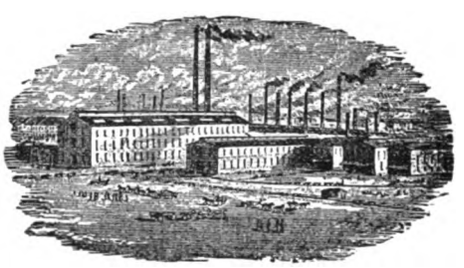


WAREHOUSE.

VULCANISED FIBRE,
PATENTED.

This new material is supplied in two qualities, Flexible and Hard.
The FLEXIBLE is a substitute for Leather, Rubber, Gutta Percha, &c., and is extensively used by Brass Founders, Axle Makers, Hydraulic, Sanitary, and other Engineers, Pump Makers, Carriage Builders, &c.
It makes the best Hot and Cold Water Packings, and for Axle Washers of all kinds it is unequalled.
The HARD is a substitute for Metals, Hard Wood, Ivory, Vulcanite, Ebonite, &c., and is a good Insulator.
Sold in sheets, 5ft. 6in. by 3ft. 6in., varying in thickness from 1-60in. to 1in.

FLEXIBLE, 2/- per lb.; HARD, 2/3 per lb.



FACTORY.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL SCIENCE, INDUSTRY AND ENGINEERING.

No. 513.—Vol. XXI. FRIDAY, OCTOBER 12, 1888. Price 4d.

NOTES.

Nature calls attention to the fact that the question of electrolysis by alternating currents was discussed at length by Sir William Thomson in a Paper which appeared in the *Philosophical Magazine* as long ago as June, 1853. It is a noteworthy fact that at that early date, and from purely theoretical considerations, Sir William was able to predict the effects of current density, which have only now been re-discovered. At the same time we are disposed to think that Sir William would himself dissent from our contemporary's remark that the communication contained "all that it is necessary to know on the subject." We print this week a Paper by Mr. A. E. Kennelly embodying some conclusions which, from a practical point of view, it seems very desirable to know.

Much as we sympathise with the individual shareholders of the Maxim-Weston Company, and firmly as we believe in the future of electric lighting, we shall, nevertheless, be heartily glad to hear that the new board has failed to obtain the money they are asking for, and that the company has gone into voluntary liquidation. In the long run, we feel assured that this would prove to have been the wisest course. The assets of the company seem to consist chiefly of more or less obsolete stock, and of undeniably worthless patents, doubtful book debts, and visionary contracts. On the other side, there are judgment debts and other debts, and continual expenses, to say nothing of a mortgage on the property. The name of the Maxim-Weston Company is not synonymous with success in this country either from an engineering or a commercial standpoint, and with the competition of younger, better equipped, and better managed firms to be faced, we altogether fail to understand what chance can possibly remain for a concern handicapped with a past such as that of the Maxim-Weston.

In our issue of October 21, 1887, we published an article embodying the results of the experience gained by the North Metropolitan Tramway Company in the running of the Elieson electric tramcars over their lines. These results were of a sufficiently satisfactory character to lead the company to desire a further extension of the experiments; but unfortunately some difficulty arose upon the question of capital outlay, and eventually nothing further was done by the Elieson Company. Meanwhile, however, negotiations were proceeding with the Electric Traction Syndicate, and it was decided to allow that company to place six cars upon the line which runs from Canning Town to Plaistow. These arrangements have just been carried out, and the cars are now running. The contract is at the rate of fourpence-halfpenny per car mile, and is to extend for six months. The arrangements adopted do not call for any special description, as the whole of the plant belongs to well-known types, which will be perfectly familiar to our readers. The cells are 92 in number, of the E.P.S. type, specially designed for traction work. The motor and gearing are by Immisch and Co. The motor is of 6 horse-power, with a 7-in. armature, and a double set of Renold's steel chain gearing is used, the ratio being ten to one. The cells are charged from an Immisch 10-unit dynamo, driven by a Davey-Paxman 8 horse-power portable steam engine. A single charge enables the accumulators to travel a distance of 36 miles, which is equivalent to half a day's work. The cells are withdrawn sideways, and the change is very expeditiously effected. The details have been worked out by Mr. Thomas Frazer, the company's engineer, and seem to have been reduced to the greatest simplicity and ease of manipulation. We look forward with confidence to the complete success of the experiment, provided always that the rate of depreciation of the accumulators is sufficiently low.

We are glad to see that the Leamington Town Council have come to terms with the Midland Electric Light and Power Company with regard to the improvement of the lighting of the Parade in that town. The replacement of twenty-five existing 16 candle-power lamps by the same number of 50 candle-power lamps and the introduction of a few 300 candle-power incandescents, besides four arcs, ought to go a long way to place the lighting on a satisfactory basis. As regards the working of the station, there is now absolutely no room whatever for complaint. Ever since Christmas last the lighting has been carried out with perfect regularity.

The *Law Times*, commenting on the Electric Lighting Act of 1888, points out that the legal effect of the clause dealing with the compulsory sale to the local authority at the end of forty-two years may shortly be illustrated by the operation of a similar clause in the Tramways Act of 1870. We may add that the operation of the Tramways Act is of interest to electrical engineers from intrinsic, as well as merely illustrative reasons. Section 43 of the Act cited provides that the companies shall sell "upon terms of paying the then value (exclusive of any allowance for past or future profits of the undertaking, or any

Digitized by Google

compensation for compulsory sale, or other consideration whatsoever) of the tramway, and all lands, buildings, works and materials, and plant of the promoters suitable to and used by them for the purposes of their undertaking." "These words," says the *Law Times*, "seem to be clearly expressed, and apparently what was intended was that a valuation should be fixed for the tramway and all lands, *taken as a connected whole*, without any reference to profit and losses. But the opinion of four counsel of great repute, including the present ATTORNEY-GENERAL and Sir HORACE DAVEY, which was published in *The Stock Exchange* last year, does not seem to favour this view. They considered 'that the local authority would have to pay when purchasing the undertaking the then value of the tramway and all lands, &c., as part of a going concern, and not merely the value of the tramway, lands, &c., considered independently of the undertaking of which they form part.' Now, the expression 'going concern' is usually applied to a concern relative to its profits and losses, which are expressly excluded by the terms of the statute. The concluding words also have no meaning unless it is intended that profits are to be taken into account, because the land, &c., comprise the whole undertaking except the carrying on of the business with reference to the profits and losses." Finally, however, our legal contemporary thinks it "doubtful whether the shareholders will realise more than the value of the actual property taken as a whole, and apart from the 'circumstances that they are in such a position as to be ready for immediate working.'" Upon the whole, we take it that the acquisition of the tramways by the local authorities will be distinctly conducive to the interests of electrical engineering, since it must lead to increased inquiry for electric traction, and in many cases this may ultimately lead to extensive municipal works, combining lighting with the transmission of energy.

IN a recent issue we spoke of the long-distance telephone line between New York and Chicago as being already in operation. We are courteously informed, by our esteemed contemporary the *Western Electrician* of Chicago, that the building of the line is not yet complete, although it is in active progress. As a matter of fact, we were misled by the recollection of some successful telephone experiments upon existing telegraph lines between the cities referred to.

THE report of the Education Commission now issued shows that, although differing on some points of detail, the Commissioners are agreed on the main outlines of a scheme for technical instruction, by which term is meant instruction in the scientific or artistic principles which underlie the industrial occupations of the people. Just a few details will suffice to show the nature of the proposed scheme. The subject of technical training is not to encroach upon general education. Elementary science, varying in its requirements with the locality, is to be a part of this instruction. Itinerant science teachers are recommended in the case of sparse populations as well as in towns. The examination in science in all the lower standards is to be oral. Manual instruction is not to be begun before a child is ten years old. It should be provided for in some higher educational institution, attendance upon such instruction by elementary scholars to count for attendance at the elementary school. Voluntary effort on the part of manufacturers and employers of labour is to be fostered and not discouraged; but care is to be taken not to lead the artisan population to trust to the artificial teaching of a school instead of to the practical and diversified training of the workshop.

DR. SESTIER, in his important work on "La Foudre"—a work which is a perfect mine of information as regards the history and tradition of the subject—hazards the opinion that the Temple of Solomon was provided with a thoroughly complete system of lightning conductors. We learn from JOSEPHUS that the roof of the inner Temple was studded all over with *flèches* of gold or gilded metal, and an immense quantity of brass was employed in sheathing the walls of the outer courts. The important question remains—Was an earth connection provided? The Temple, it must be remembered, was built upon a solid and almost isolated rock, and it would appear to be a matter of some difficulty to find a good earth. The learned Doctor is, however, of opinion that the mere fact that during a period of over a thousand years the building escaped all damage from lightning affords sufficient proof that a proper earth connection had been provided. However this may be, it is perhaps worthy of note that the system of protection adopted by SOLOMON—the Wisest of Mankind—was well adapted to meet the case of the oscillatory discharge; in fact, it is precisely that which is now recommended by Dr. OLIVER LODGE.

THE palace of the King of Roumania at Sinaia is lit throughout by electricity, motive power being derived from a mountain stream in the immediate neighbourhood. With reference to this installation the London correspondent of a provincial paper tells the following story:—

"I happened to be in the Palace of Sinaia when the electric light was being exhibited to the King on trial. The representative of the English firm who were setting up the installation was an exceedingly voluble person, and he was explaining to his Majesty at great length all the advantages which the electric light enjoyed over gas. It did not tarnish gilt, it did not consume or vitiate the air, it could be turned on or off at any moment; there was no occasion to use matches, and, greatest advantage of all, it minimised the chances of fire, and absolutely gave out no heat. The King listened with great attention, and was evidently much impressed, but just as the voluble gentleman was mentioning the fact about there being no heat, he placed his hand at the bottom of one of the lamps, and even the royal presence could not restrain an exclamation of pain—he had burnt his fingers with the heated metal. Seeing this, the King gingerly touched the lamp in turn, and he, too, got a slight burn. He smiled grimly, and turning to the electrician, said: 'Hum, well, I hope, Mr. ——, all the other advantages of the electric light are not so apocryphal as this.' But he decided to have it installed all the same."

Tamworth.—The mayor of this town is promoting a public subscription towards a "demonstration" of electric lighting.

The Statue to Ampere.—M. Carnot presided a few days since at the ceremony of unveiling the statue of Ampère at Lyons.

Digitized by Google

Cable Repairs.—The Submarine Telegraph Company's cable from Lowestoft to Norderney has been successfully repaired by Mr. J. Berdeaux, of the ss. "Lady Carmichael."

Montpellier.—The new theatre at Montpellier was opened on the 1st inst. This theatre has been fitted with a very complete installation of the electric light by M. Popp.

Personal.—We learn that Mr. G. S. Hooker has resigned his position as electrician in charge of the Bath installation, and that Mr. Orlando V. Thomas has been appointed in his place.

The Telephone in the West.—In the year ending August 31, 1888, 3,615,110 telephone messages passed over the lines of the Western Counties and South Wales Telephone Company.

Frankfort.—The aërial conductor of an electric railway at Frankfort has been struck by lightning. The flash ran along the wire to the dynamo, the armature of which it completely ruined.

Bedford.—At the last meeting of the Bedford Town Council a motion was made to appoint a committee to consider the best means of lighting a portion of the town by electricity. A decision was postponed to a later meeting.

Fulham Vestry.—At a meeting of the Vestry on October 3rd the Law and Parliamentary Committee brought up a report recommending that the solicitor to the Vestry be instructed to oppose Bills to supply the parish with electricity, which was agreed to.

Paris.—Within a month a new central station for the electric light will be opened at the Palais Royal, Paris, for the shops, the galleries, the Conseil d'État, the Cour des Comptes, the Théâtre Française, and the Palais Royal. The building of the cave in which the engines are to be placed in the courtyard is almost finished.

Interruption of the Australasian Cables.—Telegraphic communication with Australia and New Zealand is suspended in consequence of the interruption of the Port Darwin cables. The rupture was caused by the cable ship, "Sherard Osborn," while engaged in the repairs of the original cable. As the ship is on the spot, it may be expected that communication will be promptly restored.

Eastbourne.—At the last meeting of the Eastbourne Town Council a letter was read from the Eastbourne Electric Lighting Company offering to renew the contract for lighting the parade at the rate of £30 per lamp per annum. This offer was accepted, and the contract was ordered to be signed. In a previous communication the company had stated that the actual cost of running the lamps amounted to at least £32. 10*s.* per annum.

Ipswich.—At a meeting of the lighting committee of the Ipswich Town Council, on Friday last, Messrs. Lawrence, Paris and Scott applied for permission to lay cables under the footway in certain of the streets of the town. The Town Clerk reported that it was in the power of the corporation to grant the request. The matter was, however, deferred, and the applicants were informally recommended to apply for a Provisional Order.

New Submarine Cables.—The Portuguese Government has granted to the West African Telegraph Company and to the Eastern and South African Telegraph Company an exclusive concession for forty years, authorising these companies to lay submarine cables along the West African coast between St. Paul de Loanda and the Cape of Good Hope, touching at the intermediate ports of Benguella and Mossamedes. The Concession provides that these cables are to be laid before the 30th September, 1889.

The Electric Light at Indore.—The latest fad of His Highness the Maharajah Holkar, says the Allahabad *Morning Post*, has been the electric light. An engine, with all the necessary apparatus, arrived from Bombay about two months ago, and a considerable portion of the lamps, &c., had been erected, when suddenly His Highness stopped the work. So the whole of the plant has been taken up and returned to Bombay, the Maharajah agreeing to pay ten thousand rupees for this little freak.

A Portable Electric Search Light.—A new pattern of portable electric search light is now being fitted to the "Hecla," torpedo depot ship. The novelty consists in a Siemens dynamo and projector, mounted on the same carriages as a Merryweather's engine and boiler of the description so long and successfully used for fire purposes. The carriage can be drawn either by man or beast, and it is easy to see how invaluable such an arrangement might be during night skirmishing in a rough country.

A Portable Electric Lamp.—Experiments are being made at the Shireoaks Colliery by Mr. O. R. Swete, of the Associated Society of Telegraphic Engineers and Electricians, with a new portable electric lamp, the joint invention of Mr. David Urquhart, Mr. D. G. Fitzgerald, and others. It is stated that the lamp is perfectly safe, and can be placed in any position without affecting the light. The total weight is 4½lb., and its cost £1. The cost of maintenance is estimated at 3d. per week, including repairs.

Paddington Vestry.—At a meeting of the Vestry on October 2nd, Mr. Mark Judge asked that the Electric Lighting Committee's report should be considered first by the joint committee then meeting, as the subject was of great importance to the parish.—The Electric Lighting Committee having considered the report of Mr. S. J. Mackie, thought it would be to the interests of the parishioners to take the necessary steps to apply for a provisional license for electric lighting this year. This was put and carried.

St. George's Vestry.—At a meeting on October 4th, the Vestry proceeded to appoint an electric light committee, in accordance with a resolution passed at the last meeting. It was agreed that the committee consist of thirteen members, and that the following gentlemen, who were members of a former committee, be elected members, viz:—Mr. John Dovey, Admiral the Hon. A. Duncombe, Sir William J. Farrer, Lord Frederick Fitzroy, Lord Hobhouse, and Admiral Sir George Wellesley. The following gentlemen were also elected:—The Hon. Alan de Tatton Egerton, M.P.; Mr. Southern, Mr. Cove, Mr. Antrobus, Mr. Williams, Mr. J. Finch, and Mr. Adkins.

Fatal Accident in Valladolid.—The Madrid paper, *El Imparcial*, of September 21, reports a fatal accident at an electric installation in Valladolid. Two *employés* of the Sociedad Electricista Castellana, Senors Miravalles and Garcia, were inspecting the accumulators used for the service of six large arc lamps, when they met their death. According to the evidence of a child who was present, one of the *employés* had warned his companion not to touch the machinery; but he, either from foolhardiness, or judging the warning unnecessary, meddled with the conductors, at the cost of his life. His friend seized him with a view to his rescue, and received injuries which shortly afterwards proved fatal.

Retirement of Colonel Holland.—Colonel James Holland, after having filled with great efficiency, and to the entire satisfaction of the shareholders, the office of chairman of the Indo-European Telegraph Company, has felt compelled, to the great

Digitized by Google

regret of directors, officers, and servants alike, on account of advancing age, to resign his seat at the Board. Colonel Holland has been chairman of the company for twenty years, and is succeeded by Mr. J. Herbert Tritton, a leading banker, formerly president of the Chamber of Commerce, and a name too well known to need illustration. At the same time Colonel Holland resigns the chairmanship of Reuter's Telegram Company, in which he will be succeeded by Admiral the Right Hon. Sir John C. Dalrymple Hay, Bart., K.C.B.

The Progress of the Electric Light.—At the present moment, says the *Manchester Courier*, there is a fine opportunity in London for engineers with a special knowledge of electric lighting. Since the commencement of the present year the new light has grown enormously in the public favour. For some time past it has been used in many of the clubs and public buildings. Now it is being laid on generally to all private residences of any pretence both in town and country. The house decorators are preparing designs of ceilings and walls that secure a better effect from the electric light. So many are the applications from those who wish to have the electric light installed in their houses that the engineers who undertake this class of work are seriously embarrassed.

Messrs. Immisch and Co.'s Electric Launches.—We learn that Messrs. Tagg and Son, of the Island Works, East Molesey, have received orders to construct five electric launches, each 35ft. in length, for Messrs. Immisch and Co. Another launch, designed and built for the same firm by Mr. W. Sargeant, of Chiswick, has just been completed. The launch is 65½ft. long, with 10ft. beam, and is designed to carry 80 passengers, with a mean draught of 22in., 12½ tons displacement, at six miles an hour, as regulated by the Conservancy bye-law. The electrical machinery and storage being placed below the deck fore and aft leaves a clear run the whole length of the boat for passengers. In the middle is a handsomely fitted cabin with lavatories, dining table, &c. 200 E. P. S. accumulators are placed on board, and supply current for two motors of 7½ horse-power each, driving twin three-bladed propellers by Thorneycroft and Co. The hull is constructed with primary view to comfort of passengers, and is of bright mahogany and teak throughout.

University College, Liverpool.—We have received a copy of the calendar of University College, Liverpool, for the Session 1888-89. This college, together with Owen's College, Manchester, and the Yorkshire College, Leeds, form the Victoria University, by which degrees are granted in the faculties of art, science, law, and medicine. At the University College, Liverpool, the faculty of medicine at present holds the most prominent position, but in equipment and *personnel* the science faculty is probably second to none in this country. The chair of mathematics is held by Prof. F. S. Carey, M.A.; the chair of experimental physics by Prof. Oliver Lodge, LL.D., D.Sc., F.R.S.; the chair of engineering by Prof. H. S. Hele Shaw, M.I.C.E.; and that of chemistry by Prof. J. Campbell Brown, D.Sc. In electricity and magnetism, Dr. Oliver Lodge lectures regularly to elementary, intermediate, and senior classes, consisting of first, second, and third years' students respectively, and special arrangements are also made to meet the requirements of those who wish to take up electrical engineering without spending more than one year at the college.

Chelsea Vestry.—At a meeting of the Vestry on October 2nd, the Electric Lighting Committee reported having considered a letter from the Chelsea Electricity Supply Company to the Board of Trade, asking that a certain area be added to the area of supply. The committee recommended that the Board of Trade be informed that the Vestry dissents from the application of the Electricity Supply Company for the extension of Schedule A at the present time, and that the Board of Trade be further informed that the company have not exercised any of the powers of their order as to the existing Schedule A, so far as regards the execution of works therein. Also, the committee reported that they have considered the letter from Messrs. Deacon, Gibson and Medcalf, dated 20th ult., enclosing a form of license which their clients, the London Electric Supply Corporation, desire to have granted under the Electric Lighting Acts, and asking the Vestry to assent to the same. The committee on this recommended that the Vestry do dissent from the application and inform the Board of Trade to that effect. The report was adopted, on the motion of Mr. Mossop.

The Lighting of Swansea.—On the 2nd inst. there was a large attendance of the gas committee of the Swansea Town Council, which held its meeting at the Town Hall, for the purpose of considering what steps should be taken in the interests of the ratepayers consequent on the action of the Swansea Gas Company in deciding to increase the price of gas supplied to both the Corporation for public purposes and to private consumers. The present cost of lighting the borough is about £4,000 per annum. The Town Clerk had, in accordance with instructions, obtained counsel's opinion as to the powers of the gas company over the extended borough, and the answer received was favourable to the Corporation. The Town Clerk then presented a long report on the powers of the Council under the Electric Lighting Act, 1882, amended by the Act of 1888.—In the discussion which ensued, the action of the gas company was strongly animadverted upon, and ultimately it was decided that, the consent of the Town Council having been obtained, the Town Clerk should be instructed to at once apply to the Board of Trade for a Provisional Order to light the town by means of electricity.

Tynemouth.—At a recent meeting of the Watch Committee of the Tynemouth Town Council, letters on the subject of electric lighting were read from the Local Government Board, the Clerk to the Barnet Local Board, and several of the electric lighting companies. It was resolved that the matter should be left in the hands of the Watch Committee, with the addition of two members of the Council, for them to report to the Council; the borough engineer in the meantime to prepare a plan showing the public buildings in the vicinity of the market which it had been suggested should be lighted by the electric light. A special meeting of the Town Council has been convened for the purpose of considering, and if so ordered of adopting a resolution, approving of the intention of the Council, as the local authority under the Electric Lighting Act, to apply to the Board of Trade for a Provisional Order to authorise the supply of electricity for public and private purposes within their district, and also to consider the terms of the order. The question of extending the electric light in the borough is one that is now engrossing public attention, and the outcome of the special meeting of the Council is awaited with considerable interest.

The Electric Light at Dover.—At the last meeting of the Dover Town Council a letter received from Messrs. Laing, Wharton and Down, offering to light the town by electricity, came up for consideration. They asked for a reply to be given them whether the Council would be prepared to receive a tender from them for the lighting of the streets, as they would then be able to get their appliances in full working order by the time of the expiration of the gas term.—Alderman Finnis suggested that the firm should be allowed to give their quotations.—Mr. Birch moved that it be put under the table ("No, no").—The Deputy Mayor said he could not agree

Digitized by Google

to that. The electric light was bound to come, and there was no objection to the Council ascertaining what the price would be, and comparing it with the gas contract. The Councillor would not surely decline to receive an estimate from the firm.—The Mayor said he thought all firms were willing to give estimates without charge in the hope of ultimately getting an order.—The Town Clerk was then directed to write to Messrs. Laing, Wharton and Down, and ask them to give an estimate for the lighting of the town by electricity, as suggested in their letter.

Leamington Town Council.—At the last meeting of this Council a letter was read from the Midland Electric Light and Power Company, saying that they would supply four arc lamps, on poles, with raising and lowering gear provided, fixed, and lent for the sum of £12, the arc lamps and wires to remain the property of the company. The mayor had generously offered to supply and fix the poles and the raising and lowering gear, or the cost would have been much more than it was. The company would also supply five 300 c.p. incandescent lamps, fitted on existing lamp posts, with shades and arms, the lamps, shades, arms, wires, and fittings to remain the property of the company, for the sum of £18; twenty-five existing 16 candle-power lamps, on existing lamp posts, to be replaced by fifty candle-power lamps, two in each lantern, the lamps to remain the property of the company, for £3. Towards these costs the company will contribute one-third, in order to show their desire to assist the corporation in making the lighting of the parade the success that both bodies desired. The company would further agree to supply the currents used without any extra charges beyond the present contract for one month; but the company would make a charge of 10s. per week for cost of carbons, cleaning, &c., of the arc lamps. It was decided to accept these proposals.

Electric Light in Coal Bunkers.—"Verax" writes to the *Globe* on this subject as follows:—"In the 'Naval Notes and News' in your edition of Friday last, it is stated that the coal-boxes of all ships of the 'Admiral' type are, except the 'Benbow,' which has just sailed for the Mediterranean, to be lighted with the electric light, and the very natural question is asked, why was not this thought of before? Now, when the 'Benbow' was being completed for commission at Chatham Dockyard, and the electric fittings were under consideration, it was asked by an officer who had great interest in seeing the ship completed in a very thorough manner, and whose experience had taught him the necessity of well-lighted bunkers, that her bunkers might have electric lights put in. The question was referred to the chief constructor of the yard, the work being in his department. After, I presume, due consideration, his reply came, to the effect that such fittings were unusual, and it was not shown that any particular necessity for them existed in this ship. Had they not been unusual there would have been no need of a special application; that they were necessary the recent determination to fit them proves, and it is highly probable that had they been put in when asked for the recent lamentable explosion would not have occurred in the very ship where no particular necessity was shown for their being fitted."

Bell's Asbestos.—We have received from Bell's Asbestos Company a copy of their new illustrated catalogue. From the preface we learn that the company are the freeholders of extensive mines in Canada, from which about one-third of the total quantity of asbestos used in the whole world is now derived. The superiority of the Canadian over the Italian variety of the mineral is so marked that many of the Italian manufacturers are now actually importing the raw material from Canada. The growth and activity of the asbestos industry is one of the most striking facts in the recent history of the engineering trades. It is comparatively but a few years since it was first introduced upon a wholesale scale, whilst to-day the catalogue of the Bell Asbestos Company contains a list of nearly forty different methods or trades in which it finds employment. Its non-inflammable properties, and its use for engine packings are well known. Asbestos paper, specially prepared as an insulator for electical purposes, is steadily growing in favour; whilst asbestos paint is increasingly used for dynamos and solenoids. Asbestos putty as a heat-resisting and insulating material is suited for use in arc lamps, instead of ebonite. In the form of asbestoline we hear it well spoken of as a lubricant both for dynamos and engines. We may add, in conclusion, that one of the last-discovered purposes to which it may be applied is that of a filtering material, for which it seems to answer remarkably well.

Proposed Electric Railway in the New Forest.—At the last meeting of the Lyndhurst Highway Board a letter was read from Mr. J. C. St. Aubyn Angove, solicitor, of London, giving notice, on behalf of Messrs. Haines and Pool, engineers and promoters of the scheme, that it was their intention to apply to the Board of Trade for a provisional order empowering them to construct a tramway between Lyndhurst-road Railway Station and Lyndhurst. The line would be of three-feet gauge, and the tramcars would be propelled by electricity. Mr. Angove asked the board to consider the matter at once, because arrangements had been made to proceed with the work immediately after the Board of Trade had issued the order.—In answer to questions, the Clerk said the promoters proposed to lay the rails by the side of the road, on the waste land, and they did not cross the road until they reached Dunstan's Arch, near the police station, where the crossing was a level one.—Mr. Palmer, on being appealed to, said he believed the scheme meant ruin to Lyndhurst.—Mr. Head said he should object to the cars going into Lyndhurst at all.—Mr. Haines and Mr. Angove then had an interview with the board, and Mr. Haines said they intended to go entirely on the waste, and not to be within the authority of the Crown. They only proposed to go on the highway from Beaulieu-road to Gosport-lane. With regard to the passing places, they intended to arrange with the Crown for them, so as not to get on the highway at all. They proposed to carry passengers and goods. There would be no noise, no smoke, and no smell. —Messrs. Haines and Angove having withdrawn, the board proceeded to discuss the matter, Mr. Roy remarking that the plan of the promoters was incomplete. It should be clearly understood that the tramway should not be so near the road as to frighten the horses. The promoters asked to come within 15 feet of the centre of the road, and that was simply inadmissible.—Ultimately, Mr. Roy proposed the following resolution:—"That this board has a decided objection to allowing the electric tramway in close proximity to horse traffic on the score of danger, and the board observes that the promoters purpose to construct their line within 15 feet of the centre of the road, which, in their judgment, they find to be wholly inadmissible."—This was seconded by Colonel Macleay and agreed to.—Messrs. Haines and Angove were called in and informed of the decision, when Mr. Haines said he thought the difficulty might be got over by their taking in the waste on the other side of the road if the board would give it up.—Mr. Roy said the promoters must get the consent of the Crown for the passing places before they came to them again, or otherwise it would be of no use to do so.—Mr. Angove said they did not anticipate any difficulty on the part of the Crown.

ON THE VOLTAMETRIC MEASUREMENT OF ALTERNATING CURRENTS.

BY A. E. KENNELLY.

It has until apparently quite recently been generally supposed that an electric current reversing its direction with the frequency that characterises what is commonly called an alternating current would not decompose water visibly; or, in fact, that if any decomposition did take place at the electrodes, the recombination at each reversal was so speedy and complete that no free gas was developed. It has been shown, however, lately, in a Paper by Messrs. Manœuvrier and Chappuis,* that when the electrodes are small free decomposition does take place, mixed gas being liberated at each. Since that time Professors Ayrton and Perry have contributed to the data on the subject in an article appearing in *The Electrician* of July 13th, 1888, and in which some very interesting phenomena observed with polarised electrodes are described, while it is mentioned that the quantity of gas liberated under given conditions is a function not only of the current density per unit surface of electrode, but also of the rate of alternation.

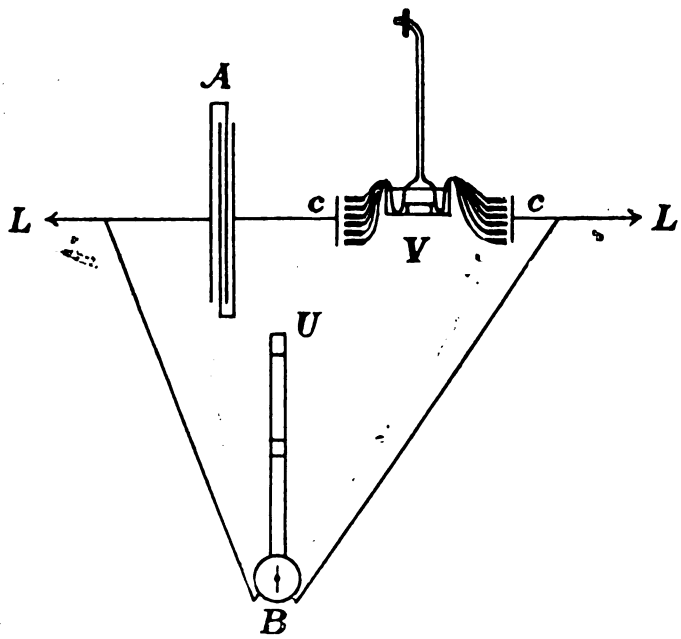

FIG. 1.

The statement of the connection that exists between these variables seems not to have yet been published. The following experiments made recently at Mr. T. A. Edison's laboratory for the purpose of investigating this matter show that under certain conditions the quantity of gas liberated is in very close accordance with that which a continuous current of equal strength would supply, and hence afford ground for the hope that it will shortly be possible to measure the strengths of alternating currents by the voltameter, as closely and as conveniently as in the case of continuous currents.

Two methods have been tried.

(1.) The condenser method, or incomplete metallic circuit.

(2.) The ordinary method with complete metallic and liquid circuit.

Several series of measurements have been made, all agreeing very fairly. The following series, taken at one time, will suffice for all.

The source of the alternating current was a Siemens alternating dynamo machine, designed for 100 volts, the electromotive force being very readily under control through the current in its field magnets, the speed of revolution being on the occasion of this experiment very steady at 1,470 per minute. At this speed its alternations being eight to the revolution are 196 per second.

The voltameter, Fig. 1, was of special construction. An ordinary glass evaporating dish, 11·5 centimetres in diameter and 6·3 high, was filled about two-thirds with a 10 per cent. (by weight) solution of pure sulphuric acid in distilled water, the density of this solution being 1·065 at 19° C. At the bottom of the dish was immersed a disc of resinous material, 5 centimetres in diameter and 1·2 centimetres high. Twelve platinum wires of different lengths, but equal diameter (0·0178 centimetres), projected vertically from the upper surface of the disc, so as to stand in a ring of 4 centimetres diameter, and equidistant from each other. These wires were ranged from 1·5 centimetres down to 0·025 centimetres in length, the corresponding wires across one diameter having as closely as possible equal lengths. Connections with rubber-covered wire, sealed in the material of the disc, made six little separate voltameters each with its own pair of insulated leads. By uniting more or less of these leads outside the instrument, the voltameter might be made to comprise any or all of the couples of electrodes, thus enabling a considerable range of electrode area to be at command, as shown by the table given below:—

Over this sextuple voltameter there rested a glass bell seven centimetres in diameter, terminating after 10 centimetres of elevation in a vertical glass tube of uniform bore 7·5 centimetres long and about 0·6 centimetres internal diameter, closed at the top by a rubber tube and fish clamp. This tube was graduated for volume by comparison with a burette, and found to have a capacity per linear centimetre, from several measurements, of 0·2684 ± 0·002c.c. In using the instrument, the tube and bell were filled with solution, and gas electrolytically generated until the latter stood at a certain mark near the top. All being ready, the measured current was then passed through the apparatus for a noted interval, at the end of which the length of tube occupied by gas was measured downwards from the fiducial mark.

In the condenser method the connections were as shown in the diagram—where A is the adjustable condenser; V the voltameter with commutators *c c* for connecting the separate couples of plates in multiple; B U a Cardew voltmeter; and LL the leads to the dynamo.

Under these conditions we know that the absolute quantity of current passing through the voltameter, assuming that the periodic variation of electromotive force follows the sine law,

$$Q = n\pi ekt \times 10^{-7} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where Q is the absolute quantity of electricity that traverses the voltameter in time t; e is the mean alternating potential = difference, as indicated by the Cardew voltmeter B; k is the absolute capacity of the condenser A; and r is the number of alternations per second.

This formula is thus independent of the resistance of the voltameter, which is quite negligible under these conditions. If V_0 be the volume of gas at zero centigrade theoretically

decomposed by a continuous current, c, in absolute measure equivalent to the passage of this quantity, Q, we have

$$c = n\pi ek \times 10^{-7} \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

and

$$V_0 = 5{\cdot}43\, nekt \times 10^{-7} \quad . \quad . \quad . \quad . \quad . \quad (3)$$

Besides the Cardew voltmeter steady potential indication, a quadrant electrometer, not shown in the diagram, with its needle connected to one pair of quadrants, was employed to measure the potential difference at the voltameter terminals, and thus indicate its mean resistance.

The above table gives the results of ten measurements. The volume of the gas is corrected for temperature, but no correction is introduced for the barometric pressure or the tension sustained by the gas in the tube.

The condenser used was adjustable from 0·001 up to 5 microfarads, and is probably accurate to at least 0·5 per cent.

The last two columns show that—

When the density of current per square centimetre of either electrode was	The percentage of gas actually generated of that calculated as due was
1·12 ampere	6·2 per cent.
7·9	38 ,,
30·04 (average)	82·6 ,,
31·35	78·4 ,,
46·1 (average)	89·3 ,,
50 1	100·8 ,,
62·6 (average)	95·3 ,,
69·7	93·0 ,,
141·8	95·6 ,,

The trials Nos. 13, 14, and 15 were taken without condenser, and with non-inductive resistances in its place. In trial No. 13 this resistance was a length of fine platinum wire (hot). In trial Nos. 14 and 15 the resistance was a 96 volt 10 candle-power Edison lamp, offering 230 ohms resistance at equivalent illumination. In calculating the current strengths for these three observations, the resistance of the voltameter itself was required. It was measured in two ways—1st, by means of the quadrant electrometer, and the potential differences it indicated on the known resistance, and on the voltameter; 2nd, by rapidly substituting a non-inductive resistance alternately with the voltameter in the lamp circuit, and adjusting this resistance until the illumination was equal in both cases. These two methods concurred in showing the resistance of the voltameter to be 30 ohms, and the maximum resistance it offered through the whole series was 35 ohms.

The table shows that

When the current density per square centimetre of either electrode was—	The per cent. of calculated gas actually liberated was—
20·9	52
59·3	95·3

These results, corroborated by several previous series, go to show that for a rate of alternation of 200 per second, and currents of between 0·1 and 0·35 amperes, the quantity of gas generated by an alternating current in a voltameter is approximately equal to that generated by an equal continuous current when the mean current density at the surface of the electrode is above 50 amperes per square centimetre of each; that below that density the quantity of gas developed rapidly diminishes, and that below one ampere per square centimetre soon disappears.

Also that the resistance of a voltameter with very small plates, traversed by an alternating current, is much less than that it would offer to an equal continuous current. Were this not the case, the resistance of a voltameter for alternating current measurements might for many purposes prove prohibitively great.

HERTZ'S RESEARCHES ON ELECTRICAL OSCILLATIONS.

BY G. W. DE TUNZELMANN, B.SC.

(*Continued from page 698.*)

Other Positions of the Secondary Circuit.—Dr. Hertz made numerous observations with the secondary circuit in other positions, but in no case were any phenomena observed which were not completely in accordance with theory. As an example of these consider the following experiment:—

The secondary was first placed in the horizontal plane in the position V. (Fig. 8*), and the air space was in the position a_5 relatively to the primary. The circle was then turned about a horizontal axis through its centre and parallel to the primary, so as to raise the air space above the horizontal plane. During this rotation θ remained equal to 90°, and the value of β remained nearly constant, but α varied approximately in the same ratio as cos Ψ, Ψ being the angle between the plane of the circle and the horizontal, for α is proportional to the number of magnetic lines of force passing through the circle. Let α_0 be the value of α in the initial position, then in the other positions its value would be $\alpha_0 \cos \Psi$, and therefore the sparking distance should be given by the expression $\alpha_0 \cos \Psi + \beta$, in which α_0 was known to be greater than β. This was confirmed by observation, for it was found that as the air space increased its height above the horizontal plane the sparking distance diminished from 6 millimetres down to 2 millimetres, its value when the air space was at its greatest distance above the horizontal plane. During the rotation through the next quadrant the sparking distance diminished almost to zero, and then increased to the smaller maximum of 2·5 millimetres, which it attained when the circle had turned though 180°, and was therefore again horizontal. Similar results were obtained in the opposite order, as the circle was rotated from 180° to 360°. When the circle was kept with the air space at its maximum

* See *The Electrician*, October 5th, 1888, page 697.

Digitized by Google

height above the horizontal plane, and then raised or lowered bodily without rotation, the sparking distance was found to diminish in the former case and to increase in the latter, results completely in accordance with theory.

Forces at Greater Distances.—Experiments with the secondary at greater distances from the primary are of great importance, as the distribution of E.M.F. in the field of an open circuit is very different according to different theories of electrodynamic action, and the results may, therefore, serve to eliminate some of them as untenable. In making these experiments, however, an unexpected difficulty was encountered, as it was found that at distances of from 1 to 1·5 metres from the primary the maximum and minimum, except in certain positions, became indistinctly defined; but when the distance was increased to upwards of two metres, though the sparks were then very small, the maximum and minimum were found to be very sharply marked when the sparks were observed in the dark. The positions of maximum and minimum were found to occur with the circle in planes at right angles to each other. At considerable distances the sparking diminished very slowly as the distance was increased. Dr. Hertz was not able to determine an upper limit to the distance at which sensible effects took place, but in a room 14 metres by 12, sparks were distinctly observed when the primary was placed in one corner of the room, wherever the secondary was placed. When, however, the primary was slightly displaced, no effects could be observed, even when the secondary was brought considerably nearer. The interposition of solid screens between the two circuits greatly diminished the effect.

Dr. Hertz mapped out the distribution of force throughout the room by means of chalk lines on the floor, putting stars at the points where the direction of the E.M.F. became indeterminate. A portion of the diagram obtained in this manner is

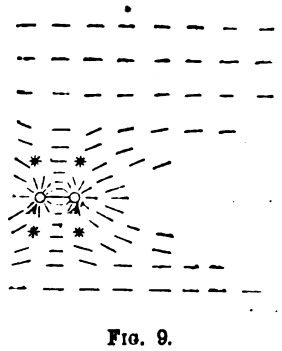

Fig. 9.

shown on a reduced scale in Fig. 9, with respect to which the following points are noteworthy:—

1. At distances beyond three metres the E.M.F. is everywhere parallel to the primary oscillation. Within this region, therefore, the electrostatic E.M.F. is negligible in comparison with the E.M.F. of induction. Now, all the theories of the mutual action of current elements agree in giving an E.M.F. of induction inversely proportional to the distance, while the electrostatic E.M.F., being due to the differential action of the two extremities of the primary, is approximately inversely proportional to the cube of the distance. Some of these theories, however, are not in accordance with the experimental result that the effect diminishes much more rapidly in the direction of the primary oscillation than in a direction at right angles to it, induced sparks being observed at a distance exceeding 12 metres in the latter direction, while they disappeared at a distance of about four metres in the former direction.

2. That, as already proved, for distances less than one metre the distribution of E.M.F. is practically that of the electrostatic E.M.F.

3. There are two straight lines, at all points of which the direction of the E.M.F. is determinate, namely, the line in which the primary oscillation takes place, and the perpendicular to the primary through its middle point. Along the latter the E.M.F. does not vanish at any point, the sparking diminishes gradually as the distance is increased. This, again, is inconsistent with some of the theories of mutual action of current elements, according to which it should vanish at a certain definite distance. A very important result of the investigation is the demonstration of the existence of regions within which the direction of the E.M.F. becomes indeterminate. These regions form two rings encircling the primary circuit. Since the E.M.F. within them acts very nearly equally in every direction, it must assume different directions in succession, for, of course, it cannot act in different directions simultaneously.

The observations, therefore, lead to the conclusion that within these regions the magnitude of the E.M.F. remains very nearly constant, while its direction varies through all the points of the compass at each oscillation. Dr. Hertz states that he has been unable to explain this result, as also the existence of overtones, by means of the simplified theory in which the higher terms of the expansion of F are neglected, and he considers that no theory of simple action at a distance is capable of explaining it. If, however, the electrostatic E.M.F. and the E.M.F. of induction are propagated through space with unequal velocities, it admits of very simple explanation. For within these annular regions the two E.M.F.'s are at right angles and of the same order of magnitude; they will therefore, in consequence of the distance traversed, differ in phase, and the direction of the resultant will turn through all the points of the compass at each oscillation.

This phenomenon appears to him to be the first indication which has been observed of a finite rate of propagation through space of electrical actions, for if there is a difference in the rate of propagation of the electrostatic and electrodynamic E.M.F., one at least of them must be finite.

At the end of the Paper in which the preceding experiments are described Dr. Hertz describes some observations which he has made on the conditions at the primary sparking point which affect the production of sparks in the secondary circuit. He finds that illuminating the primary spark diminishes its power of exciting rapid oscillations, the sparks in the secondary being observed to cease when a piece of magnesium wire was burnt, or an arc lamp lighted, near the primary sparking point. The observed effect on the primary sparks is that they are no longer accompanied by a sharp crackling sound as before. The effect of a second discharge is especially noteworthy, and it was found that the secondary sparks could be made to disappear by bringing an insulated conductor close to the opposed surfaces of the spheres forming the terminals at the primary air space, even when no visible sparking took place between the latter and the insulated conductor. The secondary sparking could also be stopped by placing a fine point close to the primary air space, or by touching one of the opposed surfaces of the terminals with a piece of sealing-wax, glass, or mica. Dr. Hertz states that further experiments have led him to conclude that, even in these cases, the effect is due to light too feeble to be perceived by the eye, arising from a side discharge. He points out that these effects afford another example of the effects of light on electric discharges, which have been observed by E. Wiedemann, H. Ebert, and W. Hallwachs.

(To be continued.)

ALUMINIUM AND ALUMINIUM ALLOYS.*

The Swiss Metallurgical Society in Lauffen-Neuhausen, Canton Schaffhausen, has succeeded in producing aluminium alloys in large quantities by means of Hérault's method. In this method the electric current is employed for fusing refractory earths containing aluminium. The negative electrode is composed of the metal, copper, iron, or tin, with which it is desired to alloy the aluminium; the positive electrode is composed of a group of carbons dipping into the molten argillaceous earth. The current is generated at these works by means of a vertical 300 horse-power Jonval turbine (Fig. 1) driving two dynamos of 6,000 amperes and 20 volts each, which are excited by a smaller Erreger

* Abstracted from the *Schweizerische Bauzeitung*, 4th August, 1888.

Digitized by Google

dynamo. The turbine has been specially built for this purpose by Messrs. Escher, Wyss and Co., of Zurich.

The dynamos were specially constructed for this large current. The construction of these giant machines—Figs. 2, 3 and 4—was undertaken by Mr. C. E. Brown, at the Oerlikon Engine Works, and this system of construction, in which the armature wire is wound through holes in the shaft of the armature, was found specially

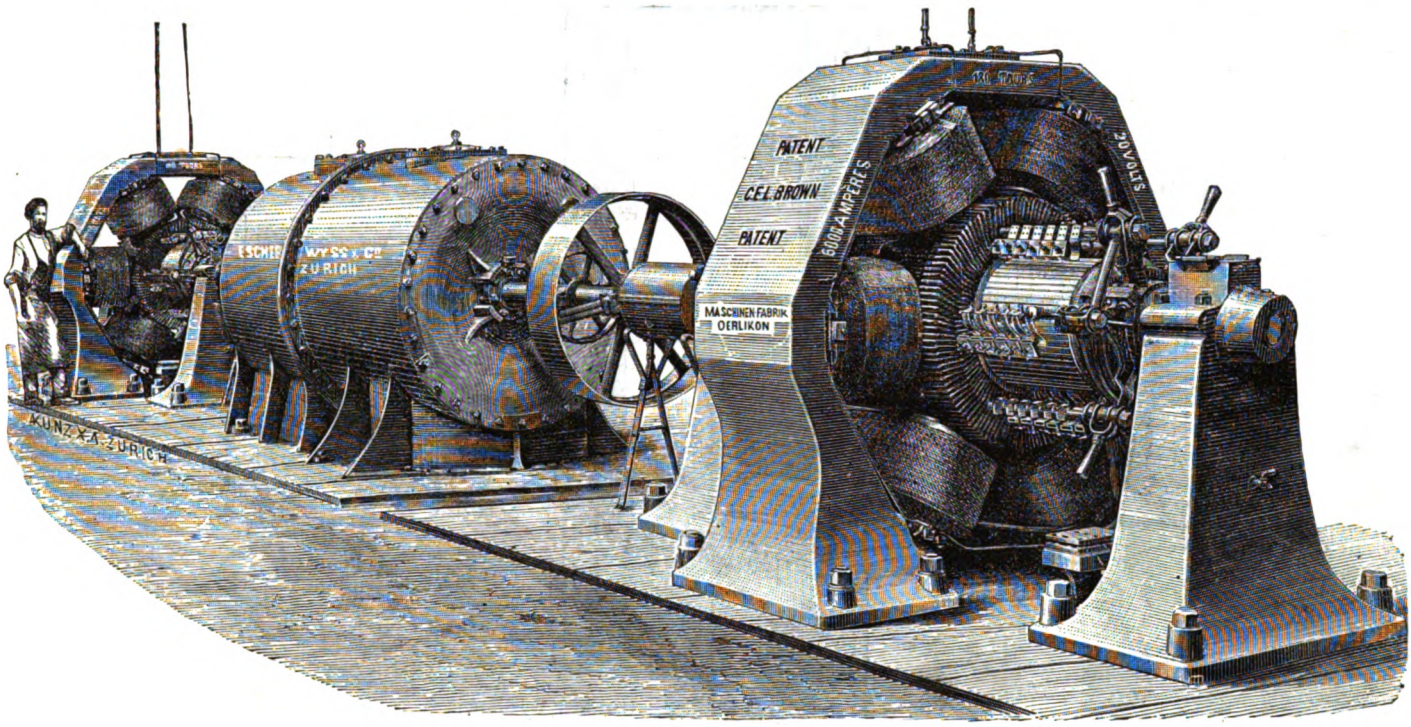

FIG. 1.—Turbine and Dynamos. Perspective View.

suitable. The machine has six field magnets, and consists of a single casting of 10,000 kilog. in weight. The field magnets are separately excited. The armature has two separate windings, each of which has six parallel divisions. Each machine has two large collectors, and no less than seventy-two brushes. Copper cables of the thickness of a man's arm conduct the electric current from the

The positive pole is formed by a group of carbons B, made up of plates *b*, while the negative pole consists of molten metal at the bottom of the carbon crucible A; the floor of this crucible has an escape closed by the carbon rod C. In Figs. 5 and 6 the general arrangement of the apparatus is represented. On the floor is a box *a* of iron or other metal, insulated at the bottom and open at top; this is fitted with a lining of carbon plates, which are then cemented together with either tar, sugar, or syrup, which surrounds and secures the basin A. In the box *a* are a number of copper pins a^1, which conduct the negative current. The positive electrode plates, *b*, are placed separately one over the other. These carbon plates may be so arranged as to have spaces between them which can be filled in with a good conductor like copper or soft carbon.

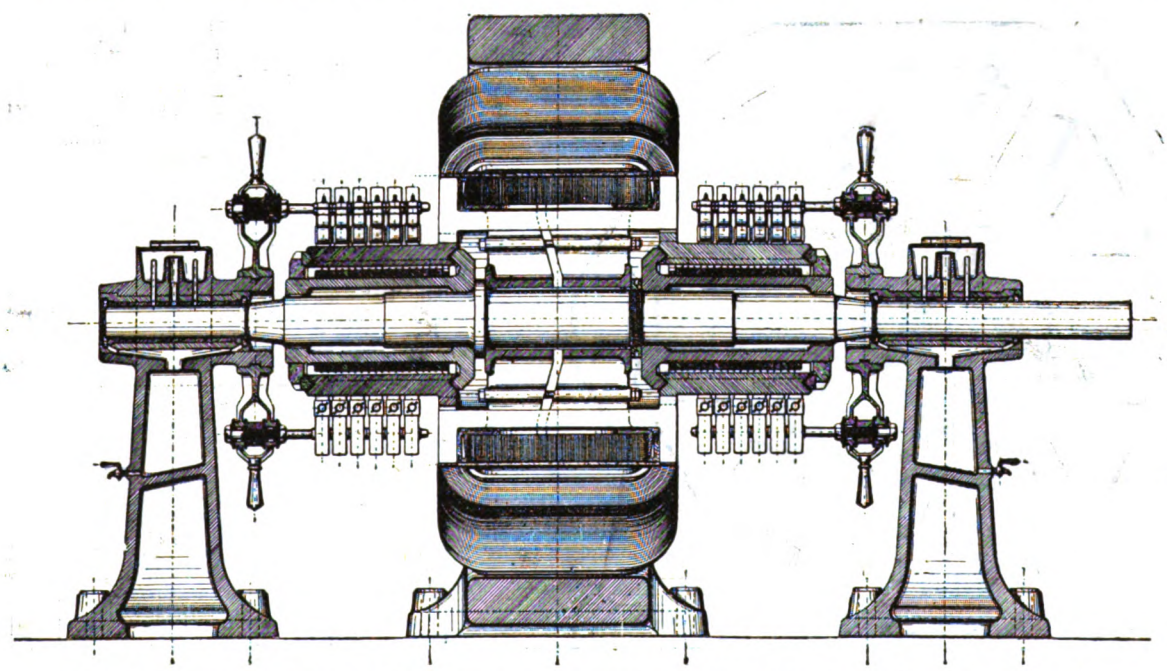

FIG. 2.—120-Kilo-Watt Oerlikon Dynamo. 6,000 amperes, 16 to 20 Volts. Longitudinal Section.

machines to the oven. The general plan of the works is shown in Fig. 7. The current from both dynamos is passed to the positive electrode in the furnace. The smelting takes place in a carbon crucible A. This is surrounded by a metallic covering connected with the negative cable.

The upper ends of the carbon plates, *b*, are connected by the cap, *g*, the loop, *e*, of which serves as a link to a chain, by means of which the carbon bundle is brought into position, and can be raised or lowered as desired.

With the exception of the space *i* necessary for the play and the

Digitized by Google

vertical motion of the carbon bundle, the opening of the basin B is covered by graphite plates, k, in which are left a few holes, n, for the introduction of materials. Corresponding to the openings, n, grooves, m, are necessarily made in the side walls of the basin. These channels, $m\,n$, also serve as an escape for the gases generated in the basin. The movable plates, o, provided with handles, o^2, serve as coverings to the openings, n, during certain phases of the smelting process. The space, k^1, between the graphite plate, k, and the rim of the box, a, is fitted with charcoal powder.

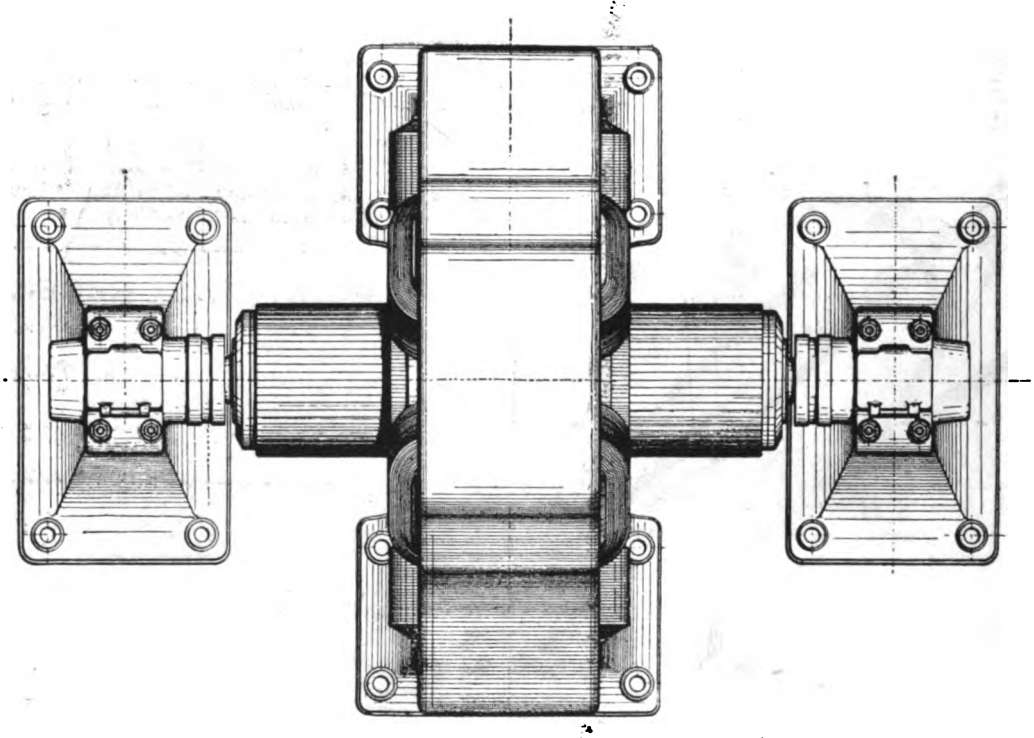

FIG. 3.—Plan of 120-Kilo-Watt Oerlikon Dynamo.

earth, Al^2O^3, is put into the basin and the bundle B is lifted a little higher. Now the current will pass through the argillaceous earth, which melts and decomposes. The oxygen attacks the carbon $b\,b\,b$ and breaks it up, so that carbonic oxide gas escapes from the basin; the aluminium dissociates from its oxygen combination and flies to the copper, so that direct aluminium bronzes are formed. The basin is now fed according to the progress of the smelting with copper and argillaceous earth.

The carbon bundle must, as stated before, be raised or lowered according to the resistance. But this can be automatically regulated by means of the chain supporting the bundle B, which can be put into communication with a reversible electric motor—regulated by the ammeter—which acts as an electrical regulator. To let off the collected fluid aluminium bronzes, the ingot mould l is placed under

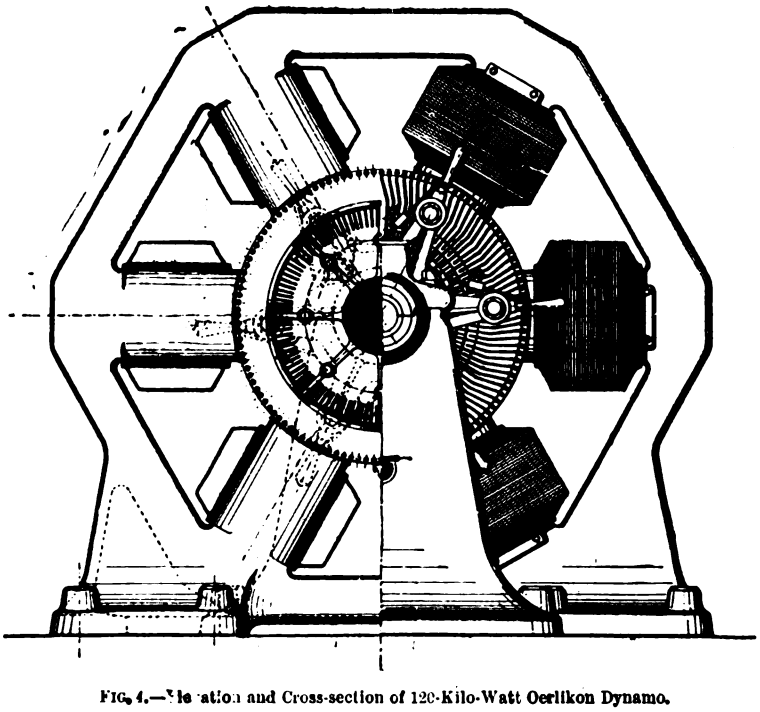

FIG. 4.—Elevation and Cross-section of 120-Kilo-Watt Oerlikon Dynamo.

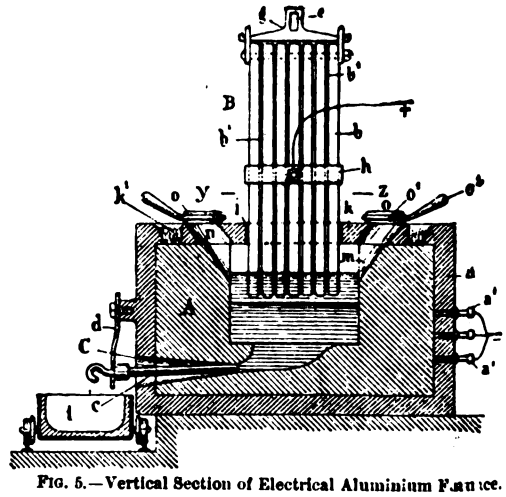

FIG. 5.—Vertical Section of Electrical Aluminium Furnace.

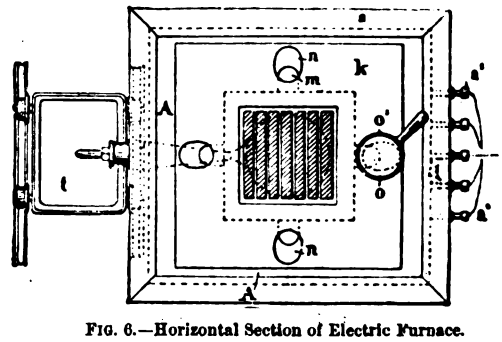

FIG. 6.—Horizontal Section of Electric Furnace.

The process is commenced by placing copper broken up in small pieces into the bottom of the crucible A; the carbon bundle B is hereupon brought nearly into contact with the copper; the current goes through the copper and melts it. As soon as the bath of fluid copper, which serves as the negative pole, is ready, argillaceous

*Verified by Professor Tetmajer.

This process admits of the production of all forms of aluminium alloys, excepting such metals as evaporate at the melting point of aluminium. Directly mixed combinations can also be effected, as, for instance, a combination of copper with silicium and aluminium, by the use of silicate of alumina instead of argillaceous earth.

With the installations of the Swiss Metallurgical Society it is possible to produce daily 300 kilogs. of aluminium, or 3,000 kilogs. of 10 per cent. aluminium bronze. Production is continuous, as the furnace can be worked for months day and night, and can be either entirely or partially emptied by means of the tap-hole. Below are some results of experiments made by Professor Tetmajer, at the Polytechnic of Zurich, with aluminium obtained from the furnace.

The brass used in the experiments is an aluminium bronze; and brasses were cast, and had not undergone any further manufacturing process beyond being turned. These aluminium copper alloys need not, however, be cast, since they can be easily hammered, rolled, or drawn.

Aluminium brass and ferro-aluminium are two very remarkable aluminium compounds. The former is distinguished for its hardness and tensile strength; the latter, if added in small quantities to steel, insures this a clear and limpid casting. The production of ferro-aluminium is similar to that of the bronzes, inasmuch as the iron takes the place of the copper.

On July 30th the inauguration of this installation took place in the presence of the shareholders and directors. It worked very satisfactorily. Although designed for 12,000 amperes, the dynamos could yield 25,000 amperes without any interruption.

"THE ELECTRICAL WORLD" IN THE UNITED KINGDOM.

Arrangements have been made by which "The Electrical World" of New York *can be obtained from* "The Electrician" *Office, 1, Salisbury-court, Fleet-street, London, E.C.*

The Rate of Subscription (payable in advance), including postage, is **£1. 1s. 0d.** *per annum to this Country and Abroad.*

Single Copies of "The Electrical World" *can also be obtained,* **price 6d. each.**

The Rates for Advertisements in "The Electrical World" of New York *can be obtained on application to* "The Electrician" Printing and Publishing Company, Limited, *as above.*

PRACTICE versus THEORY.

It is one of the commonplaces of modern physical science to say that pure theory has advanced *pari passu* with the growth of the practical applications of scientific knowledge, and that their indebtedness is mutual. There was a time when this fact was not recognised, and a still earlier period when it was not even true. The cultivation of knowledge for its own sake has in most departments of science preceded its application to the useful arts. It is also true that a quite unnecessary feeling of superiority was once manifested by the devotees of pure science towards those whose labours were more directly devoted to the immediate service of mankind—including themselves, of course. Now, however, it must be confessed that the tables have been turned. It is the practical man who talks with good-natured pity of the "mere theorist," and it is the theorist who comes with hat in hand to the man of practice and begs to know if he is disposed to consider favourably this or that suggestion. Of course, amongst the leading exponents of either branch of the craft this demeanour, if it exist at all, must be taken to be more or less assumed for the occasion. The practical man has seen too many of the triumphs of theoretical prediction to feel quite comfortable, even when he affects to despise its latest prognos-

Digitized by Google

tications. The theorist, on the other hand, possesses a well-founded conviction that the result of a mathematical investigation, so long as it is based on correct and sufficient data, affords the nearest approach to absolute certainty which is permitted to us in this mundane sphere. He knows, however, that the data must be obtained by experimental methods, and that both the experiments and the deduction may be liable to misinterpretation. The theorist is, therefore, too well aware of the advantages of long continued experiment on a scale of magnitude unapproachable in the laboratory to feel quite satisfied until theory and practice have been finally reconciled. In view, then, of the somewhat sharp dissension which at this moment exists on the subject of lightning flashes, and particularly in view of the somewhat irreconcileable attitude which the "practical" side appears for the moment to have assumed, we may be pardoned if we venture to offer a few considerations on the general question of the relationship between Theory and Practice.

In the first place, it may be remarked that no useful purpose is served by any treatment of the question which sets or attempts to set these two in sharp antagonism. Both Theory and Practice advance by and appeal continuously to Experiment. But to some extent it may with truth be said that the former is content to end where the latter begins. Theory appeals to Experiment for confirmation of the conclusions which exact reasoning—usually, that is, mathematical reasoning—has deduced from the data previously in its possession. Thus the work of the theorist ends with Experiment. But it is with Experiment (guided more or less by theory) that Practice begins, and it is not until reiterated Experiment has developed into Experience that Practice becomes firmly established. But here we must carefully distinguish between the experiment of the practical man and that of the theorist, for in general these are quite distinct in kind. The latter may be described as Pure, and the former as Mixed, experiment. Without intending anything invidious, we may say that the distinction is like that between a chemist performing an analysis and a cook concocting a soup. In Pure experiment we seek to reduce a single phenomenon to its most elementary form, and to eliminate every extraneous condition. It is true that this ideal type is seldom or never fully realised, and it is here that the aid of mathematics is invaluable in enabling us to estimate the direction and the extent of the various perturbations. The experiments of the practical man, on the other hand, are not at all of this character. He aims at producing some particular concrete result, and, provided the working conditions are ascertainable and "practicable," he cares little how complex they may be from the theoretical standpoint. As a general rule, his experiments entirely defy complete theoretical analysis. If he meets with a perturbing element his chief anxiety is not so much to discover its ultimate cause, but merely to know enough about it to enable him to ensure its suppression. The attention of the theorist, on the contrary, is immediately arrested by any such unexpected effect, and, so far from endeavouring to get rid of it, he will probably make it the subject of special investigation. When he has succeeded in bringing the phenomenon to a certain stage of development he comes, perhaps, in conflict with the practical man, who tells him that in the whole course of his experience he has never met with anything of the kind, overlooking the fact that his endeavour has been to mask or eliminate the conditions of its existence.

Another source of discord, and another reason, perhaps, for the evident scorn with which the theorist is sometimes regarded, arises from the fact that the problems which are so readily and so successfully attacked by the practical man, with a view only to the practical result, are nearly always much too hard for the theorist to grapple with in their entirety—we mean, of course, with an eye to what, from *his* point of view, would be regarded as their complete elucidation. The theory of the transmission of signals upon a telegraph wire is a much simpler matter to Mr. PREECE than it is to Mr. OLIVER HEAVISIDE. Mr. PREECE, no doubt, is quite sufficiently acquainted with the facts of the case to enable him to secure a remarkably efficient telegraph service, but it may yet prove that Mr. OLIVER HEAVISIDE'S far more complex theory approximates nearer to the ultimate truth. We hear sometimes of the "sweet simplicity of Nature;" but to the man of science the sweet simplicity seems to be chiefly exemplified in the brains of those who employ the phrase—if in any other than a poetic sense. For all that can be asserted to the contrary, it may rather be that the complexity of Nature is infinitely profound. As some one has finely said, "Every enlargement of the area of light within which we stand but increases the periphery of the surrounding darkness."

With regard to the particular controversy which is now raging, it may be remarked that the difficulties of the question are much increased by the fact that the data must necessarily be derived from observation as well as experiment. Now it is only since theory has indicated the probability of certain conclusions being justifiable that attention has been directed to the particular kind of observation which is required to furnish evidence for or against these conclusions. This fact should at least lead to a suspension of judgment until the needed observations have been made. And meanwhile, seeing that the opinions arrived at on theoretical grounds are by no means devoid of experimental evidence, we think it unwise, to say the least, for anyone to assume an air of superior knowledge, and to assert positively that practical experience has already proved the theory to be untrue.

REVIEWS.

The Steam Engine Indicator and Indicator Diagrams. By W. WORBY BEAUMONT, M.Inst.C.E., M.Inst.M.E., &c. (*The Electrician* Printing and Publishing Company, London: 1888.)

This is a thoroughly practical work embodying much useful information on the various indicators now in use, and containing a very good collection of diagrams. Though divided into 14 parts or chapters, the book really consists of two sections, the first dealing with the history, construction, and use of the indicator, and the second being devoted to the study of the various diagrams to be obtained from the many types of engines now in use, both steam and gas, and the lessons to be learnt from them, with a short account of the theoretical steam curves. We will deal with the book in these two divisions; the first covers Parts I. and II., and after a brief account of the value of the indicator, proceeds to describe the instrument, beginning naturally with the historical Watt and ending with the modern Crosby. The simultaneous progression of the indicator with the engine is clearly brought out; with the early slow speeds and pressures, the long-range spring, and a board moved backwards and forwards for the paper answered quite well, but with increased speeds and pressures both these devices failed, the first step being to substitute the paper drum with its enclosed spring for the board, and the next to do away with the old long-range spring, the violent oscillations of which absolutely destroyed all the value of the cards. Richards' indicator, with its parallel motion for enlarging the spring motion and other valuable improvements, held the field and did grand service

Digitized by Google

till once more the march of progress carried the engine beyond its powers. As speeds and pressures again increased the indicator behaved almost as badly as of old in the way of oscillations, and again inventors set to work to produce instruments fit for their purpose, such as Darke's and Crosby's. The great object, as the author points out, is to reduce the range of the spring, and to decrease the weight of the moving parts so as to do away with oscillations and the effect of inertia. From practical experience we can pay testimony to the excellence of the Crosby for high speeds; it is really a most beautiful instrument, every detail of which has been most carefully thought out, from the socket joint where the spring sits on the piston (allowing the piston and spring free play and reducing greatly the chance of jamb) to the reduction of length of one of the two clips on the paper drum. One point in this indicator of great importance is dwelt on to some length in the text, namely, the increase of tension of the spiral spring in the drum as the latter revolves, thus securing a uniform tension in the card. In dealing with the method of attachment of indicator to cylinder we gladly note that much stress is laid on the necessity of short wide connections, and also on the importance of obtaining a correct motion for the paper drum, an apparently trifling error in the driving of which may often hopelessly distort a card. We regret that a little more information is not given as to the probable causes of errors in indicators, and the best means of overcoming them. Thus, it is quite certain that the springs, though nominally graduated hot, when tested often fail to give results in agreement with their scale, the error being sometimes as much as 2 or 3 per cent., and, further, they do not give the same results going up and coming down; no engineer should think of using springs, at any rate if he wishes to obtain real results, without testing them for himself. Other errors, such as those due to excessive pressure of the pencil on the paper, can be guarded against by care on the part of the operator. We would refer those interested in this important subject to the Paper, and discussion on it, "On the Theory of the Indicator and the Errors in Indicator Diagrams," Vol. LXXXIII. of the *Proceedings* of the Institution of Civil Engineers. The second division we have above referred to, consisting of Parts III. to XIV., deals with cards obtained from various engines, discussing their form, comparing them with the theoretical cards, and pointing out how errors in valve-setting, &c., and the amount of condensation and re-evaporation of steam in the cylinders, may be learnt from them. On page 57, in dealing with the card taken from an old atmospheric engine, there is a slight error; the horse-power should be 15·31, not 15·83, as given, so that there is a distinct gain of power even at the reduced speed. We do not quite follow the reasoning in regard to this card on page 60, which seems somewhat involved. We would here point out that there is some slight confusion caused by the way the expression "high pressure" is used; thus, it seems rather awkward to speak of an engine using 30 or 40lb. steam as "high pressure." Surely, it should, if used at all, be confined to engines using 100 to 200lb. steam, but it would be better to keep the expression as a means of distinguishing a non-condensing from a condensing engine, and use it only for engines of the first of these two classes.

In our opinion the construction given on page 79 for finding the true point of cut-off is a little easier for use in drawing the hyperbolic curve than the one actually given on page 76, as it involves drawing rather fewer lines. While thanking the author heartily for his insistance again and again on the necessity of taking the clearance spaces into account, we would remark that if any real results are to be obtained the correct clearance must be used (it can generally be pretty accurately measured off the drawings), and not a mere guess made at it. It is a slip, we suppose, when on pages 114 and 119 the author speaks of the construction giving a means of ascertaining the amount of clearance, since before the construction can be carried out the clearance must be known. What it does do, however, is to fairly well approximate to the amount of initial condensation (it can never give this accurately, since there is probably always some of this condensed steam not re evaporated even in the very best of engines), and taken along with actual feed measurements it may yield very valuable results.

The useful formula given on page 81 for calculating the mean pressure, viz., $p = \frac{P(I+H)}{R}$, is quite readily adapted to the case when clearance is taken into account, by substituting for I in the formula, $\frac{V_1}{V_0}$, where V_1 is the volume of steam at cut off neglecting clearance, V_0 this volume plus the clearance, and for H and R using the real expansion, including clearance volume, thus, in the example given $\frac{V_1}{V_0} = \frac{2}{3}$, and, therefore, $p = 75\left[\frac{\frac{2}{3}+1\cdot098}{3}\right] = 25 \times 1\cdot765 = 49\cdot125$. Similar tables to those given for the adiabatic curve are also given for the constant-weight curve in Northcott's "Steam Engine," and will be found extremely useful by students. In discussing the advantages in reducing the range of temperature in the cylinder, and thereby the initial condensation of steam by using compound systems, the tandem compound hardly receives its due. The author seems to have overlooked the fact that in a single cylinder engine the lowest temperature is really that of the condenser, for the cylinder is in direct connection with it during exhaust, while in the tandem, even if steam is not cut off till quite late in the stroke in the low-pressure cylinder, the high pressure lowest temperature is considerably greater (probably 70 or 80 degrees) than that of the condenser. Part XIII. is devoted to gas engines and their cards, and is a highly interesting chapter, while Part XIV. briefly describes methods of measuring cards by ordinates and by planimeter. The great value of the planimeter is its use as a check on the ordinate method when a great number of cards have to be worked out, which can be done by picking out a few cards and going over them with the planimeter. In conclusion, we have to express a warm welcome for a most useful, practical, and thoroughly readable book, which will prove a valuable addition to the library of those engaged directly or indirectly with prime motors.

T. H. B.

Telegrafia Militar: Applicaciones de la Cana Bambu a la Telegrafia Semi-Permanente. Por el Capitan D. RAFAEL PERALTA. (Madrid: 1888.)

This pamphlet, consisting of about eighty pages, is written solely with the object of advocating the use of bamboo canes for telegraph posts, not only for temporary military lines, but also, in the author's words, for "semi-permanent telegraphy."

The author does not pretend that the use of bamboo for military lines is a new idea, and acknowledges that such posts actually form part of the telegraph equipment of several European armies; but he entirely disagrees with the generally accepted mode of employing them, and quotes from a variety of reports (principally English) referring to the Abyssinian, Ashantee, and Afghan campaigns, and experiments made in different countries; the result of his investigations being—first, that the length of the bamboo poles hitherto used has never exceeded from 6 to 7 metres—being generally about 4 metres; second, that only in Abyssinia has bamboo been used without insulators, and that the line worked satisfactorily; third, that the weak point is the preservation of the poles.

In the second chapter, the writer affirms from actual experience in the Philippines that the bamboo sometimes attains a height of 35 metres, but it usually does not exceed from 20 to 25, and in the latter case the outside diameter at the base would be about 20 centimetres, while in the third-class canes this measurement would be reduced to 7 centimetres. In consequence of the immense destruction of bamboo at the time of the earthquakes in 1880 the canes now found in the market rarely exceed 13 metres in length, the price being about £7 per hundred. The author is without data as to the strength or breaking strain of the bamboo, but he considers they possess very great resistance and elasticity. That the bamboo cane has an extremely low conductivity is proved, he says, 1st, by the fact that it is never struck by lightning, notwithstanding its height, thus forming a very favourable contrast with the palm, which in this respect has a bad reputation

Digitized by Google

2nd, the structure of the cane, which is full of air cells; 3rd, its fibrous nature, being composed of numberless cells and channels; 4th, that a short time after being cut no sap or moisture is to be found in it; 5th, its excellently-polished surface forming a natural insulator; 6th, the unanimous opinion of telegraph-engineers, who state that both in wet and dry weather it insulates better than any wood. The writer then proceeds to criticise the manner in which the bamboo has hitherto been used, and expounds his own ideas on the subject. Better results may, he thinks, be obtained by using canes 13 metres long—2 metres below ground and 11 metres above—the distance from post to post being 300 metres. The copper wire adopted by the German War Office does not find favour with the author; although its diameter is two millimetres, its breaking strain is only 150 kilogs, and he decides for the type used in Holland, viz., steel wire of 2·5mm., whose breaking strain is 414 kilogs, weight 40 kilogs per kilometre, and resistance 8·5 ohms. Insulators proper he considers unnecessary, and, after discussing various plans, the choice finally falls on a piece of bamboo a few inches long, which is to be passed over the top of the pole, and is detained a little way down by the increased diameter of the post. This novel insulator is encircled by an iron ring turned up at the joint to form a hook or loop, though which the line passes. The insulator is slotted, to prevent, as the author says, a continuity of water during heavy rains.

The end of the post to be buried is recommended to be cut at 10 centimetres below a knot, and this hollow filled with tar or a like substance. The hole for the reception of the post may be opened to 80 centimetres with a bar, and after this, the pole, which is provided at the end with an iron screw, may be worked down to the required 2 metres.

No damage whatever to the line is apprehended from the wind when blowing at right angles to it. Although on account of the great elasticity of the bamboo the oscillations of the posts would be considerable, yet they would coincide, but injury is admittedly possible when the wind blows along the wire, and it is insisted upon that the conductor should run very freely through the iron loop on the insulator.

Two points in this marvellously ingenious scheme require further elucidation. How does the author propose to bind his wire (say, at every second or third post) to prevent, in case of breakage, his line from running down from end to end, since he insists that the wire is to run freely through all insulators? And further, should such a calamity occur, where does he purpose seeking the fire escape necessary for replacing his wire on the top of a bamboo cane 11 metres in height?

"Betrieb der Galvanoplastik mit Dynamo-Elektrischen Maschinen zu Zwecken der graphischen Kunste" (Electro-deposition with Dynamos in its Application to Engraving). By O. Volkmer. 246 pp. (Hartleben, Leipsic, 1888.)

This little work forms the hundred-and-sixtieth volume of Hartleben's chemico-technical library. The first fifty-eight pages of the text are devoted to a short sketch of the dynamos and steam and gas engines used in electro-plating works in Germany and Austria, with some brief explanations of the general principles of continuous-current dynamos. Pages 173 to 217 are occupied with short descriptive accounts of the various chemicals used in electroplating. These portions of the book appear to be designed to give intelligent workmen employed in this industry some general idea of the principles on which it is founded, a purpose for which the exposition is very well adapted, and calculated to lead the more aspiring ones to further inquiries into the science of their work.

The rest of the volume, beginning with the second chapter, is of considerable interest to electricians. This chapter, in addition to some general remarks on electrolysis, contains much valuable information on the composition and management of the depositing solutions, and the conditions which must be fulfilled in order to get deposits of the best quality. The description of the results of a series of experiments by Baron von Hübl, a captain in the Austrian artillery, on the relation between the physical properties of electrolytic copper and the density of the depositing current, are of exceptional interest. The third chapter contains an account of some important works in Vienna, where electro-plating for engraving purposes is carried out on a considerable scale—viz., the Institute of Military Geography, of which Baron Hübl is the technical referee, and the Imperial printing works. The fourth chapter deals in some detail with the various processes of electro-typography, and the information contained in it, which is the result of the author's extensive practical experience, is of the highest value to all who are interested in this branch of electrical industry; and principally on account of this chapter we would specially recommend the book to the attention of all such as are able to read German. It will perhaps not be out of place in this connection to point out to students intending to devote themselves to any branch of electrical industry, the great importance of acquiring a knowledge of this language, which will open up many otherwise unavailable sources of information.

Applied Mechanics Questions. By the Professor of Engineering in the Glasgow and West of Scotland Technical College. (Morgan and Co., Glasgow. 1888.)

This collection of questions (with answers to some) is divided into three distinct sections—Elementary, Advanced, and Honours, and each of these sections is again subdivided and arranged in a natural order under sub-headings, so that a student may have as little trouble as possible in selecting suitable examples. These questions should form a great and much-needed help to engineering students studying for the Science and Art and City Guilds of London examinations. They are neatly printed, and published at 8d. by Messrs. John W. Morgan and Co., 129, Sauchiehall-street, Glasgow. No teacher or student of applied mechanics should be without a copy.

The New County of London, showing the practical working of the Local Government Act, 1888, as applied to the Act. By Harry Wilkins. (London: G. Shield, 30, Sloane-square, Chelsea, 1888.)

In a pamphlet of 24 pages, Mr. Wilkins, Vestry Clerk of St. James, Westminster, gives a popular summary of the main provisions of the Local Government Act, as applied to the metropolis. After a reference to the area of the new county, he describes the constitution of the electorate, and then proceeds to mention the constitution of the council, the qualifications and disqualifications of councillors and aldermen, the powers and duties of the council, the financial arrangements of the Act, the police, and the judicial officers of the new county, concluding his remarks by criticising the principles of the Act, so far as relates to the creation of London into a county, and winding up by suggesting certain simple and effective reforms in the system of local government in the smaller areas.

The pamphlet may prove of considerable use to those of our friends whose duties bring them into conjunction—conflict we were going to write—with the public authorities of the metropolitan area.

LETTERS FOR LEARNERS AND UN-PROFESSIONAL READERS.

BY H. D. WILKINSON.

Section II.—Electro-Magnetic Fields.

(Continued from page 707.)

131. *Apparatus for Measuring the Relation between Magnetising Force and Intensity of Magnetisation.*—We shall now consider some of the practical details of a simple test to measure the changes in the intensity of magnetisation acquired by an iron or steel rod, when the current in the coil which surrounds the rod is gradually increased. The practical example given below of a test of this kind will serve as a guide, although the effects may be observed equally well with iron wires of much smaller diameter and currents of less strength than those employed below. The apparatus is connected up as in

Digitized by Google

Fig. 112, where the magnetometer M and distance table are shown in plan, the current meter G and adjustable resistance R in elevation, and the battery, in this case a secondary battery of 21 cells, is shown conventionally. The galvanometer is placed at five or six feet away from the magnetising coil C, and is connected to the rest of the circuit by well insulated and twisted leading wires (para. 67), in order that its needle may not be affected by any magnetic field but that set up by its own coil. A brass tube of about ½ centimetre bore and a little over a foot long was provided with cheeks at the ends, fixed so that the distance between them was exactly 1ft. The tube was then wrapped round evenly with No. 16 double cotton-covered copper wire, and the ends firmly secured by twine. This gave a magnetising coil (C in the figure) 1ft. long and of 135 turns, which was then placed on the table at 20 centimetres distance from the magnetometer needle in the position shown, and held there firmly by a wooden clamp.

The resistance R is made with German silver wire spirals connected in series and fastened to a wooden frame. German silver is chosen because less length of wire of a given thickness is required than if copper or iron were used, owing to the higher specific resistance (para. 29) of German silver, which is some 12 or 13 times that of copper. Less space is therefore taken up by the coils. The bights between each spiral are soldered to wires running to contact stops on the switch S.

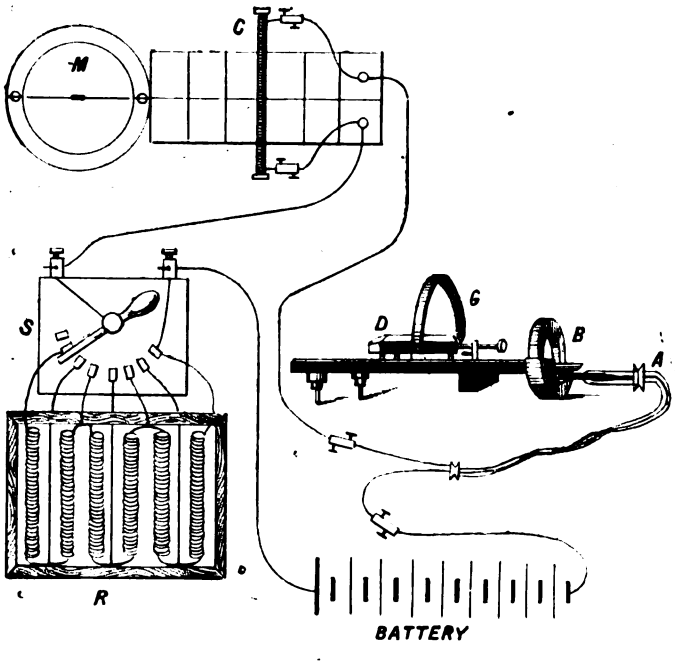

FIG. 112.

When the switch lever rests on the extreme left hand contact the circuit is disconnected, when on the second stop (as in figure) the circuit is closed, and a current will flow from the cells through all the resistance coils, the magnetising coil, and galvanometer. The current may then be increased step by step by moving the lever to the right. It is advisable to make the spirals of very low resistance on the low-resistance side (right side) of the switch, say of a quarter and half ohm, owing to the fact that when the rest of the circuit is of low resistance, very slight changes in the adjustable resistance produce great variations in the current strength. The spirals near this end of the switch should also be of thicker wire, say No. 14 or 16 B.W.G., as they have to carry the heaviest currents, while the rest may be of No. 18, and wound in spirals of 1, 2, and 5 ohms. The best arrangement, where great variation in resistance is required, is to have two separate switches; for example, suppose the total variation in resistance required was about 20 ohms. If one switch (A) of seven contacts were connected to six coils, in the manner shown in the figure, three coils being of five ohms each, and three of a quarter ohm each, and another switch (B) of five contacts connected to four coils, each of one ohm, the total resistance would be 19¾, and it could be reduced by one ohm at a time down to four ohms, and below four by a quarter ohm at a time by working the two switches. Supposing all the resistance in to start, B would be reduced four ohms by one ohm at a time first, and then its switch put back so as to add the four ohms again; then A would be moved one stop, reducing five ohms, and then again B one ohm at a time, and so on. In a test of this kind, where we are measuring the magnetisation of iron by gradual increments of current, care must be taken that if the resistance is reduced too much by mistake in one step, the reading on the magnetometer must be taken with *this* resistance in; it is no use to increase it up to what was intended at first, as the increased magnetisation of the iron due to the larger current would not be lost entirely on decreasing the current. The actual resistance in ohms is not required to be known in this test, so that the lower variations in resistance may be obtained very well by two similar metallic plates of, say, a foot square, immersed in slightly acidulated water, whose distance apart can be varied to a maximum distance of about two feet.

We must now turn our attention to the galvanometer. At the outset it will be noticed that in a test of this kind we are varying the strength of the current within fairly wide limits. In the test presently to be detailed, taken with the above apparatus the current was a little over half an ampere to start with, and was gradually increased to nearly 40 amperes. Now, with wide variation in current the galvanometer must have different degrees of sensitiveness in order to allow of reading the deflections with the least chance of error. Suppose a large current through the instrument gives a conveniently large deflection, then if the instrument remained in the same state of sensitiveness, as the current was reduced, the deflections would get smaller and smaller till the very smallness of the deflection would prevent accurate readings being taken, the movement of the needle being very slight for given changes in the current either at very low or high deflections from zero. Now, if the sensitiveness of the instrument is increased n times the deflections will be n times as large, and therefore the feebler currents can be read with ease and accuracy. The converse holds in the case before us. We are increasing the current strengths, and therefore must *decrease* the sensitiveness of the galvanometer as we proceed. We may do this in four ways, viz.:—

1. Shunting the galvanometer at intervals with shunts of gradually decreasing resistance.

2. Increasing the magnetic controlling field by bringing the controlling magnet nearer the needle.

3. By using a galvanometer wound with four or five separate coils, commencing with the fine wire coil of many turns, and changing at intervals on to the thicker wire coils of decreasing number of turns.

4. By gradually moving the needle and scale further from the coil.

As we wish to measure the currents accurately, and are working from a half to 40 amperes, the first method would be impracticable. When the current increased towards its larger values the shunts on the galvanometer would require to be so low in resistance that they would be difficult of accurate measurement, to say nothing of providing them of thick wire or stout copper ribbon, so that their resistance should not alter by heat; and to calculate the total current from the deflection of a shunted galvanometer, we must, of course, know accurately the resistance of the shunt (para. 95). As regards the second method of shifting the controlling magnet, the readings might first be taken without the magnet, and when beyond the limit of accurate reading, say 50 degrees, the magnet would be placed at a vertical height over the needle, such that the deflection of 50 was halved (or if a tangent galvanometer, a position found for the magnet, such that the deflection was the angle whose tangent was equal to half the tangent of 50 degrees). The magnet would be kept in this position until 50 degrees deflection was reached again, and then lowered to a position in which the deflection of 50 was halved, and so on. For each re-adjustment, we should know

Digitized by Google

that the same strength of current gave half the deflection, and therefore we should multiply the deflections (or their tangents) by 2, 4, 8, 16, 32, &c., for each consecutive change. The galvanometer would have to be wound, however, with wire thick enough to carry the strongest current without dangerous heating, and therefore could not hold many turns.

The third method requires a specially-wound galvanometer. If such an instrument is available it is very convenient to use, since the constants (para. 100) may all be determined beforehand, once for all. The resistance of the coils is not taken into account, the variation in sensitiveness, as regards current, being effected *only* by the different number of turns. The reason why the coils of fewer turns are made of thick wire is that they may carry the large currents sent through them without heating sufficiently to cause injury to the insulation.

The last method can best be explained by describing Sir William Thomson's graded galvanometer, the sensitiveness of which can be varied in this way, and, in fact, was the instrument used for the test we are now considering. We shall come in the chapter following the present to a detailed consideration of galvanometers, but, although it may be considered as deviating widely from the usual custom, to digress from the main subject in hand in this manner, it is hoped that the reader will not find it altogether without interest to have instruments explained at the time they are used.

(*To be continued.*)

MINERS' ELECTRIC SAFETY LAMPS.*

BY NICHOLAS WATTS, ASSOC. MEM. INST. C.E.

It is not necessary, the writer thinks, to devote time to inquiry into the reasons which have caused so much attention to be given to the subject of this Paper by those interested in coal mining. It will suffice to say that the modifications made from time to time by numerous inventors, by providing additional gauzes and shields, and in other ways, to adapt lamps constructed on the principle of the Davy, Clanny, Stephenson, and other like lamps, to the increased velocity (20 to 35ft. per second) of the ventilating currents now obtaining in our collieries, have resulted only in rendering such lamps less unsafe than they were, but have failed to make them free from danger, and have in some cases introduced considerable complication and other objectionable features. There being, therefore, apparently not much prospect that a thoroughly satisfactory and safe lamp of the aforesaid types would be forthcoming, it was most natural that the incandescence electric lamp should be seized upon as a probable solution of the difficulty. It appears, on the face of it, most suitable for the purpose, inasmuch as the light depends for its existence on the absence of air, a condition the direct reverse of that necessary to the maintenance of the flame in oil lamps. The white-hot carbon filament is wholly enclosed in an air-tight glass bulb, from which all the air is withdrawn before the bulb is sealed. No currents of air or explosive mixture can reach it.

Attention having once been directed to the production of electric lamps for miners' use, the field speedily became well tenanted with inventors.

The writer does not propose to refer in detail to the successive developments, but rather to present to the meeting the position as it now is by passing in review some of the best lamps obtainable.

It became clear early in the history of the matter that illumination of collieries by fixed lamps connected to mains was not practicable so far as the working places were concerned. The difficulty of preventing injury to or severance of the wires, combined with other objections, left no doubt on that head. For like or analogous reasons, portable lamps, connected by leads to mains, were not satisfactory. Consequently, all energies were concentrated upon the production of an independent lamp containing its own source of light, and which could be carried about by the miner as freely as a Davy or other like lamp.

How to produce such a lamp, to compare favourably with a miner's ordinary oil lamp in price, weight, illuminating power, capability of standing rough treatment and hard knocks, and in other respects, became the problem. A good lamp of the Clanny and like types is bought for about 8s., it weighs about 4lb., and gives a light of from 0·4 to 0·5 of a standard candle.

To Mr. Swan belongs the credit of being the first to produce an electric safety lamp with an incandescence lamp as the novel feature thereof. This he did in 1881.

*The Swan Lamp** (exhibited).—Secondary battery. The elements, lead and lead-oxide, are cylindrical and are arranged concentrically in each cell. They are contained in a block of gutta percha with four cell compartments enclosed in a wooden case. The exciting liquid is dilute sulphuric acid. The cells are recharged by placing the lamp on a stand connected to a dynamo. The lamp proper is attached to the side of the case and is protected by a "bull's-eye" of thick glass. A light of from 1 to 1½ candle-power is given for a period of ten hours. The weight is 7lb. and the price 27s.

Several hundreds of these lamps are now in use at Risca and elsewhere, and the writer is informed by Mr. Wilkinson, manager at Risca, that they give satisfaction.

The Walker Lamp.†—Primary battery. Bichromate-carbon-zinc battery, the carbon being itself the containing vessel. On one side is a strong lens faced by a parabolic reflector, the two being held by a strong brass cylinder attached to the outer case, which is also of brass or copper. The lamp is made in two sizes, of which the smaller weighs 5lb. The battery is composed of two carbon-zinc cells. The liquid used is a mixture of bichromate of potash, nitric acid and plain sulphuric acid. The electromotive force is 4 volts, and the current 0·3 of an ampere.

The price is, for single lamps 30s., for dozens 27s., and for grosses 25s. The light afforded by the small lamp is sufficient to enable ordinary newspaper print to be read at a distance of 6ft. from the lamp for 10 hours. The battery of the larger lamp, which weighs 7lb., has three carbon-zinc cells. The electromotive force is 6 volts, and the current 0·5 of an ampere. Price 48s., 35s. and 32s. respectively. The cost of renewing the chemicals used, the incandescence lamp and incidental repairs, is stated to be not more than ¾d. per day for the small and 1d. per day for the large lamp. The cost of the liquid has been frequently tested, and has come out at ½d. per day of 12 hours' run. The operation of renewing, which is effected in a few minutes, consists in running off the liquid and washing out the cells, running in fresh liquid and replacing the cover, by which last act the connections between the battery and the lamp are made.

The Pitkin Lamp‡ (exhibited).—Secondary battery of four cells (seen last year in use underground at Tyldesley Colliery by some members of the British Association). The weight of this lamp is 8lb., and the price £2. 2s. Illuminating power, 4 to 5 candles; a reflector is employed to concentrate the light. The battery is composed of 4 cells, each having 8 plates or fingers, the elements being peroxide of lead and spongy lead. The battery takes 8 hours to charge. Mr. Pitkin estimates the life of the battery at about two years. Electromotive force, 8 volts; current, 0·4 of an ampere. The Pitkin lamp is furnished with a switch, and a resistance to regulate the expenditure of the electromotive force, which, if allowed to act without check, would, when the battery was started, destroy the filament. Mr. W. W. Hood, Llwynpia, tried 50 Pitkin lamps, and found that the switch was a difficulty. The men, unless very careful, put on the switch too full, and broke the filament.

The Schanschieff Lamp§ (exhibited).—Primary battery. The exciting liquid employed is a solution of basic sulphate of mer-

* Paper read before the British Association Meeting at Bath, September, 1888.

Digitized by Google

cury in the acid sulphate, one part of the salt being entirely dissolved in three parts of water (according to Schanschieff's patent). The battery can be charged in fifteen seconds. The elements are zinc and carbon; the latter not being of a porous nature. As a single liquid only is employed, no porous cells—producing resistance and causing waste of energy—are required. The weight, with a battery of four cells, is 4½lbs. Each cell takes 5 fluid ounces of the mercurial solution. The light ranges from 1½ to 2 candle-power. The consumption of zinc is $\frac{1}{12}$lb. per shift, or ½lb. for 48 hours (6 shifts of 8 hours). The liquid is supplied at 5s. a gallon, and is said to be worth, when spent, 4s. 3d., in consequence of the solid residue and free mercury precipitated by the action of the cells. The working cost of the 4-cell lamps for 6 shifts of 8 hours, is 5d., or $\frac{5}{8}$s. for one shift. In some forms of the lamp the solution occupies a little less than half the height of each cell, and the elements occupy the other half or opposite end of the cells. Thus the lamp is capable of being put out of action by inverting it. The liquid is changed every eight hours. The price is 30s.

The New Portable Electric Lamp and Power Syndicate Company's Lamp (exhibited).—The battery is secondary, and consists of two cells, the elements being lithanode (peroxide of lead) and spongy lead. The weight of the lamp is 4½lbs. The light given is 1¼ candle over a period of 10 to 12 hours. With a reflector the candle-power is about doubled. The battery takes four hours to charge, the cost of recharging being threepence per week. The price is one guinea. The lamp is fitted with an automatic arrangement in connection with the incandescent lamp, whereby, if the outer casing of toughened glass be broken, the current is cut off, and explosion of fire-damp guarded against.

The question, which is the most suitable battery for miners' lamps, though keenly debated, has not yet been finally settled. The secondary battery is, doubtless, more durable, but where dynamos are not already employed the primary battery will find favour.

The position of the light on the top or at the side of the case has given rise to much discussion, but the balance of opinion is that the side is the most suitable place.

FIVE APPLICATIONS OF FOURIER'S LAW OF DIFFUSION, ILLUSTRATED BY A DIAGRAM OF CURVES WITH ABSOLUTE NUMERICAL VALUES.*

BY SIR WM. THOMSON.

1. Motion of a viscous fluid.
2. Closed electric currents within a homogeneous conductor.†
3. Heat.
4. Substances in solution.
5. Electric potential in the conductor of a submarinecable.‡

1. Fourier's now well-known analysis of what he calls the "linear motion of heat" is applicable to every case of diffusion in which the substance concerned is in the same condition at all points of any one plane parallel to a given plane. The differential equation of diffusion,* for the case of constant diffusivity κ, is—

$$\frac{dv}{dt} = \kappa \frac{d^2 v}{dx^2},$$

where v denotes the "quality" at time t and at distance x from a fixed plane of reference. This equation stated in words is as follows:—Rate of augmentation of the "quality" per unit of time is equal to the diffusivity multiplied into the rate of augmentation per unit of space of the "quality."

The meaning of the word "quality" here depends on the subject of the diffusion, which may be any one of the five cases referred to in the title above.

2. If the subject is motion of a viscous fluid, the "quality" is any one of three components of the velocity, relative to rectangular rectilineal co-ordinates. But in order that Fourier's diffusional law may be applicable we must either have the motion very slow, according to the special definition of slowness in Article XCVII. of my collected Papers or the motion must be such that the velocity is the same for all points in the same stream-line, and would continue to be steadily so if viscosity were annulled at any instant. This condition is satisfied in laminar flow, and more generally in every case in which the stream-lines are parallel straight lines. It is also satisfied in the still more general case of stream-lines, coaxal circles with velocity the same at all points at the same distance from the axis. Our present illustration, however, is confined to the case of laminar flow, to which Fourier's diffusional laws for what he calls "linear motion" (as explained above in Sec. 1) is obviously applicable without any limitation to the greatness of the velocity in any part of the fluid considered (though with conceivably a reservation in respect to the question of stability).† In this case the "quality" is simply fluid velocity.

3. If the subject is electric current in a non-magnetic metal, with stream lines parallel straight lines, the "quality" is simply current-density—that is to say, strength of current per unit of area perpendicular to the current. The perfect mathematical‡ analogy between the electric motion thus defined, and the corresponding motion of a viscous fluid defined in Sec. 2 was accentuated by Mr. Oliver Heaviside in *The Electrician*, July 12, 1884; and in the following words in the *Philosophical Magazine* for 1886, second half-year, p. 135:—"Water in a round pipe is started from rest and set into a state of steady motion by the sudden and continued application of a steady longitudinal dragging or shearing force applied to its boundary. This analogue is useful because everyone is familiar with the setting of water in motion by friction on its boundary, transmitted inward by viscosity." Mr. Heaviside well calls this analogue "useful." It is, indeed, a very valuable analogy, not merely in respect to philosophical consideration of electricity, ether, and ponderable matter, but as facilitating many important estimates, particularly some relating to telephonic conductors and conductors for electric lighting on the "alternate-current" system. In a short article to be included in Vol. III. of my collected Papers, which I hope will soon be published, I intend to describe a generalisation, with, as will be seen, a consequently essential modification of this analogy, by which it is extended to include the mutual induction between conductors separated by air or other insulators, and currents in solids of different conductivity fixed together in contact.

4. If the subject is heat, as in Fourier's original development of the theory of diffusion, the "quality" is temperature.

5. If the subject is diffusion of matter, the "quality" is density of the matter diffused, or deviation of density from some mean or standard density considered. It is to Fick, thirty-three years ago Demonstrator of Anatomy, and now Professor of Physiology in the University of Zurich, that we

* Paper read before the British Association meeting (Section A) at Bath, September, 1888.

† This subject is essentially the "electro-magnetic induction" of Henry and Faraday. It is essentially different from the "diffusion of electricity" through a solid investigated by Ohm in his celebrated Paper, "Die Galvanische Kette mathematisch bearbeitet," Berlin, 1827; translated in Taylor's *Scientific Memoirs*, Vol. II., Part VIII., "The Galvanic Circuit investigated Mathematically," by Dr. G. S. Ohm. In Ohm's work electro-magnetic induction is not taken into account, nor does any idea of an electric analogue to inertia appear. The electromotive force considered is simply that due to the difference of electrostatic potential in different parts of the circuit, unsatisfactorily, and even not accurately, explained by what, speaking in his pre-Greenian time, he called "the electroscopic force of the body," and defined or explained as "the force with which the electroscope is repelled or attracted by the body;" the electroscope being a "second movable body of invariable electric condition."

‡ This subject belongs to the Ohmian electric diffusion pure and simple, worked out by aid of Green's theory of the capacity of a Leyden jar (*see* "Mathematical and Physical Papers," Vol. II., Art. LXXIII.).

§ *See* "Mathematical and Physical Papers," Vol. II., Art. LXXII.

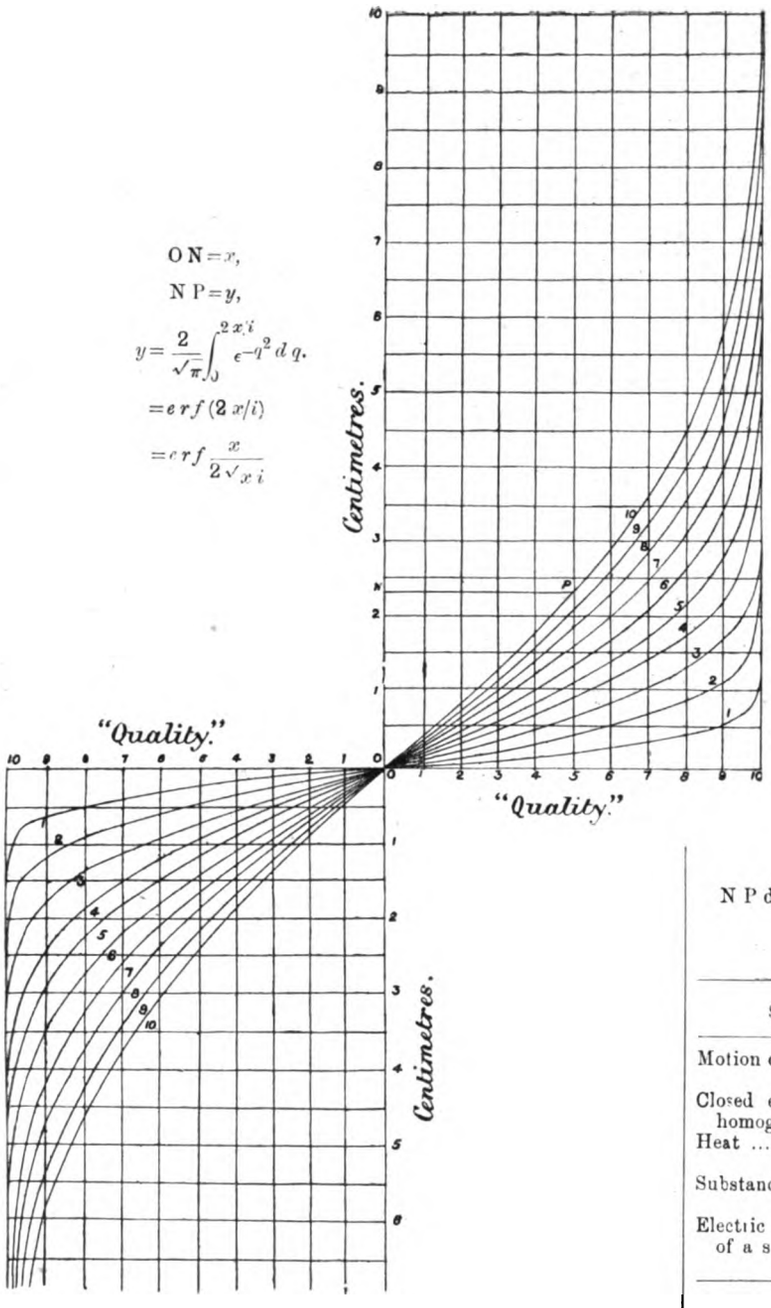
† *See* "Stability of Fluid Motion," § 28, *Philosophical Magazine*, August, 1887.

‡ It is essentially a mathematical analogy only; in the same sense as the relation between the "uniform motion of heat" and the mathematical theory of electricity, which I gave in the *Cambridge Mathematical Journal* 46 years ago, and which now constitutes the first article of my "Electrostatics and Magnetism," is a merely mathematical analogy.

Digitized by Google

owe this application of Fourier's diffusional theory, so vitally important in physiological chemistry and physics, and so valuable in natural philosophy generally. When the substance through which the diffusion takes place is fluid, a very complicated but practically important subject is presented if the fluid be stirred. The exceedingly rapid progress of the diffusion produced by vigorous up-and-down stirring, causing to be done in half a minute the diffusional work which would require years or centuries if the fluid were quiescent, is easily explained; and the explanation is illustrated by the diagram of curves, Sec. 7 below, with the time-values given for sugar and common salt. Look at curve No. 1, and think of the corresponding curve with vertical ordinates diminished in the ratio of 1 to 40. The corresponding diffusion would take place for sugar in 11 seconds, and for salt in 3½ seconds. The case so represented would quite correspond to a streaky distribution of brine and water or of syrup and water, in which portions of greatest and least salinity or saccharinity are within half a millimetre of one another. This is just the condition which we see, in virtue of the difference of optic refractivity produced by difference of salinity or of saccharinity, when we stir a tumbler of water with a quantity of undissolved sugar or salt on its bottom. If water be poured very gently on a quantity of sugar or salt in the bottom of a tumbler with violent stirring up guarded against by a spoon, the now almost extinct Scottish species called "toddy ladle" being the best form, or, better still, a little wooden disc which will float up with the water; and if the tumbler be left to itself undisturbed for two or three weeks, the condition at the end of 17×10^5 seconds (20 days) for the case of sugar, or $5{\cdot}4 \times 10^5$ seconds (6 days) for salt, will be that represented by No. 10 curve in the diagram.

DIAGRAM SHOWING PROGRESS OF LAMINAR DIFFUSION.



6. If the subject be electricity in a submarine cable, the "quality" is electric potential at any point of the insulated conductor. It is only if the cable were a straight line that x would be (as defined above) distance from a fixed plane; but the cable need not be laid along a straight line; and the proper definition of x for the application of Fourier's formula to a submarine cable is the distance along the cable from any point of reference (one end of the cable, for example) to any point of the cable. For this case the diffusivity is equal to the conductivity of its conductor, reckoned in electrostatic units, divided by the electrostatic capacity of the conductor per unit length insulated as it is in gutta-percha, with its outer surface wet with sea water, which, in the circumstances, is to be regarded as a perfect conductor. For demonstration of this proposition, *see* Vol. II., Art. LXXIII. (1855) of my collected Papers.

7. Explanation of Diagram Showing Progress of Laminar Diffusion.

In each curve—

$$\frac{1}{10} \text{N P} = \frac{2}{\sqrt{\pi}} \int_0^{2x/i} dq \, . \, \epsilon^{-q^2},$$

where x denotes the number of centimetres in O N, and i the "curve number." The curves are drawn directly from the values of the integral given in Table III. appended to De Morgan's article "On the Theory of Probabilities," "Encyclopædia Metropolitana," Vol. II., pp. 483-84.

N P denotes the "*quality*" (defined below) { at distance = O N from initial surface or interface, and at time equal in seconds to ["curve-number"]² divided by sixteen times the diffusivity in square centimetres per second.

Subject of Diffusion.	"Quality" represented by $\frac{1}{10}$ N P.
Motion of a viscous fluid	Ratio of the velocity at N to the constant velocity at O.
Closed electric currents within a homogeneous conductor	Current-density.
Heat	Ratio of temperature minus mean temperature to mean temperature.
Substance in solution.....	Ratio of density minus mean density to mean density.
Electric potential in the conductor of a submarine cable	Ratio of potential at N to constant potential at end O.

Examples.

"Curve-number."	Time in seconds.	Case of Diffusion.
1	27056	Zinc sulphate through water.
1	25720	Copper sulphate through water.
1	17000	Sugar through wood.
1	5400	Common salt through water.
5	1180	Heat through wood.
5	118	Laminar motion of water at 10°C.
5	30	Laminar motion of air.
5	7·1	Heat through iron.
5	1·31	Heat through copper.
		Electric current in a homogeneous non-magnetic conductor:
10	·0488	Copper,
10	·0040	Lead,
10	·0038	German silver,
10	·0023	Platinoid.
1,000,000,000	2·15	Electric potential in the Direct U.S. Atlantic Cable.

THE LIPPMANN MAGNETOMETER.

M. Lippmann's discovery of the action of a magnetic field on a column of mercury through which a current is passing has been recently utilised by M. George Miot, of Paris, in the construction of an "inductometer," or instrument for determining the strength of the magnetic field (perhaps "magnetometer" is the better word for this class of instrument). The effect of the magnetic field, it will be remembered, is to cause the mercury to rise to a height depending upon the strength of the current, or of the magnetic field when the current is constant. The inductometer is shown in the accompanying engraving, Fig. 1; and Figs. 2 and 3 show respectively sections on the lines 1 2 and 3 4.

The apparatus consists essentially of a tube, A B C, the lower portion of which is flattened in such a way that it can be placed in a short magnetic field, such as found in dynamo-electric machines. To the base B is soldered a capillary tube, D, which is surmounted by a bulb, E, above which rises a graduated tube, F. The two other bulbs, G G', are placed upon the extremities of the U-shaped tube, and are provided with branch tubes, $g\,g'$, into which the mercury is poured until its level reaches to about the middle of the three bulbs. Then on top of the mercury are poured several drops of glycerine into the bulbs G G', and a few drops of water or alcohol into the tube F.

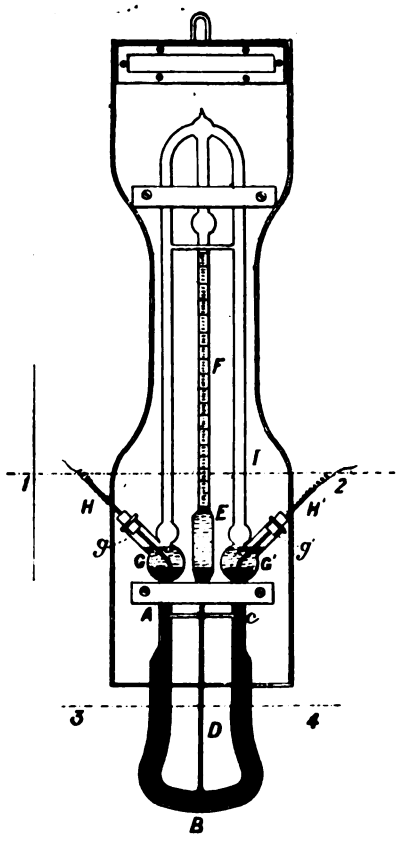

Fig. 1

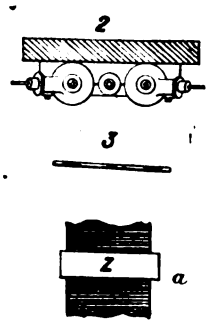

Fig. 4.

In order to preserve the mercury and other liquid from contact with the air, the U-shaped tube is prolonged above the two bulbs to unite again with the central tube at the top of the apparatus, as shown in Fig. 1. In this way the liquids are enclosed in an atmosphere of their own, having no communication with the external air.

In order to measure the intensity of the magnetic field by this apparatus, metal rods, H H', are introduced through the tubular branches $g\,g'$ into the bulbs G G', so that their ends are immersed in the mercury. The rods H H' are then connected with the poles of a generator, and the part B of the tube is placed in the magnetic field to be examined, and with the tubes B and D at right angles to the line of magnetic force. The mercury will immediately rise in the bulb E and force up the liquid therein, which may be coloured, into the tube F. The diameter of the latter being much smaller than that of the bulb, the movements of the liquid therein are correspondingly amplified.

Referring to Fig. 4, if it is desired to measure at the point a the intensity of the field of a magnet-pole Z, it suffices to place at a the part of the apparatus representing the intersection of the horizontal tube B with the middle tube D, to pass through the tube B a known current of, say, from 1 to 10 amperes, and to read the change of level produced in the column of coloured liquid in the tube F. If d represents this height read on the scale F, and C be the current traversing the apparatus at a, then the magnetic force H at that point will be represented by $\frac{d}{KC}$, K being the constant of the instrument.

The rise of the mercury is due to the reaction between the electric current traversing the tube B and the magnetic field. For the examination of a vertical field it suffices to curve the lower part of the tube at right angles.

THE WATERHOUSE METHOD OF DYNAMO REGULATION FOR CONSTANT CURRENTS.

The Waterhouse Electric and Manufacturing Company of New York makes use of a somewhat interesting method of regulation for their high-tension arc lighting machines. The following description has appeared in several of the American journals:—

Fig. 1 is a diagram of the Waterhouse type of dynamo, with a closed circuit armature, A. On the commutator C are three brushes; a and b are the main circuit brushes, and c the auxiliary brush. From the positive brush a the current passes on the conductor around the field-magnets F to the resistance R. The current from the auxiliary brush c passes directly to resistance R, leaving the field-magnets out of circuit. The currents from both circuits (field and local) join at R, and pass to the lamps, the current on the lamp line being the sum of the two. The amount of current

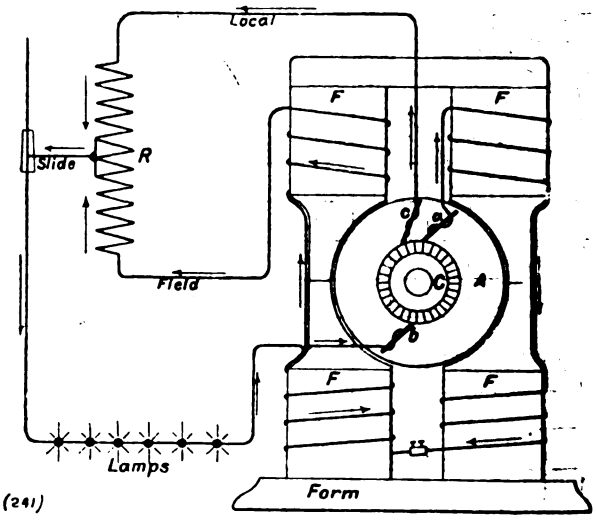

Fig. 1.

in the field and local circuits is in proportion to the resistance R in each. The brushes have a fixed position.

There is in every dynamo a point of maximum commutation on the armature, which changes with the resistance on the lamp line, moving with the rotation (towards brush c) when the resistance decreases, and back when it increases. This affects the current in the local and field circuits as follows:—When lights are turned out the line resistance is decreased, and the maximum point moves forward and forces more current out of brush c and less out of brush a. This reduces the current in the field-magnets and the E.M.F., and consequently the power required to operate the dynamo; but the current on the lamp line remains constant because the local circuit is increased proportionally to the decrease of the field-circuit. The remaining lamps therefore retain their full brilliancy, while the current cannot increase and destroy the apparatus. Thus the very tendency of the machine is to perfect regulation without

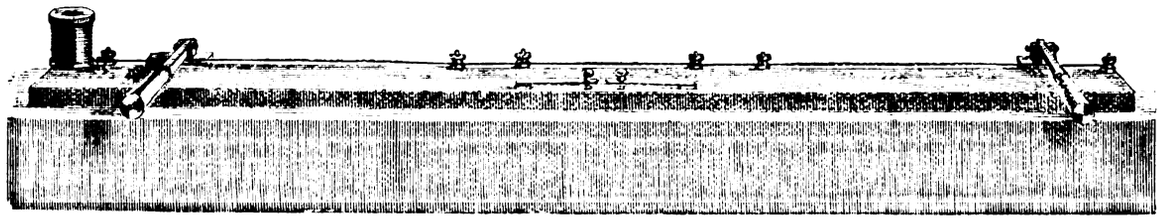
Digitized by Google

the aid of mechanism; but when to this is added the simple regulator, which makes the regulation instantaneous by assisting the current to pass out at brush c and opposing its passage around the field-magnets by way of brush a when lights are cut out, and forcing it out at brush a around the field-magnets by opposing its passing out at brush c when lights are cut in, the efficiency of the method can be appreciated.

The regulator is illustrated diagramatically by the slide, which is controlled by a solenoid. Any tendency of the current to increase raises the contact, and the result is a decrease of resistance in the local circuit, and an increase of the resistance in the field-circuit. More current will therefore flow through the local circuit and less through the field-circuit. The generating capacity of the dynamo is instantly reduced, and any tendency to produce a current above the standard is overcome. Should the tendency of the current be to decrease, say by a reduction of the speed of the armature, the slide lowers, increasing the resistance in the local, and reducing it in the field-circuit. More current will then flow around the field-magnets, and less out on the local circuit. The generating capacity of the dynamo will therefore increase to maintain the current at standard. It should be stated that the use of resistance for balancing the field and local circuits is a small amount compared to that used by the lamps, and is not interposed, as can be seen, for the purpose of compensating for lamps turned off.

CONVENIENT WIRE-TESTING APPARATUS.

A convenient instrument has lately been designed in Messrs. Woodhouse and Rawson's test room by Mr. C. Ashmore Baker, principally for testing the conductivity of wire. Two pairs of shears of peculiar construction are mounted on a mahogany base board, their cutting edges being exactly one metre apart. The wire to be tested is connected at one end with one terminal of a standard coil of suitable resistance placed at one end of the board outside the shears, and then stretched between the two pairs of shears, which also do duty as galvanometer contacts; the other end is held rigidly by a clamp at the opposite end of the board to that carrying the coil. A fairly constant current is next sent through the standard coil and wire in series, and by means of a reflecting galvanometer the differences of potential are measured first between the ends of the coil and then between the points on the wire at which the shears make contacts; from these the resistance of the wire per metre is obtained. The wire is then cut at both points simultaneously, and the metre thus cut off accurately weighed. From the quantities, weight, length and resistance, the conductivity may be easily calculated by means of a simplified formula which takes specific gravity into account.



Woodhouse and Rawson's Wire-Testing Apparatus.

The apparatus effects a great saving of time when a number of samples of wire are to be tested, and by cutting the wire off as it is fixed when the resistance is tested any error in the measurement of length due to elasticity is eliminated. With average care and a properly set up galvanometer the accuracy of the test is all that could be desired. The standard coil, keys, &c., are mounted on the same board with the shears, and there are no complicated connections to be made in setting up.

THE ACTION OF LIGHT UPON THE STATIC CHARGE.*

BY M. E. BICHAT.

Several investigators have recently shown that the passage of electricity across a gas is aided in a most singular manner when the electrified body is lighted up by the most refrangible rays of the spectrum. In a previous communication by M. Blondlot and myself, we showed that when a sheet of water is substituted for the metallic plate in M. Stoletow's experiment, no deflection is observed on the galvanometer. This fact seemed to show that the charge is not carried by conduction, and the following experiments confirm this view. A metallic cylinder, coated on the inside with lampblack, is negatively electrified and connected to an electrometer. The rate of loss of charge is not altered when, by means of a lateral opening, the inside of the cylinder is lit up by ultra-violet rays, while on the other hand, the dissipation is greatly accelerated when the ray of electric light falls on the outside of the cylinder. Now, if the luminous ray was a sort of conductor, it would equally affect the discharge, whether it fell on the exterior or on the interior of the cylinder. The electric tourniquet,* placed in a non-insulated conducting cylinder, began to turn in diffused light for a negative potential of 63 C.-G.-S. units. When illuminated by an arc light, the positive carbon of which contained an aluminium core, it began to revolve for a potential of 22 C.-G.-S. units. If a sheet of glass was interposed, all the effects of the light disappeared. It seems, therefore, that convection plays the essential part in these phenomena.

Whilst investigating the action of ultra-violet rays under various conditions, I have observed certain phenomena which seem to me worthy of notice. If a conductor connected to an electrometer is lit up by ultra-violet rays, the electrometer immediately shows a positive potential of seven to eight volts—that is to say, the air surrounding the conductor becomes negatively charged. This is M. Righi's experiment in another form. Copper has been observed to be negatively electrified under these circumstances, but the electrification was always very weak. The highest potentials obtained were with plants placed on insulating stands, the charge being, as a rule, negative. The electrometer was often deflected through more than 200 scale divisions, which correspond to a potential of over 20 volts. In this case the air surrounding the plant was positively electrified. Once only, with a geranium, was positive electrification of the plant itself observed.

THE MERSANNE ARC LAMP.†

The Mersanne lamp is distinguished from most other arc lamps by the manner in which the carbons are arranged, as well as by the way in which the feeding is effected. The carbons are horizontal instead of vertical, and are actuated by a series of grooved rollers. This arrangement allows very long rods to be used, without introducing undue resistance into the circuit. There are two fine wire electro-magnets, which are placed in series with one another, and in parallel with the main circuit; one governs the clockwork apparatus, and the other strikes the arc. In order to properly understand the mechanism of the Mersanne lamp it is necessary to examine every detail carefully.

In Fig. 1 A is a clockwork drum actuating the longitudinal shaft $a\ a$, which transmits the motion to the vertical shafts $b\ b$ (Fig. 2), $a\ a$ being divided into two unequal lengths, united by a Cardan coupling, and carefully insulated from one another. The transverse shaft d (Fig. 2) actuates the wheel e, which actuates in turn the grooved rollers $g\ g$; these rollers move the carbon rod, which is pressed tightly against them by the rollers $h\ h$, the pressure of which is regulated by the screw i. The electro-magnet B (Fig. 1) has an armature, n, which is acted on by the spring o; n alternately clutches and liberates the ratchet wheel e, the teeth of which are just visible in the figure. Whenever the arc lengthens, causing the current in the shunt to increase, the electro-magnet B overcomes the spring o, and attracts the armature n; this disengages the ratchet wheel e, and allows the clockwork drum A to move the carbons together by means of the series of shafts and cog-wheels. When the arc attains its proper length, the current in the shunt diminishes, and the weakening of the electro-magnet B allows the armature n to engage the wheel e, and stop the movement of the carbons. The pull of the armature spring is regulated by the screw v. The rod q, which is fixed to one

of the carbon holders, carries at the top the armature Q of the electro-magnets c c, by which the arc is struck; Q is retained by a spring strong enough to hold the armature against the attraction of any but the maximum current traversing the shunt. The attraction of Q causes q to give the carbon holder a slight jerk, and strike the arc.

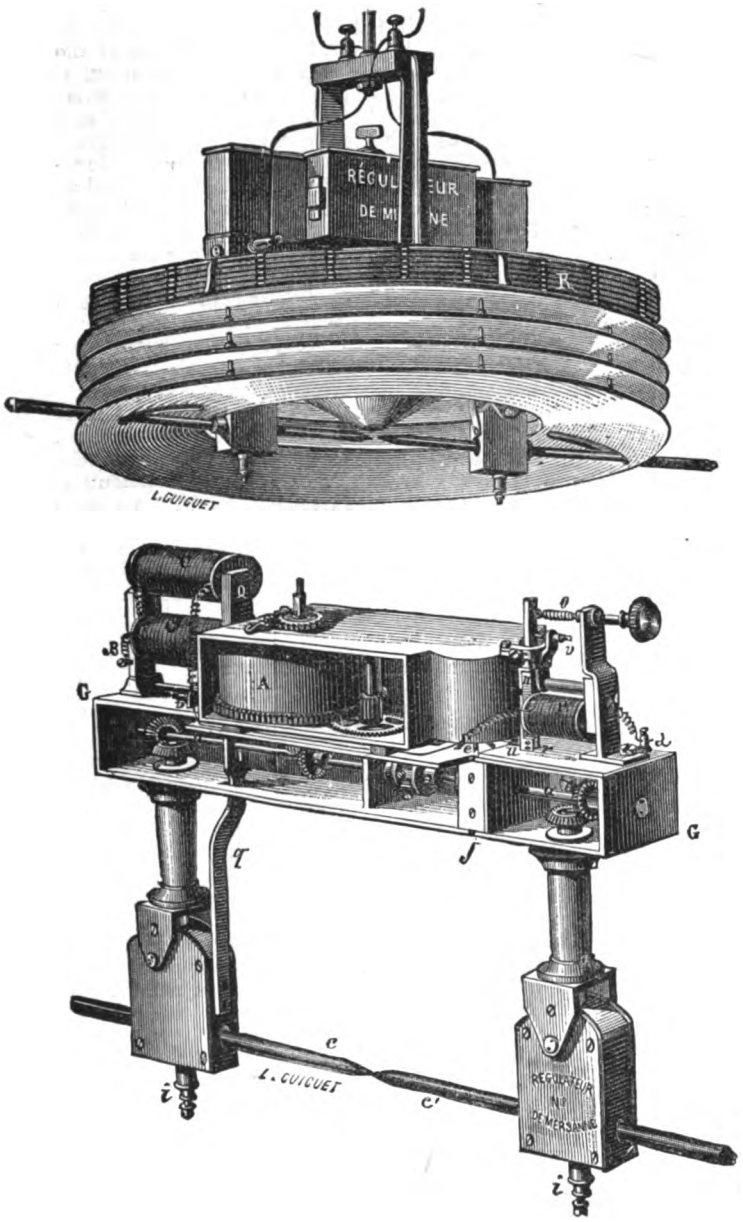

FIG. 1

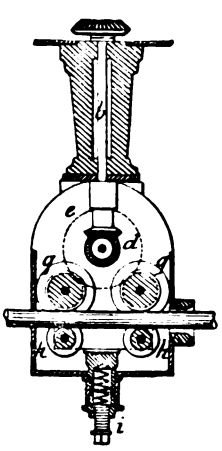

FIG. 2.

It is necessary in the Mersanne lamp to wind up the clockwork whenever the carbons are renewed. The lamp works very regularly, and is much used; amongst other places it is to be seen on the Place du Carrousel at Paris.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *September 29th*, 1888.

An interesting case was decided last week in this city, which may have considerable bearing on the installation of electric light stations within city limits. It seems that a station which had been running for some time without any objection on the part of the owners of neighbouring property was obliged to increase its capacity; and being cramped for room, instead of employing belt gearing, connected the engine to the pulley shaft by means of a large gear wheel. The introduction of the latter caused such a jar that complaint was made, and suit brought for the cessation of the nuisance. In view of the fact that the Electric Light Company has already begun the construction of a new station at another point which is to replace the present one, the judge decided that for the present the company should not be molested, but upon the prolonged continuance of the nuisance, the existence of which he considered established, the same would be followed by the issuance of an injunction.

American electrical papers describe the Waterhouse constant-current dynamo, which, as your readers may know, is provided with a third brush, as a means of regulation. According to the explanation given by the inventor, the current from the auxiliary brush passes direct to a resistance, leaving the field magnets out of the circuits. The current from both circuits, field and local, join at the resistance, and pass to the lamps, the current on the lamp line being the sum of the two. The amount of current of the field and local circuits is thus claimed to be in the proportion of the resistance in each. It is further explained that in this dynamo there is a point of maximum commutation on the armature, which changes with the resistance on the lamp line, moving in the direction of rotation when the resistance decreases, and back again when it increases. This affects the currents in the local and field circuits, so that when the lights are turned out the line resistance is increased, and the maximum point moves forward and forces more current out of the auxiliary brush and less out of the main brush beside it. This decreases the current in the field magnets, and consequently the E.M.F., and hence, also, the power required to operate the dynamo. At the same time, however, the current on the lamp line remains constant, because the local circuit is increased proportionately to the decrease of the field circuit. It is, of course, somewhat difficult to explain this without a diagram, but this method of regulation is certainly an interesting one, and is said to give good results.

The work of chopping down poles in this city goes merrily on, under the supervision of the Board of Electrical Control. It may seem ludicrous to your readers to be told that entire pole lines carrying dozens of wires have, on investigation, been found to be "dead," not a single wire being used for any purpose whatever. Considering the frequency with which companies are started here, and are later on absorbed or combined, this condition of affairs will readily be understood. The Board of Electrical Control, however, is making short work of these, and already several hundreds of poles and many miles of wire have been taken down and carted off to the Corporation yard. A curious circumstance in connection with this is that in many cases no owner can be found for these poles and lines; or, at least, those owning them disclaim ownership. The reason for this will be apparent when it is considered that it requires considerable money to take down the pole lines, and as the owners have no further use for the same, they prefer that the city incur this expense rather than themselves. At a recent meeting of the Board, quite a scene took place between Commissioners Hess and Gibbens. The question was as to the granting of privilege for one company to erect pole lines and wires. Commissioner Hess insisted that the company asking for the privilege had already been granted as much as it was entitled to. Commissioner Gibbens retorted that another company, which seemed to be in favour with Commissioner Hess, had also been granted large privileges.

Digitized by Google

The whole matter was finally tabled, but permits for erected poles are becoming very scarce.

In a long article on the subway, the *New York Herald*, in a recent issue, gives the history of the company which has been authorized to construct the conduits in this city, and elaborates a long story of the manner in which these conduits are under control of the Metropolitan Telephone Company, by the affiliation of the latter with the Conduit Construction Company. There is, however, little in the story that was not well known before, and I think there is no fear that with an honest Board of Commissioners any undue preference will be given to any one company desiring to run wires in this city.

One of the most progressive and enterprising electric motor concerns in this country is the Baxter Electric and Manufacturing Motor Company. Starting two years ago with a small shop, they have increased their business to such an extent as to make the construction of a large factory an absolute necessity. This building has been in course of construction for some time, and was opened last week with due ceremonies, including a reception, and ball and concert. The building, situated in Baltimore, has a length of 300 feet, and is 60 feet wide and two stories high. The Baxter Company have recently constructed a 100,000-watt generator, designed for distributing power from central stations, and we learn that they now contemplate the construction of another of twice the capacity.

Electric railway work in this country continues unabated. Within a week the West End Railway of Boston has contracted with the Thomson-Houston Company for the equipment of a line running out to one of the suburbs which will require 30 cars. The Sprague Company will also put in operation 20 cars at Scranton, Pa., where fuel, in the shape of "culm," or anthracite waste, can be obtained at the rate of 10 cents a ton. Another railway company of the same city is now equipping with the Van Depoele-Thomson-Houston system, so that that town will be able to afford a good means of comparing the two systems. The Sprague Company have also entered into a contract to equip an electric railway in Minneapolis, Minn. The length of the line is 3½ miles, and power will be furnished from the Edison central station, whose plant is now in course of construction. Work on the Sprague road in Boston is also being rapidly pushed on, and there will be a special equipment of three working cars to keep the track clear of snow and ice in winter.

THE BRUSSELS EXHIBITION.

(FROM OUR OWN CORRESPONDENT.)

BRUSSELS, *October* 6, 1888.

A new pattern continuous-current transformer and a new multipolar dynamo, both of which are the invention of M. Hoho, chief engineer to the Société Electrique de Bruxelles, have just arrived at the exhibition, and will take part in the trials coming off next month. The continuous-current transformer is very similar to the one exhibited last year at the Newcastle Exhibition, its main feature being an armature with two separate windings. The field magnets are shunt-wound, and to avoid the employment of a high-tension current to excite the field, the shunt is taken off the secondary circuit. Under these circumstances, however, the generation of the magnetic field would demand an interval of time, during which the primary current would be excessive. M. Hoho has therefore wound a few turns in series with the primary circuit, and thereby obtained an initial excitation. This transformer seems likely to be very applicable to long-distance transmission and especially so to the transmission of power for charging accumulators and working motors.

M. Hoho's multipolar dynamo is a four-pole machine, with pole-pieces embracing the armature very completely. From a mechanical standpoint the machine is remarkable for its strength and solidity, arising from the compactness of the field. The machine exhibited is compound-wound, and has an output of 8,000 watts (100 volts and 80 amperes) at 1,400 revolutions a minute, its total weight, including everything, being 405 kilogrammes, which is about equal to 10 watts per pound.

SOUTH OF ENGLAND TELEPHONE COMPANY.—At yesterday's meeting the directors of this Company elected Mr. Charles Billett, of Copthall-buildings, E.C., to a seat at the Board, in place of Mr. T. F. Campbell, deceased.

CORRESPONDENCE.

BALLISTIC GALVANOMETER MEASUREMENTS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I should like to mention that the method of measuring strength of magnetic field or magnetic induction with a ballistic galvanometer, by means of comparison with a standard condenser and known E.M.F., as described in Mr. Kennelly's Paper in your last issue, has been given by me in the course of my lectures at the School of Electrical Engineering, Hanover-square, as being in most cases more convenient than the employment of an earth induction. Thus, if B be the induction in any iron core of cross section A, and n the number of turns in the coil round it which is connected to the ballistic galvonometer, the quantity in coulombs passing through the ballistic galvonometer when the exciting current is reversed will be

$$\frac{2\,A\,B\,n}{10^8\,R} = a\,D;$$

where R is the resistance of the ballistic galvanometer and coil in ohms, a a constant, and D the throw produced. If now a condenser of K microfarads is charged from an E.M.F. of E volts and discharged through the galvanometer, producing a throw d

$$\frac{E\,K}{10^6} = a\,d.$$

Hence

$$B = \frac{100\,E\,K\,R}{2\,A\,n} \cdot \frac{D}{d} = \frac{50\,E\,K\,R\,D.}{A\,n\,d}$$

Yours, &c.,
E. C. RIMINGTON.

Lynton House, The Park, Norwood, S.E.,

THE SPECIFIC RESISTANCE OF PURE COPPER.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: I wish to give my hearty concurrence with the proposition which Mr. W. H. Preece laid before Section A at the recent meeting of the British Association with reference to the necessity for the redetermination of the specific resistance of pure copper.

The time has certainly arrived for us to alter the old constant of ·1516 ohm as representing the resistance of a pure copper wire 100 inches and 100 grains at 60° F.

Owing to the great care and skill shown by the manufacturers, copper wire can now be obtained of a conductivity which was unattainable in Dr. Matthiessen's days, but the above change is rendered still more desirable owing to the introduction of the new process for obtaining pure copper wire *direct* from the deposited metal by the electro-burnishing method.—Yours, &c.,
CHAS. J. SIMMONS.

London, W.C., October 8, 1888.

GUTTA PERCHA AS AN INSULATOR FOR ELECTRIC LIGHT LEADS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: A sick bed carries its patient as effectually from his course as does a raging storm many a ship; at least that is my experience. I am gradually endeavouring to make up my leeway by reading of what has been done during my enforced absence, and, in so doing, have just come across a document, which to me is certainly curious reading, and am much surprised to see some of the names that are attached thereto. It appears that the Society of Telegraph-Engineers and of Electricians formed a committee from among its members to draw up rules and regulations for the guidance of those interested in electric lighting. In April of this year the committee presented their report, and the society published and freely distributed the same. Of course, what they say about insulation, joints, different potentials, &c., should be the A B C of an electrical engineer's education; but I wish princi-

Digitized by Google

pally to call attention to clauses Nos. 1 and 4. In the former clause they say, "Conductors.—They must have a sectional area and conductivity so proportioned to the work they have to do that if double the current proposed is sent through them the temperature of such conductors shall not exceed 150° F." And in the latter, "Whatever insulating material is employed it should not soften until a temperature of 170° F. has been reached, and in all cases the material must be damp proof." Now I quite fail to see why, with such a large margin for safety as the enforced use of a conductor capable of carrying double the required current, they should fix the softening point of the insulator at 170° F., which entirely excludes the use of gutta percha. I write with no biassed pen, as, personally, it is immaterial to me what insulator is used; but, from my forty years' experience of gutta percha, I say a great injustice has been done to an old and well-tried servant, and I have no hesitation in saying that for *well*-planned installations for electric lighting, gutta percha as an insulator for the leads will be found to fulfil all the necessary requirements. In my inaugural address as president of the Society, in January, 1883, I said: "The conductivity of conductors diminishes in well-known ratios with an increase of temperature; consequently it is essential that conductors, especially those used for electric lighting, should be of sufficient capacity so as not to be affected by the current. If the current passing along a conductor increases the temperature of the same it is plain that the resistance of such a conductor is too great, and therefore its temperature and resistance will continue to increase until very prejudicial effects are reached. Perhaps the results of actual experiment will make this more clear. The experiments were made with a dynamo, the resistance of the armature of which was 0·6 of an ohm, and an arc lamp, the resistance of which was 0·38 of an ohm. In each case the circuit was metallic, and the total length of the conductor fifty yards, insulated to a thickness of ·065 of an inch. At one part of the circuit the conductor leading to the lamp, and that leading from it, were placed so as to touch each other, the consequence of which was as follows: When the resistance of the conductor was ·28 of an ohm, and the strength of the current 27 amperes, the dielectric became soft, and allowed the conductor to form contact in twenty-five minutes; with a conductor of ·21 ohm resistance and a current of 30 amperes the same results follow after forty minutes; but with a conductor of ·07 ohm resistance and a current of 33 amperes no heating effects were perceptible during the two hours the lamp was kept burning." Nothing since then has occurred to cause me to alter my opinion; in fact, I am more than ever convinced that the conductor must be so proportioned to the maximum current it has to carry as not to increase its temperature.—Yours, &c.,

WILLOUGHBY SMITH.

COPPER: AUDI ALTERAM PARTEM.

A very careful criticism of the position of the copper syndicate has been issued by Messrs. Everitt, a firm engaged in the copper trade, and as the conclusions arrived at are somewhat different from those generally held, our readers will probably like to see the following extract:—

The advantages of the rigging of the market have not been confined to the syndicate alone, as the shareholders in many large engineering concerns can testify. It is a singular feature in the present departure that the complaining has chiefly emanated from those who probably have never purchased a ton of copper. We do not suppose that the higher rates of the present moment will hamper the copper trade any more than did the extraordinary prices in iron and steel at the commencement of the last decade cripple that industry. An increased usefulness for copper is what we anticipate. Not the least of its triumphs was that which only eighteen months ago attended upon a comparison by the Government between copper and iron wire for telegraphic purposes. The verdict for copper was conclusive, and proved its indispensability—a lighter wire, with proportionately greater strength, and a marvellous increase in the average velocity of transmission. With a favourable Budget to rest upon, it is impossible to forecast the value and the magnitude of the revolution which a capable administrator like the present Postmaster-General would initiate. The modern tendency to quick and cheap telegraphic communication is here justified. A further question suggests itself as to what the syndicate can do, having due regard to the full maintenance of the use of copper in sustaining prices in the future. What prospect is there that, for some time at least, opponents will be able to discover a corrective to the present upward tendency? It was thought such remedy was at hand when the coalition between the English smelters and the syndicate came to naught. It has since appeared that the smelters have but placed themselves between the syndicate and the deep sea. They are responsive to the inarticulate but real influence of the syndicate; and prices now move in sheer obedience to the dictates of the operators. The reason is at hand. The former available supplies of material for smelting have been securely locked by the ubiquitous key of M. Secrétan and his coadjutors; for the production of the largest mines in the old and the new world is under their control. To calculate upon a fiasco by virtue of the increased volume of Chili bars is to court disappointment; so to hope for a breakdown of present rates from any increase in refined or select copper is equally futile. So long as the wealth of the syndicate can carry the one, and its power can govern the other, they will remain passive in the progress of the struggle. The world is now waking up to the fact that the present combination is only in its infancy, and that to the relief of the strain upon the syndicate may be brought, when necessary, the federation of the mining interests which the syndicate has done so much to improve. Should, however, new forces work the defeat of the now victorious corner-men at last, the influence of the present movement will live after many days. Whenever the hour of liberation arrives, and the market again breathes its quondam freedom, it will doubtless leave hostages behind. Not the least important will be that touching the prices of the future. It is certain that the result will be the establishment of a condition which shall give to the producer and the manufacturer a fair return for their capital, to the operative a livelihood for his skill and labour, and to the consumer merchandise of a value proportionate to his money. But for ourselves at this moment, and without regard to the future, against all the drawbacks to the situation we place the living fact that the trade has, by the syndicate's daring in the application of its resources, been lifted out of a depression which, had it continued, would have proved calamitous.

ANGLO-AMERICAN BRUSH ELECTRIC LIGHT CORPORATION (LIMITED).

The following circular has been issued to the shareholders of this Corporation:—

"In compliance with the request of several shareholders, and in view of many important events during the last few months, the Directors, while not anticipating the approaching annual report, consider that a brief statement as to the present position of the Corporation as regards prominent questions may be of interest.

"By the Electric Lighting Amendment Act, which received the Royal Assent on 28th June, 1888, the chief obstacles to the investment of capital in central lighting stations have been removed. Although the alteration of the law does not meet all wishes, nevertheless the extension from 21 to 42 years of the period after which the local authorities can require the undertakers to sell, and the improvement in the terms of purchase which the Act effects will be of material benefit to the industry.

"There are, indeed, good grounds for hoping that the recent amendment of the Act of 1882 will prove a turning point in the history of the industry, and there are already many indications that the long-anticipated revival in the electric lighting business is now at hand.

"Among the electric lighting companies which have already been formed for the supply of electricity may be mentioned the Chelsea Electricity Company, in which the Corporation are interested as contractors for the generating plant.

"This company, which has been established for the purpose of supplying electricity to one of the most important residential districts of London, possesses a Provisional Order which secures to the company the benefit of the new Act. It proposes to put down plant in the first instance sufficient to supply 6,000 lights. The system of distribution which is being adopted is one in the economy and efficiency of which the Directors have the fullest confidence. The electricity generated at the central station will be conveyed by underground mains to sub-centres where accumulators, which the Electrical Power Storage Company are supplying, will be charged. From these storage stations the current will be distributed to the surrounding buildings.

"The Corporation have also made arrangements for establishing central stations at Bournemouth and other places.

"The negotiations with the Commissioners of Sewers with a view to the electric lighting of a part of the City of London have been resumed, and the Corporation having submitted to the Commissioners' proposals, which will meet the objections made by some of the members of the Commission to the former scheme, there is every reason to hope for a satisfactory issue.

"The volume of the Corporation's business during the year shows a very considerable increase as compared with the corresponding period of previous years, and the factories are at present fully employed.

"Among the more important and remunerative work that has been done may be mentioned the contracts in connection with the Glasgow, Barcelona and Melbourne Exhibitions.

"At the Melbourne Exhibition the Australasian Electric Light and Power Company has installed, besides a large Victoria incandescence plant, about 40 Brush arc dynamos and 1,000 arc lamps. The whole of this plant was supplied by the Corporation, and shipped within a period of two months, and is now in very satisfactory operation in the Antipodes as the largest temporary installation on record.

"The Continental business of the Corporation is also developing very satisfactorily. The factory at Vienna is now a source of revenue, and at

Digitized by Google

Temesvar, where the lighting has hitherto been confined to the streets, the Corporation are putting down extensive plant, with a view to supplying the light to private consumers. The theatre and other buildings are already supplied, and the demand for the electric light has very largely increased.

"In July last the Directors had reason to congratulate the shareholders on the decision of Mr. Justice Kay in the action brought by the Edison and Swan United Electric Light Company, by which judgment was given in favour of the Corporation upon the main issue, viz., the Edison patent, and in favour of the Edison-Swan Company upon the minor issue of the Cheesbrough patent.

"The well-known 'Victoria' incandescent lamp, which is manufactured by the Corporation, is absolutely independent of patents other than those held by this Corporation, and is superior to any in the market either in this country or abroad, in cheapness, durability, and efficiency. In order to cope with the increasing demand, a new factory for the manufacture of these lamps upon a very large scale is being fitted up in the neighbourhood of London.

"The Directors feel they are able to congratulate the shareholders upon the improved prospects of the electrical industry generally, and having regard to the fact that during the past few years of comparative stagnation the efforts of the Corporation have been directed to developing its resources for undertaking large contracts, it is now in a very favourable position for profiting by the revival which is at hand.

"By order of the Board,

"E. GARCKE, Manager and Secretary.

"112, Belvedere-road, Lambeth, 3rd October, 1888."

COMPANIES' MEETINGS.

Eastern Extension, Australasia and China Telegraph Company (Limited).

The thirtieth ordinary general meeting of this Company was held on the 10th inst., at Winchester House, 50, Old Broad-street, under the presidency of Sir John Pender, K.C.M.G.

The SECRETARY (Mr. F. E. Hesse) read the notices convening the meeting and the minutes of the last meeting, which were confirmed by the present meeting, and signed as correct by the Chairman. The report of the Directors was taken as read.

The CHAIRMAN: Before asking you to approve of the first resolution, I will, as usual, go over some of the details in the report, so as to give you a more accurate idea of the working of our system during the last six months. The gross receipts for the half year amounted to £239,926, against £219,201 for the corresponding period of 1887, or an increase of £20,725, which is due to general increase of business throughout the system. The working expenses for the half-year have been £69,297, against £76,241 for the corresponding period of 1887, showing a decrease of £6,944, of which nearly £4,000 is on account of the repairing ships—a fluctuating item as you know—and the remainder is spread over the general working. The net revenue for the half year amounted to £125,804, against £97,662 in the corresponding period of 1887, showing an increase of £28,142. One interim dividend of 1½ per cent. has been paid for the six months, and another of like amount will be distributed on the 16th inst., leaving a balance of £47,903 to be carried forward, after charging against revenue £15,401, the balance of the cost of the Singapore-Saigon cable renewal, to which full reference was made at the last meeting. Now, gentlemen, before going a little into the details of what we have done during the last six months I think it is only right and respectful to an old shareholder that I should refer to the subject of the bonus. I do not know whether Mr. King is present, but he addressed me on the subject of paying the bonus half yearly, instead of at the end of the year only. Mr. King, however, has overlooked the fact that 12 months ago we laid down the principle, after full discussion, that it was not wise to pay a bonus before we had made up our accounts to the end of the year. This is, as you are aware, only the interim half year, consequently we are adhering to the policy which was then accepted by the shareholders, and upon which we have decided to act in the future. I think we are fully justified in taking this course. In the first place, by keeping in hand such a sum as we carry forward at the present time—because we simply carry it forward—we maintain in the market a more uniform rate for our shares. Those who hold our shares as a permanent investment have the satisfaction of seeing the value of their property from day to day rather increasing than decreasing; and, on the other hand, those who are disposed to sell their shares at any particular period during the three months, or the six months, receive a higher market price than they would obtain if there was a smaller reserve. I think that that is a very clear and good reason for paying our bonus at the end of the year. There is another reason, and a very important one, too. Those who are watching our system closely observe that we have interruptions, and during the past six months we had the two Australian cables suddenly and simultaneously interrupted for nineteen days, cutting off Australasia from telegraphic communication with the rest of the world. That might have had a tendency to cause almost a panic in regard to our property, had we not our large reserve; but the event passed off without any material change taking place in the value of our property. We found that the breaks arose from volcanic action, and, curiously enough, when we picked up the cables we found all sorts of things attached to them, even roots of trees. The whole thing seemed to be a great upheaval of Nature. In order, however, to avert a recurrence as far as possible of the inconvenience caused to the telegraphing community by the interruptions, your Directors resolved without any hesitation to have a third cable laid between Java and Australia, the policy of the Company being to do its work in such a way as to command the confidence of the public; and when we see that we can do anything to strengthen our system we do not fail to do it. We purpose connecting that cable with the land lines of Western Australia, which will give an alternative land system to the existing South Australian overland line. The manufacture of the new cable is all but complete, and we believe that within a comparatively short period the cable will be laid, with the approval of the Western Australian Government and of our Home Government; and altogether this active and prompt operation is one that should, I think, reflect credit on the Company, and give satisfaction to the telegraphing public, besides which it has put aside a competition which threatened to lay a line from a certain point in Western Australia to India, and left us, as we ought to be, masters of the position. I have given you these details, gentlemen, so as to show you that your interests are daily—I may say, hourly—cared for, and that what we are called upon to do requires a great deal of ready money at hand. Look at the changes that take place suddenly in the value of money. If we had had to go to our bankers before we contracted for this cable, we should probably have been in rather an uncomfortable position to-day; but, as things are, we have been able to undertake this work in such a manner as will, at all events, give a greater amount of permanency to your dividends, even if it does not add to them. The last time I addressed you I referred to certain renewal operations which were going on, since which we have sent out some two hundred miles of new cable of the most improved type to be inserted in the Java-Australian sections, off the Lombok Straits, near Banjoewangie, where we have experienced serious troubles from time to time, owing to the cables at this spot being on bad bottom and in too close proximity to each other. The Company's steamship "Sherard Osborn" is now engaged on the work, and although every care was taken to avoid interrupting the duplicate cable till the work on the original line was finished, we have this morning heard that the communication with Australia is interrupted about eighty miles from Banjoewangie. I believe, however, that before the day is over we shall hear of its repair. The ship is on the spot, and we believe that the vessel engaged in working on the one cable has caused the interruption to the other. A great deal has been said in the Colonies in regard to the interruptions which occur. I see that the Government of Queensland even considered it so important as to have the subject alluded to in the speech which was delivered in August last, on the opening of Parliament, by the late Governor, Sir Anthony Musgrave, whose sudden death, I regret to state, took place yesterday morning. He was Governor of Queensland for a considerable time, and his death is a great loss to that colony and to the country also, for he was a very valuable servant of the Crown. In his speech last August—the speech, no doubt, being inspired by the Premier of the day—it was stated that it was very desirable to encourage a competing cable in the Pacific as against this Company, simply for the purpose of reducing what they consider the very exorbitant rates we charge. I may say in regard to Queensland that from the very beginning that colony has given no credit whatever to the Company as the pioneer of cable communication, though deriving immense benefit from our connecting them with the mother country and the other colonies. The whole cry in Queensland has been, get a competing system and reduce the rates. I may tell you that we have done everything we possibly could to meet the requirements of Queensland, but it seems to me that nothing will satisfy them. I therefore beg publicly to say—and probably I shall take the opportunity of making my remark better known in the colony—that when Queensland comes forward and shows that she is in earnest in doing something to reduce the rates we shall be only too pleased to negotiate with her. The Company submitted a proposal some time ago to all the Australian Colonies by which a 4s. or even a lower tariff could be brought about, provided the Governments would guarantee the Company three-fourths of the receipts from the Australian traffic, the Company accepting the remaining one-fourth of the guarantee risk. So far, however, they have declined to give us this guarantee, or to take any part with the other colonies in reducing rates. What they are prepared to do, as I understand, is this, though I doubt if they are ready to find any money to do it—but, so far as I understand, they are prepared to join the other colonies to form a Pacific line, so as to force down our rates by competition, losing sight of the fact that if two cables are liable to interruption, as above explained, a single line *vid* the Pacific, consisting of long stretches of cable across enormous and practically unsurveyed depths, terminating in coral reefs, would inevitably be exposed to greater danger of interruption. Moreover, if the rates were forced down, as advocated in the Governor's speech, the traffic would probably be found to be so unremunerative that when interruptions took place the companies would be unable to bear the expense of repairing them. I am glad to say that our connection with the other colonies has been of a very satisfactory and pleasant character. They acknowledge that we have been the pioneers in this great enterprise, and they appreciate the work that we have done for them. Since direct telegraphic communication with Australia was established in October, 1872, until 1880, when the duplicate cable was laid, only two total interruptions occurred, namely, in 1877 for 38 days, and in 1879 for 18 days, making a total of 56 days, or an average of seven days per annum. From the date of duplication until the present date the communication has been thrice interrupted, aggregating 32 days, including the recent breakdown from volcanic disturbance already referred to, or an average of less than four days a year. I now pass from that matter to the next point, and I am again brought back to the subject of interruptions, and

Digitized by Google

the necessity for looking ahead, with the view of preventing any interruption in our traffic. We have at the present moment our Madras-Penang cable interrupted. That is a most unfortunate part of our system, because our cable lies on very bad ground near the Nicobar Islands, where nearly all the interruptions to this cable have occurred, and the time is not far distant when, to meet the steady increase of traffic, we shall have to lay a second cable between Madras and Penang. We have, however, lately had a survey made, with the view to finding, if possible, a better ground. All this leads me to the point from which I started—that we must not forget that these important additions require money, and therefore, by keeping in hand the reserve to which I have referred, we are enabled to do our work more promptly and more cheaply. I think all the prophesies I have made during many years as to the progress of this system have been pretty well verified. I think you will also agree with me that you have received your dividends very regularly, and we are particularly anxious that they should be continued to be steadily paid. To ensure that, however, we have to keep a sharp look out, and keep ahead in every respect of the work we shall require to do, and avoid interruptions as much as possible occurring in our system. Curiously enough, shortly after our two Australian cables were repaired, we had two cables interrupted for a short time between Aden and Bombay. It is our desire and intention to keep our system so well up to time that there can be no complaint on the part of any of our customers, and we also wish to establish this point—that we have surrounded ourselves in such a way as to render our position, I may say, invulnerable, and being invulnerable, other people will be prevented from coming into our waters, because I do not believe it is possible for any one to go into those waters and live. Occupying the position we do we must not assume the position of monopolists, but we must conduct our business on such broad and liberal principles as will satisfy you with the dividends, and the general telegraphing public with a cheap, efficient, secure, and expeditious system of telegraphy. Before I conclude, I may say that we are on very friendly relations with the Dutch Government. We have just finished some important work for them, which has been executed in a spirit which they appreciate, and at such a price that they could not do better elsewhere. All this work will, we hope, become an important feeder to our system. Whenever a Government is disposed to help themselves we are ready to assist them as far as lies in our power. I now beg to move—

"*That the report and accounts now submitted be received and adopted.*"

The Most Hon. the MARQUIS of TWEEDDALE: I beg to second that.

The CHAIRMAN: If any gentleman is desirous of making any remarks I shall be very pleased to answer them to the best of my ability before I put the resolution.

No shareholder rising to address the meeting he put the motion in the usual way, and declared it carried unanimously. Continuing,

The CHAIRMAN said: This being only the half-yearly meeting, and merely a meeting for giving you information, I am glad to state that the business is now concluded.

Mr. L. J. BAKER (Liverpool): Before we separate I beg to propose a vote of thanks to the Chairman for the remarks he has made and the enlightenment he has given us respecting the affairs of the Company and the progress it is making.

Mr. WELLS: I beg to second that.

Mr. BAKER put the motion, which was carried unanimously.

The CHAIRMAN: Gentlemen, on behalf of my colleagues and myself, I beg to return you our thanks. Looking at the care which we are obliged to give to your system, there is nothing so encouraging and gratifying as to find at a meeting like this that you are all so well satisfied that you have not one question to put to me. I am always pleased to listen to any remarks from the body of the meeting, but apparently, from your silence to-day, you are all perfectly satisfied, and you cannot pay us a greater compliment than we have received to-day. We thank you for it, and it will make us more earnest, if possible, in looking after your affairs in the future.

The meeting then separated.

PATENT RECORD.

APPLICATIONS FOR PATENTS.

13,629. W. H. SCOTT. Lakenham. Improvements in brush holders for dynamo-electric machines. September 21, 1888.

13,643. W. SNELGROVE. Birmingham. Improvements in circuit making and interrupting devices for electric bells and other purposes. September 21, 1888.

13,653. E. R. WIDDICOMBE. Forest Gate. An electrical automatic money call box. September 21, 1888.

13,687. R. E. B. CROMPTON. Chelmsford. Improvements in and connected with electrical furnaces. September 22, 1888.

13,717. S. ELOESSER. London. Means for automatically feeding electric batteries with induction liquid. September 22, 1888.

13,725. T. M. SARGEANT and O. R. SWETE. London. Improved means or devices for making electrical contacts in coupling-up electric conductors. September 22, 1888.

13,778. T. N. VAIL and J. A. SEELY. London. Improvements in telephone central station apparatus. September 24, 1888. [Date applied for under Section 103 of the Patents, &c., Act, 1883, February 25, 1883.]

13,805. F. WYNNE. London. Improvements in the application of electricity to vehicles on tram and railways, and in the apparatus for effecting the same. September 25, 1888.

13,825. H. H. LAKE. London. Improvements relating to electrical conductors and insulating conduits therefor (R. F. Silliman, United States). September 25, 1888.

13,937. P. NEIL. London. Improvements in transmitters for telegraphic purposes. September 27, 1888.

8,170A. H. J. ALLISON. London. Electric shunting device (The Baxter Electric Manufacturing and Motor Company, Incorporated, United States). June 5, 1888 [Note.—This application having been originally included in No. 8170, dated June 5, 1888, takes, under Patents Rule 23, that date.]

13,954. S. CHARLESWORTH and J. P. HALL Manchester. An improved portable electric light apparatus. September 28, 1888.

13,964. M. MCMULLIN. London. Improvements in the application of portable electrical batteries and incandescent lighting to articles of wearing apparel and other analogous purposes. Septemper 28, 1888.

13,984. B. J. B. MILLS. London. Improvements in electric accumulators (J. Barbier, France). September 28, 1888.

13,987. L. SAUNDERSON. London. Improvement in electric lighting. September 28, 1888.

13,994. J. KENDALL and O. COOPER. London. Improvements in and relating to cut-outs or safety devices for electric circuits. September 28, 1888.

14,030. T. B. GRANT. London. An improved apparatus for generating, graduating the strength of, and distributing electro-magnetic currents for medical and curative applications. September 29, 1888.

14,090. H. C. HAROLD and R. JENKINS. London. An improvement in combination with electric light switches for securing better contact. October 1, 1388.

14,095. J. SWINBURNE. Chelmsford. Improvements in and connected with dynamo-electric machines and electric motors. October 1, 1888.

14,156. W. Y. HARDIE London. Improvements in the precipitation and the mechanical, chemical, pneumatic, and electric treatment of towns' sewage, and the utilisation of the solids therein, as well as the preparing from towns' refuse a deodorising and purifying power, which is also applicable for other purposes. October 2, 1888.

14,161. L. BOLLMANN Vienna, Austria. Improvements in the method of producing electro-magnetic inductions for transformers, motors, or generators, and in the apparatus therefor. October 2, 1838.

14,184. W. BOGGETT. London. Improvements in obtaining electricity for electric lighting, motive power, and other purposes. October 2, 1888.

14,191. S. R. LOWCOCK. Moseley. An apparatus for automatically transmitting electric currents. October 3, 1888.

14,225. R. DICK and R. KENNEDY. Glasgow. Improvements in and relating to continuous current dynamo-electric machines and electro-motors. October 3, 1888.

14,230. J. S. RAWORTH and W. M. MORDEY. London. Improvements in electricity meters. October 3, 1883.

COMPLETE SPECIFICATIONS ACCEPTED.

September 29, 1888.

14,996. E. HOPKINSON. London. Improvements in gear for transmitting motion from electric motors to driving axles of vehicles. November 3, 1887.

15,760. W. WEBSTER, jun. London. Improvements in the electrolytic treatment of sewage and sea water for the production of certain products therefrom, and apparatus therefor. November 17, 1887.

15,877. J. B. WILLIS. London. Improvements in telegraphic apparatus suitable for indicating the position of a ship's rudder. November 18, 1887.

16,185. W. J. S. BARBER-STARKEY. London. Improvements in electric meters. November 24, 1887.

16,772. J. A MACDONALD. Birkenhead. Improvements in electric bells. December 6, 1887.

October 6, 1888.

13,326. J. DOUGLAS and H. ABBOTT. London. Improvements in machinery or apparatus for producing and administering electric shocks and currents. October 1, 1887.

15,063. P. SKRIVANOW. London. Improvements in galvanic batteries. November 4, 1887.

16,623. W. T. GOOLDEN and L. B. ATKINSON. London. Improvements in dynamo-electric generators and motors. December 2, 1887.

17,089. M. IMMISCH. London. Improvements in the construction of the cores of armatures of electro-motors and dynamo machines. December 12, 1887.

5,390. J. SHERRIN and J. V. SHERRIN. London. Improvements in velocipedes and other vehicles propelled by electricity. April 11, 1888.

THE MAXIM-WESTON ELECTRIC COMPANY.

The following is the report recently submitted to the Board of Directors by the firm of chartered accountants who have been instructed to examine the affairs of this Company :—

TO THE DIRECTORS OF THE MAXIM-WESTON ELECTRIC COMPANY (LIMITED).

Gentlemen : In accordance with your instructions we have investigated the accounts of your company, and beg to report as follows :—

We have taken the balance-sheet and profit and loss account for the year ending 31st December, 1887, and have confined our investigation to these accounts, except where we have found it necessary to go back into former years for the purpose of elucidating certain items appearing in the 1887 accounts.

The assets are set forth in the 1837 balance-sheet as follows :—

Patents	£40,737	1	1
Stock of machinery, lamps, &c., at factory	19,817	7	6
Machinery, plant, and tools	3,603	15	2
Furniture and fittings at offices	228	1	8
Shares in the Electric Sun Lamp and Power Company (Limited), estimated value	239	7	6
Debtors	15,001	12	6
Cash	2,370	11	0
	£81,997	16	5

We will deal with these items in their order.

Patents : £40.737 1s. 1d.—This item appeared in the 1886 balance sheet as £38,229 17s. 1d., showing an increase during the year of £2,507 4s. This increase is arrived at by charging to patents account the following sums :—

Renewal of patents	£44	0	0
Wages	718	4	0
Material used and destroyed casting patterns, &c.	325	0	0
Managing director, proportion of salary	750	0	0
Works manager ,, ,,	200	0	0
Secretary's time taken up experimenting on dynamos, lamps, &c.	100	0	0
Clerks' time taken up on experimental work	270	0	0
Men's time	100	0	0
	£2,507	4	0

There being no sinking fund for the gradual extinction of the item for patents, the cost of experimenting such as above should, in our opinion, be paid out of revenue. In our judgment the value of the patents should not be permanently increased by charging to them a large proportion of the salaries of the managing director, works manager, secretary, and clerks, which would have been a charge upon revenue whether experiments had been made or not. The auditor refers to this matter in his report on the 1886 accounts. The amount at which the patents are entered in the books should, in our opinion, be subject to a very heavy depreciation—to the extent of the amount added during 1887, or, say, £2.500.

The amount expended upon the Watt dynamo during 1837, as worked out by the works manager, was :—

Labour	£153	0	2			
Material	158	9	9			
				£311	9	11
and in 1888						
Labour	£129	6	6			
Material	121	10	0			
				250	15	6
				£562	5	5

The amount expended upon the Watt lamp was :—

1887. Labour	£30	12	2			
Material	4	1	11½			
				£34	14	1½
1888. Labour	98	17	8			
Material	37	15	1½			
				136	12	9½
				£171	6	11

Stock	£19,817	7	6
Machinery, plant, &c.	3,603	15	2
Furniture and fittings	228	1	8
	£23,649	4	4

Digitized by Google

The stock has recently been re-taken, and the plant and machinery re-valued by the works manager, who puts upon them now a lower value than at 31st December, 1887. Taking his new valuation as the basis it would appear that the value of the stock, plant, machinery, tools, furniture and fixtures, at 31st December, 1887, was about 14,950, instead of £23 649, as stated in the balance-sheet. This shows a difference of, say, £8,700. A comparison of the stock lists will show how this difference is made up.

Debtors: £15,001. 12s. 6d.—The good debts owing at that date were, so far as possible, collected prior to the resignation of your late chairman and managing director. A large sum is represented by plant in the hands of agents, some of which has since been returned, and much is reported by the agents to be unsaleable in their districts. A large proportion of the remaining accounts is in dispute. We have gone carefully into all these accounts, and are of opinion that in order to arrive at a fair estimate of their value a sum of £7,600 should be written off or provided for. The details of this sum we give in a separate list, showing the amount we recommend should be provided for in each case. This item is particularly mentioned in the auditor's report on the accounts to 31st December, 1887.

Shares of the Electric Sun Lamp Company, in Liquidation: £239. 7s. 6d. We can gain no information about this company, and think it doubtful if there will be a further dividend. It would be prudent, therefore, to provide for the amount, or the greater part of it.

Cash: £2,370. 11s.—This item is correct.

Applying the foregoing estimate of the assets to the figures given in the balance-sheet at December 31st, 1887, we find that, in our opinion, the assets are stated in excess of their value at that date, as follows:—

Patents	say	£2,500	0	0
Stock, Machinery, plant, &c., Furniture	,,	8,700	0	0
Debtors	,,	7,600	0	0
Shares in Electric Sun Lamp Company	,,	200	0	0
Total	,,	£19,000	0	0
Deduct balance of profit and loss account	,,	1,555	0	0
Total		£17,445	0	0

Profit and Loss Account.—During the years 1884 and 1885 goods were sent out to various agents abroad, and entered up in the company's books as though actually sold to the extent of £5,334. 0s. 7d., and the assumed profit in consequence was taken into the profit and loss accounts for those years. A few additional items have been sent out since, bringing up the total to £5,412. 10s. 5d.

Of this amount goods to the value of £699. 8s. 5d. only have been sold. The remainder is in the hands of the agents unsold, or has been returned into stock.

Mr. Watt has drawn 5 p. c. commission, amounting to £571. 17s. 6d., on the alleged profits of the years 1884 and 1885, which includes about £145 on the assumed profits on these alleged sales.

In the directors' report accompanying the accounts for 1885 are the following clauses:—

1. "The directors beg to remind shareholders that no allowance was made during the past two years for contingencies, such as referred to in section R of clause 75 of the articles (which states that the directors may 'set aside *out of the profits of the company* such sums as they think proper to meet contingencies, &c.'), and they have now deemed it prudent to pass the sum of £3,606. 5s. 0d. to the credit of a general reserve fund."

2. "After making the above reserve, the total balance to the credit of profit and loss account, including amount brought forward from previous years, is £5,284. 19s. 8d."

It would *appear*, therefore, from the foregoing, that the reserve was created out of profits on trading. It was *actually* created in the following manner:—

Premium on new shares issued				£3,000	0 0
Less paid to cover commission on placing shares	£1,000	0	0		
Brokerage	122	18	4		
				1,122	18 4
				1,877	1 8
On the reduction of capital there was a balance on the books to the credit of the company of				1,729	3 4
The two items added together made				£3,606	5 0

the amount at which the reserve fund appeared in the 1885 balance-sheet.

Clause 6 of the same directors' report is as follows:—

6. "The directors estimate that £600 will cover the total bad debts incurred by the present management, including outstanding debtors."

The "outstanding debtors" amounted to £12,794. 15s. 6l, and this sum included the goods in the hands of agents, amounting at that date to £4,902. 19s. 9d.

During 1886 a sum of £2,074. 11s. 5d. is written off the agency accounts alone, and £1,531. 13s. 7d. from other accounts. These items together absorb the reserve fund of £3,606. 5s., which accordingly does not appear in the 1886 balance-sheet. No explanation of its disappearance is given in the directors' report accompanying the accounts for that year, but the auditor in his report on the 1886 accounts draws attention to the fact. The result of this operation was that the profits of the years 1884 and 1885 were swollen by goods sent out to agents at enhanced prices being treated as sales, without any provision being made for bad debts, or for the contingency that the goods might not be sold. The reserve fund—created by reduction of capital and premium on shares—being utilised to reduce the amount appearing as book debts, the appearance of profit was maintained, and a dividend 7½ per cent. was paid in March, 1886.

A subsequent dividend of 5 per cent. was paid in March, 1837, out of the amount shown as profit in the accounts for the year 1886, no provision being made for loss on book debts during that year.

From the foregoing it will be seen that the results of the trading have not been truly stated in the past by reason of the non-provision for bad debts, and by the over valuation of the stocks.

BOYCE and RAMSAY, Chartered Accountants.

2, Metal Exchange-buildings, E.C.

Mr. Hugh Watt has addressed the following letter to the Editor of the *Financial News*:—

Sir: I regret feeling compelled to beg a few lines of your valuable space to correct the renewed misstatements of Mr. John Marks, chairman of yesterday's meeting of the Maxim-Weston Company. I need hardly say that nearly all which is referred to in his speech has been the subject of correspondence between myself and the company since I resigned my position as director, and all the matters therein referred to were exhaustively explained, as I am entitled to assume, to the satisfaction of the company, as after receipt of my explanations they closed the correspondence. Mr. John Marks is aware that the payments made to me by the secretary were in terms of Board minutes, the validity of which has never

been disputed, and at the time that I received £650 the company was owing me £600 for cash advances, and from £1,000 to £1,500 more for rent, salary, and disbursements made by me on behalf of the company.

To show the worthlessness of Mr. Marks' statements, I may state that the engines he refers to were taken over from the Lancashire Company, and that no money whatever was paid for them; or, in other words, in partial settlement of a bad debt, and that they were otherwise unsaleable.

With regard to the plant sent to Mauritius, this was all conditionally sold, the condition being that, as the firm who agreed to purchase the plant shipped by us were not strong financially, and could not pay for the plant upon delivery in Mauritius, they undertook to pay our agents there fixed prices in terms of an agreement entered into with the company as soon as they received the money from their customers. I cannot at this date recollect the cause of the failure of this agreement, which was either owing to the firm in question retiring from business, or their having been unfortunate, and thus unable to carry out their agreement. All the plant which was sent abroad was unsaleable in this country, and was taken over from the original management in 1883.

With regard to the Lancashire plant spoken of, no one, I think, could have foreseen the death of a mortgagee, which compelled the company in question (which was then in a sound financial condition) to go into liquidation; but Mr. John Marks is either unaware or has not the common honesty to state that a large business resulted from this introduction, which would have been five times larger had the company been in a financial position to undertake extensive contracts which were offered them, including the lighting of the entire town of Birkdale.

I cannot understand Mr Marks' statements with regard to another Lancashire account referred to; but, speaking from memory, I feel satisfied that I am right in stating that the transaction referred to left a profit —or, in other words, the plant, which was valued by us as worth £1,000, was returned intact, and £300 (assuming his figures to be correct) obtained in cash from the hirers of the plant in question.

From what Mr. John Marks states as to the accounts for 1887, it would be inferred that these were not passed. Allow me to remind him that Mr. J. M. Klenck proposed the passing of the accounts, and, if I am not mistaken, Mr. John Newton (another member of the committee) seconded this motion, which was carried unanimously.

Mr. Marks states that I owe the company £2,113; but it is surely extraordinary that the committee were appointed in March and exhaustively examined into my connection with the company, and that they did not discover till the middle of September that I was owing the company any money at all. I regret I am unable to go into details of this extraordinary claim, the matter being now *sub judice;* but would state that the total sum represented by my two actions against the company amounts to about £2,500.

The insolence of Mr. John Marks with regard to my staff is almost unworthy of notice, and I might have treated it with silent contempt; but I would, in conclusion, venture to repeat that the total sum I received from the Maxim Company was £2. 18s. per week in excess of the sum received for transfer fees; that my staff at that time consisted of 16 clerks; and that the character of the assertion that the company were paying for my staff, when the total sum received was little more than half the salary of one of them, is worthy of the source from which it emanated. —I am, sir, yours &c.,

HUGH WATT.

78, Queen Victoria-street, E.C., October 4th.

The secretary of the Maxim-Weston Company has addressed the following letter to the Editor of the *Financial News* in reply to the above:—

Sir: In the absence of the chairman, who is out of town, I do not propose replying at any length to the letter from Mr. Watt, which appeared in your issue of yesterday.

I will merely give one instance of the manner in which he represents facts, which can easily be ascertained on reference to the company's books.

In the last paragraph of his letter he says, with reference to clerks, "the total sum I received from the Maxim Company was £2. 18s. per week *in excess of the sum received for transfer fees.*"

Mark the words which I have italicised.

The amount actually paid during 1887 for salaries of clerks (exclusive of secretary) was £462. 8s. 1d., or nearly £9 per week.

The value of Mr. Watt's other assertions may be estimated by the above specimen.—I am, sir, yours, &c., SAMUEL J. BOYCE, Secretary.

A. W. Wells, Greenhill-park, Harlesden, accountant.....	1
J. B Lawson, 30, Cambridge-street, S.W., assistant secretary	1

The number of directors is not to be less than 3, nor more than 7; the subscribers are to appoint the first, and act *ad interim*; qualification, 50 shares; remuneration, £2,000 per annum.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—We are informed that the accounts of this company, subject to audit, show a profit sufficient to enable the directors to recommend a final dividend of 3s. per share, making, with previous distributions, a total dividend of 6 per cent. for the year ended 30th June, 1888, and also the payment of a bonus of 2s. per share, both free of income-tax, which, together, will amount to £32,500, being a distribution in the aggregate of 7 per cent for the past year, leaving a balance of £34,539. 3s. 7d., of which amount £30,000 has been placed to the reserve fund, increasing that fund to £170,175. 11s. 5d., and £4,539. 3. 7d. carried forward. The above dividend and bonus will be payable on the 31st inst. The traffic receipts for the week ended October 5th, 1888, amounted to £5,216.

CUBA SUBMARINE TELEGRAPH COMPANY.—The number of messages passing over the lines of this company during the month of September was 3,550, estimated to produce £2,700, against 3,069 messages, producing £2,494, in the corresponding month of last year.

EASTERN EXTENSION, AUSTRALASIA, AND CHINA TELEGRAPH COMPANY.—The traffic receipts of this company for the month of September, 1888, amounted to £41,095, against £36,400 in the corresponding period of 1887.

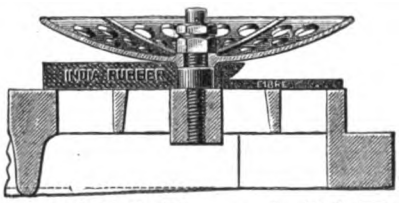
GLOBE TELEGRAPH AND TRUST COMPANY.—The Stock Exchange Committee have appointed Tuesday, October 16, as special settling day for Ordinary shares Nos. 179,178 to 180,227, and Six per Cent. Preference shares Nos. 178,993 to 180,042.—The directors of this company have declared an interim dividend of 3s. per share on the preference shares, less income-tax, and of 1s. per share on the ordinary shares, free of income-tax, for the quarter ending October 18, payable on and after that date.

GREAT NORTHERN TELEGRAPH COMPANY.—The traffic receipts of this company for September amounted to £23,400, and for the period from 1st January to 30th September to 202,600. For the corresponding months of 1886 and 1887 they amounted to £195,560 and £197,720 respectively.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended October 5th, 1888, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company (Limited), were £4,359.

NEW VALVE

No Rubber, Percha, or Leather.



One-half the price of Rubber or Metal.

FOR CIRCULATING AND AIR PUMPS.

Unaffected by any Lubricating Oils. Does not Expand in diameter. Feed Water may be worked at any temperature. Suitable for any shaped guards. Only one quality manufactured.

"12, John-street, Sunderland, 26th Sept., 1885.

"DEAR SIRS,—In reply to your letter of the 25th inst., the Valves I got from you have done their work well, and ARE AN UNQUALIFIED SUCCESS. I will continue to get them from you as required.—Yours faithfully, JAMES WESTOLL."

For further Testimony and Prices, apply to MOSSES & MITCHELL, 68-71, Chiswell Street, London.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL SCIENCE, INDUSTRY AND ENGINEERING.

No. 544.—Vol. XXI. FRIDAY, OCTOBER 19, 1888. Price 4d.

NOTES.

The new views of electrical action which are being developed with such rapidity and apparent success by the work of Hertz, Lodge, Thomson, Hicks, FitzGerald, Lindemann, and others, are, we need hardly say, now being studied with avidity by students of electrical science of every grade, more especially since nearly all the experiments can be repeated without the slightest difficulty by anyone who possesses the usual appliances for the study of static electricity. We are also persuaded that even the practical electrical engineer cannot safely neglect a new departure so fundamental and wide-reaching in extent. No "practical application" may at this moment be in view, or may even be imaginable; but, nevertheless, the extension of our knowledge of the relation between electricity and light, and of the nature and functions of the ether, can hardly fail, sooner or later, to have a powerful influence upon our present rough-and-ready methods of utilising electric energy. Meanwhile we are happy to believe that with the valued co-operation of Dr. Lodge and Mr. de Tunzelmann we have been enabled to present our readers with the results of the latest and most advanced theoretical and experimental research in a form at once accurate and easily intelligible to the non-mathematician.

Of the many crucial and far-reaching questions upon which the Hertz experiments will almost certainly throw much new light, one of the highest theoretical importance is that which has been referred to as "the murder of Ψ," about which Dr. Lodge says something in his "Sketch of the Electrical Papers in Section A" (*The Electrician*, September 21st, 1888, p. 624). This, as many of our readers will recollect, relates to the question of the manner and the velocity of the transmission of electrostatic potential. The elimination of Ψ (electrostatic potential) from the general equations of the electro-magnetic field has long been aimed at by mathematicians, and during the recent British Association meeting the informal suggestions of Profs. Rowland and FitzGerald to this end were received with some acclaim. As explained by Dr. Lodge in the Paper above referred to, this amounts to the suggestion that "an electrostatic field is not developed *sui generis*, but is always the consequence of a previously existing electro-magnetic one, which, on subsiding, leaves it as its permanent record." Thus Ψ breathes its last. But ere the last gasp comes Dr. Hertz to the rescue. The experiment (described by Mr. de Tunzelmann on p. 726 of our last issue), which proves the existence of a region in which the direction of the resultant of the electrostatic and electro-magnetic E.M.F. is indeterminate, can be explained only—so far as has yet been suggested—on the supposition that the electro-magnetic and electrostatic potentials possess different velocities. If this be established, it would seem to be inconsistent with the view that electrostatic potential is merely the result of the dying-out of electro-magnetic potential, so that the fate of Ψ is still left hanging in the balance.

Prof. Lindemann has recently shown reason for believing that if a particle of matter easily susceptible of electrification be made to approach a source of light with a velocity *exceeding that of light* by a certain definite amount it will become electrified. The higher the refrangibility of the light rays the greater will be the effect. The experimental verification of this prevision might at first sight appear to be a task of some difficulty. We hope shortly, however, to publish a *résumé* of Prof. Lindemann's research, from which it will be found that the theorem is applied to the explanation of striæ in vacuum tubes—a phenomenon which has never yet been satisfactorily accounted for—and in this way indirect evidence of at least a high degree of probability is obtained.

A valued correspondent writes as follows:—

"I appreciate your article on Practice *v.* Theory, but it hardly goes far enough. The distinction between a complex phenomena in practice and the simplified aspect of it which is suitable for calculation is undoubtedly true; but there is more in the controversy than that. The so-called 'practical' man not infrequently misunderstands the whole problem, and is unable or unwilling to seize the true mode of regarding the facts. It is not only a question of perturbing effects—the fundamentals themselves are differently regarded. But usually the only cure for the 'practical' generation is to die off, and for a new generation to arise. They are usually one generation behindhand."

If this is severe, it is, perhaps, not wholly unmerited. Our own purpose last week, however, was, if possible, to play the part of moderator. We may add that some remarks on the same subject from Mr. Oliver Heaviside will be found in our correspondence columns.

The Waterhouse system of regulation for constant current which we described last week bears a striking resemblance to a method which is credited to Edison, and which was described by Mr. Mordey, in our issue of July 31st, 1885, in the follow-

Digitized by Google

ing terms:—"A combination of the two methods of brush movement and shunt-current alternation was proposed by EDISON, viz., to use an additional brush, to which one end of the field shunt was connected, the other end of the shunt being joined in the usual way to one of the ordinary brushes or terminals. This additional brush was to be moved on the commutator, between the two main brushes to the position which was necessary to obtain the proper current for the shunt. As any difference of potential, up to that maintained between the brushes, could in this way be obtained for the field circuit, the shunt current could be varied without the use of additional resistance coils, or the employment of divided field windings. Perhaps the difficulties connected with the construction of incombustible and infusible brushes prevented the extensive application of this very ingenious idea." It will be seen that the only difference lies in the fact that EDISON proposed to adjust the position of the brush; in the Waterhouse system the resistance in shunt on the field is varied. We doubt whether either system is consistent with the conditions of maximum efficiency.

IN the *Berichte der Berliner Akad.* C. BRAUN claims to have discovered a new method of producing an electric current. This is a claim which should be supported by the fullest proof before it can expect to receive recognition, and therefore we regret that the author does not furnish more exact information. The experiment is, however, sufficiently simple, and many of our readers will doubtless repeat it. A wire of nickel—though we learn afterwards that any other metal will serve—is twisted into a spiral, and the two ends are connected to a sensitive galvanometer. When the spiral is sharply extended a deflection is observed, and when it is again compressed the needle is deflected in the opposite direction. "This phenomenon," says the author, "is the more astonishing since the spiral being perfectly symmetrical there is no apparent cause by which the direction of the current is determined." We think, however, that it will immediately occur to most people that this is perhaps an instance of the Thomson effect. In winding the spiral it seems quite probable that in each turn one side of the wire will undergo a slightly greater molecular change than the other; then the change in temperature due to the alteration of configuration would set up differences of potential in each turn, which would be added together at the galvanometer terminals. The author mentions the effect of induction in the earth's field, but he thinks this is not sufficient to account for the observed deflections; he also finds that when the spiral is heated or cooled *as a whole* the same phenomenon is produced.

AMONGST our correspondence this week will be found an interesting letter, in which Mr. H. E. DOLAN describes an electric tramway in the neighbourhood of Toronto. Before the introduction of electricity the passengers were accustomed to be asked to walk up the steepest hills; now we are told a car 16ft. in length has carried as many as 127 people, and, though its back was broken by the load, "it got there all the same." In fact, the line is evidently worked with the usual American vigour and with the usual American success. We commend this letter to the attention of all who are interested in the commercial development of electric traction.

WE would call the attention of our readers to the circular (which will be found in another column) issued by the Secretary of the London Chamber of Commerce, convening a meeting of the Electrical and Allied Trades Section for Monday afternoon, at which, the report of the Provisional Committee having been read, a permanent committee will be elected. Up to the present over 180 members have joined, so that the movement already rests on a substantial basis.

A PROVINCIAL paper states—we know not with what degree of accuracy—that many of the fishermen of the Welsh and South West Coast are now regularly employing the glow lamp in night-fishing, the current being furnished by accumulators. Even if this statement be a little too "previous," as the Yankees say, yet there certainly appears to be some reason to believe that at the larger fishing ports a profitable business might be done in the charging of accumulators for this purpose. As to the efficacy of the light in attracting fish to the nets, this has been proved over and over again. In some recent experiments, which were attended by several gentlemen who are interested in the question, two nets were let down in the first instance, one with and the other without a single glow lamp. The former came up full of fish, the latter was comparatively empty. This was repeated several times at different depths. Both nets were then illuminated and taken up after a certain time with a good catch; they were then sunk for the same time without the lights and came up nearly empty. With a little judicious management in the preliminary stage, there certainly ought to be a demand for accumulators in this line of business.

"WE are glad," says the *Electrical World*, "to see that Prof. AYRTON has a good word to say for telpherage." There is a refined and delicate sense of humour in this remark which is very enjoyable. But on second thoughts we are seized with a painful doubt; surely our esteemed contemporary is not referring to telpherage as an American invention?

Telephone between Vienna and Prague.—A telephone line between these two cities is under construction by the Austrian Posts and Telegraph Department.

Repairs to the Australasian Cables.—The Eastern Extension, Australasia and China Telegraph Company notify that telegraphic communication is now restored with Australia and New Zealand.

The Submarine Cables Convention.—The English Government has notified the adhesion to the Submarine Cable Convention of Canada, Newfoundland, the Cape, Natal, New South Wales, Tasmania, Western Australia, and New Zealand.

The Waterhouse System.—Messrs. Shippey Bros. inform us that the Waterhouse System, particulars of which were illustrated in our last week's issue, has been awarded two diplomas and the gold medal at the Cincinnati State Exhibition.

Digitized by Google

A Correction.—In our last issue we stated that Mr. G. S. Hooker had resigned his position as electrician in charge of the Bath installation, and that Mr. Orlando V. Thomas had been appointed in his place. We should have said that Mr. G. S. Hooker having been appointed to take charge of the Bath installation, Mr. Orlando V. Thomas had succeeded to the Taunton station.

The Van Rysselberghe System.—According to the *Indépendance Belge*, the inter-urban telephone lines on the Van Rysselberghe system yielded a revenue of 50,000fr. in 1887, and it is expected that the State will by the end of the current year have recouped itself for the outlay in adapting the telegraph lines to this system.

Redruth.—A local paper says:—"It seems the rumour which has been afloat that an electric light company is about to be formed at Redruth will most likely become a reality. A meeting of those interested in the movement was held last week, when an engineer versed in lighting by electricity was present to give information on the subject. Although, we believe, nothing decisive was arrived at, a syndicate was formed with the view of seeing what could be done to form a company."

Blyth.—A public meeting of the ratepayers of the Cowpen township, Blyth, was held last week, under the auspices of the Cowpen Local Board, to take into consideration the advisability of lighting the Cowpen township with electricity. Mr. William Thompson, of Waterloo, occupied the chair. Having heard the estimated cost of lighting by electricity and by oil the meeting unanimously agreed to urge upon the Local Board the advisability of adopting the electric light without further delay.

The Biography of the late Sir William Siemens.—We learn that the executors of the late Sir William Siemens have placed the preparation of his biography in the hands of Dr. William Pole, F.R.S., who was a personal friend of Sir William and his family. The work will be published shortly, in one volume, by Mr. Murray, and will be followed by other volumes, containing reprints of Sir William's most important scientific Papers, lectures and addresses, edited by his secretary, Mr. E. F. Bamber.

The "Popular Educator."—A new and revised edition of Cassell's "Popular Educator" will be commenced at the end of this month. The text will be revised throughout, and a considerable portion of the work rewritten; it will be furnished with new illustrations, and a series of coloured plates and maps will form an entirely new feature, whilst the work will be reset in clear type. Inasmuch as it will thus be practically a new work, it will be issued under the title of Cassell's "New Popular Educator."

The Electric Lighting of French Steamships.—The French Steamship Companies are gradually introducing the electric light into their vessels. The Messageries Maritimes has just placed it on the "Rio Grande," and has ordered the "Senegal," the "Amazone," and the "Mendoza" to be furnished with it. The "Rio Grande" possesses 100 incandescent lamps of 10 candles. The "Eugène Pereire," running between Marseilles and Algiers, has 300 lamps, and the packet "Amerique" has just been furnished with installations of 350 lamps.

Ivory Tablets.—The Endolithic Ivory Company, of 24, Well-street, Jewin-street, E.C., have submitted to us a sample of their method of writing or printing on bone or ivory, which seems to possess several advantages for switch board labels and address tablets. In this process the ink sinks into and combines with the material, so that it is practically indelible, and the surface, including the letters, takes a high polish. The process is said to be cheaper than engraving, and the company guarantees the durability of the lettering.

Cheltenham.—The Cheltenham Town Council, notwithstanding their advanced views in the matter of electric lighting, are hard to convince that it would be to their benefit to allow the West of England and South Wales Telephone Company to connect the Police Station and Fire Brigade with the local Exchange. Seeing that the company, with their customary generosity, ask only to be allowed to make the connection free of charge, this hesitation is really very difficult to understand. Is Cheltenham so small a village that the advantages of the *fernsprecher* are inappreciable?

Liverpool.—The Liverpool Electric Supply Company have been for some time engaged in negotiations with the Corporation with regard to the laying of their mains for lighting the streets and public buildings by electricity. The impervious pavement which is universally adopted in Liverpool has given rise to many difficulties, for when once it is laid it cannot be broken into without at once destroying its principal advantage. A satisfactory arrangement has, however, at last been made, and the cables are now being laid. This is the third attempt to light the public streets by electricity.

Mica in Australia.—An important discovery of mica has recently been made in the northern territory of Australia, by Mr. David Lindsay, F.R.G.S. The discovery consists of two mica outcrops, one showing 30 feet in width. Sample slabs of this valuable mineral have been sent to London, and brought to the Society of Arts. These, though taken from the surface, are of large size. As the consumption of mica is rapidly increasing through its use in electrical apparatus, and as sheets of large size are comparatively scarce and expensive, any new source of supply of the mineral is of considerable importance.

Electric Lighting at Sea.—The ss. "Cambria," of the Dundee, Perth, and London Shipping Company, has lately been fitted throughout with the electric light by Messrs. Paterson and Cooper. The plant comprises a Phœnix compound dynamo, driven by a 12 horse-power engine, and supplying 90 sixteen candle-power Edison-Swan lamps. The lamps are arranged in five circuits, to suit the working requirements of the vessel. Messrs. Paterson and Cooper have contracts at the present time for three ship installations, besides a contract for lighting the London wharf of the Dundee, Perth, and London Shipping Company.

Proposed Electric Lighting at Harrow.—On the 10th inst. a meeting of the ratepayers of Harrow was held to consider the advisability of adopting electric lighting in the town. Mr. Russell Biggs presided. Mr. Frank Taylor expatiated on the advantages of the electric light, remarking that this light was bound to come sooner or later, and that the time had arrived when it could be supplied as cheap as, or cheaper than, gas. He did not, however, cite Barnet as an instance of the successful introduction of the system of illumination he advocated. After some discussion it was resolved to ask the Local Board to investigate the matter.

A New Method of Amalgamating Zincs.—A Mr. Beattie has devised a new method of amalgamating zincs, which he says gives results far superior to those obtained by the ordinary process. It consists in melting together a mixture of zinc, mercury, bismuth, and antimony. Mr. Beattie tested his zincs in a Callaud gravity battery, which is largely used in the United States in connection with fire alarms. While the E.M.F. of a battery furnished with ordinary zincs was only 8·5 volts on starting, and fell to 8 volts at the end of 38 days

Digitized by Google

and to 7·2 volts at the end of 54 days, the E.M.F. of a similar battery having the new zincs remained at 9·2 and 9·6 volts for a period of sixty days.

The Influence of Joints in the Magnetic Circuit of Dynamos. M. Larroque has recently carried out a series of experiments on this subject, which, although apparently not so exact as those of Prof. Ewing and Mr. Low (see *Electrician*, Sept. 30th, 1887, p. 439), lead to the same conclusions. It is therefore confirmed that the magnetic resistance of a joint diminishes as the pressure between the two surfaces increases, and that for the same applied pressure the resistance of the joint decreases as the total induction is increased. M. Larroque adds to this that in a practical machine when the iron approaches saturation the influence of mechanical vibration is so marked that the field is equivalent to that of a magnet of the same size and form without any joint.

Electric Lighting in a South Wales Colliery.—The Albion Steam Coal Company have decided to light their new colliery near Pontrypridd with electric light. The installation, which is to be of a very complete character, has been placed in the hands of the Gülcher Electric Light and Power Company (Limited), who also lighted the Ynishir colliery some two years ago with highly-satisfactory results. The installation for the Albion Company will consist of a horizontal engine, with automatic gear, driving a Gülcher dynamo, which will supply current to 114 16 candle-power incandescent lamps, 54 of the lamps being under ground; in all cases exceptionally strong fittings will be used in order to withstand the rough wear and tear of colliery work.

"Parts of Steam Engines."—Under this title the well-known firm of Tangyes (Limited) has issued a catalogue which involves a somewhat new departure in the engineering trades, the idea being to enable customers to purchase parts or portions of steam engines, either in the rough casting or forging, or partly or wholly machined. There can be no doubt that this arrangement will prove a convenience to many of the users of Tangye engines, as well as to others who have the necessary machinery for turning out work of a special kind, but who have neither patterns nor tools of the kind required. The catalogue is well printed and illustrated, and contains detailed dimensions of a large number of engine parts, such as steam cylinders, pistons, crossheads, connecting rods, lubricators, excentrics, &c.

Steam Power at the Paris Exhibition, 1889.—Messrs. Davey, Paxman and Co., of Colchester, have been selected by the executive committee to supply the whole of the steam power required for driving the machinery in the British section of the Paris Exhibition. Their engines have also been selected for supplying a portion of the motive power in the French section of this exhibition. It will be remembered that Davey, Paxman and Co.'s engines and boilers were selected four years in succession for supplying the whole of the motive power required for driving the electric light machinery at the Great International Fisheries Exhibition, 1883; the International Health Exhibition, 1884; the International Inventions Exhibition, 1885; and the Colonial and Indian Exhibition, 1886; receiving on each occasion a gold medal and diploma of honour.

Forthcoming Books.—Amongst the new works which will shortly be issued by Messrs. Crosby, Lockwood and Son, are the following:—"The Mechanical Engineer's Office Book." By Nelson Foley. Second Edition, much enlarged.—"Turning," a Text-book on the Elementary Principles and Practice of Using the Lathe, with numerous Engravings and Diagrams. By P. N. Hasluck. Crown 8vo.—"The Number and Weight Calculator," showing in single tables the value at 421 different rates (from $\frac{1}{8}\frac{1}{4}$th of 1d. to 20s.) of any number of articles from 1 to 20,000, or any number of tons, cwts., qrs., and lbs. from 1 to 1,000 tons. By Wm. Chadwick. Second Edition. 8vo. Revised and specially adapted to the apportionment of mileage charges for railway traffic.—"Modern Workshop Practice." By J. G. Winton. A new edition. Carefully revised and much enlarged.

The Institution of Civil Engineers.—The Institution of Civil Engineers has issued the annual list of subjects on which Papers are specially invited during the Session 1888-89. The following are the subjects connected with electricity: The Generation of Alternating Currents in Dynamo Electric Machines, and their Utilisation for Lighting and Power Purposes; Electric Meters for Recording the Consumption of Electrical Energy; the Construction and Maintenance of Secondary Batteries; Central Station Electric Lighting; the Application of Electricity to the Working of Street Tramways, and of Railways; the Application of Electricity to the Working of Cranes, Pumps, Tools, &c.; the Application of Electricity to Smelting and Metallurgical Operations; the Application of Electricity to the Purification of Water and Sewage; the Purification of Copper and the Reduction of Copper Ores by Electrolytic Processes.

Obituary.—Herr Carl Dornfeld, electrical engineer attached to the German Commission to the Melbourne Centennial Exhibition, died on Saturday, August 18th, after an illness of only 26 hours' duration. The *Melbourne Age* says Herr Dornfeld's great intelligence and superior professional knowledge in the various branches of engineering work have been of excellent service in the management of the German machinery court, while his amiable character enabled him to make a host of friends during his short stay in the city. He had been for some years partner in a leading firm of electrical engineers at Cologne, and he was at one time superintendent of the famous steel works of Krupp in Essen. His visit to the colony, made primarily for the benefit of his health, was also as representative at the Exhibition of several important engineering firms. His untimely death, at the age of 43, has occasioned much regret among the German residents in Melbourne.

Electric Lighting in Denmark.—Although the electric light, writes our Copenhagen correspondent, has been very slow in finding favour in Denmark, compared with Germany, Sweden, and Norway, there are at present several rather large installations either in contemplation or already in course of erection. The contract for the large "National" establishment, comprising a theatre, restaurant, &c., has been secured by the representative of S. Schuckert, of Nürnberg, Mr. Ludvig Lund. The contract is for about 28 arc lamps and 250 incandescent lamps. The boilers of 60 horse-power will be supplied by the large Belgian firm of De Nayer. There is also some talk of the Theatre Royal being lighted by electricity, but nothing definite has transpired in connection with this. Some of the buildings of the army are also having electric light installed, and there seems altogether to be more inclination to move in the matter. The first attempt to light a Danish town by electricity has just been made; it is an exceedingly modest one, however, viz., the small town of Lyngby, close to Copenhagen, where incandescent lamps have been substituted for petroleum lamps.

North of England Mining Institute.—At a meeting of the members of the North of England Institute of Mining and Mechanical Engineers, held on Saturday in the Wood Memorial Hall, Newcastle, Mr. Oswald Swete exhibited an electric safety miner's lamp, made by the New Portable Electric Lamp and Power Syndicate Company, London. He briefly explained the

Digitized by Google

construction of the lamp, in which improvements had been made since it was shown to the members of the institute early this year. The weight of the lamp is 4½lb., its first cost about £1, and the cost of maintenance 3d. per week of six days per week, and running twelve hours per day; the 3d. includes the cost of repairs, interest on plant, depreciation of machinery, and renewals of incandescent lamps when necessary. A one-unit dynamo will charge 130 lamps. The light is protected by toughened glass, and if the glass should be broken a lever falls forward and puts out the light. The lamp has not any apparatus for detecting the presence of gas; but Mr. Swete stated that he hoped to succeed in getting such an apparatus. On the motion of Mr. G. B. Forster, seconded by Mr. Stevenson, a vote of thanks was passed to Mr. Swete.

Vestry of St. Margaret's and St. John's.—At a meeting of the St. Margaret's and St. John's Vestry (Westminster), last week, Mr. C. C. Piper presiding, the Parliamentary Committee submitted a report dealing with the lighting of the district by electricity. They recommended that the applications for licenses by the London Electric Supply Corporation, Limited, and the Metropolitan Electric Supply Company, Limited, be objected to on the grounds that the Vestry should retain the control of the lighting of the parish in its own hands; and, in view of the importance of the subject, have to ask the Vestry for an expression of opinion as to applying for a license empowering the Vestry to undertake the lighting of the parish. Mr. Thomas Horn moved the adoption of this, and, as a practical man, said that the electric lighting of districts up to the present time had been an utter failure. Mr. Henry Verity said that the opposing of such a grand improvement as this would lay them open to the charge that they were interested in the gas company. After a long discussion, the Vestry adopted the report and recommendation by a large majority. The committee, however, were requested to prepare a report as to the suggestion of the Vestry itself taking the necessary steps to supply electrical power for lighting.

St. James's Vestry.—At the last meeting of this Vestry the Lighting Committee, in answer to an application on behalf of the Metropolitan Electric Supply Company (Limited) for consent to apply to the Board of Trade for a license under the Electric Lighting Acts, recommended a reply to the effect that the Vestry was not prepared to assent to a license in the form submitted by them; but with a view to expedite the commencement of operations they would be disposed to consent to an application for a license in the form of the South Metropolitan Electric Lighting Order, 1888, which is awaiting confirmation by Parliament. Also that Messrs. Deacon, Gibson and Medcalf be informed, in reply to their application on behalf of the London Electric Supply Corporation (Limited) for consent to apply to the Board of Trade for a license under the Electric Lighting Acts, that the Vestry have already consented to the establishment of two electric-lighting installations in this parish, and that they are not prepared to assent to any further license or provisional order until these installations are either fully at work or have been abandoned.—This was adopted.—Mr. Pool thought two or three competing companies not at all bad, and objected to the streets being in an uproar with wires to be laid down underground.

Exports of Telegraph Wires.—The trade returns for September, as regards the exports of telegraph wire, &c., are again very disappointing. Our exports of iron and steel wire and manufactures thereof, except telegraphic wires, continue to expand, the total shipments from January 1 to September 30 this year having been £643,097, as against £450,761 in the same period of last year, and £417,632 in 1886. The reverse has been the case with telegraph wires, &c. The September shipments were the smallest of the year, and the total exports to date show a considerable shrinkage, which is especially noticeable in face of the appreciation in prices and the reports of an improvement in the electrical industries of the country. The following is the usual comparative table:—

Exports of Telegraph Wires and Apparatus connected therewith.

	1886.	1887.	1888.
First quarter	£124,074	£131,879	£88,077
Second „	354,331	56,933	156,136
Six months	£478,405	£188,812	£244,213
July	219,463	195,950	21,571
August	154,789	114,162	110,323
September	37,964	158,140	21,032
Nine months	£890,621	£657,064	£397,139

Paddington Vestry.—At a meeting of this Vestry on October 9th, the Electric Lighting Committee recommended "That they are of opinion that, after full consideration of the Electric Lighting Acts, and the rules thereunder, and having considered the report of Mr. Mackie, and the various notices and applications from electric lighting companies, the Vestry will be best studying the interests of the parishioners and inhabitants of Paddington by at once taking the necessary steps to apply this year for a provisional order or license. That the Vestry oppose the granting of all applications for provisional orders or licenses which may be made by any public companies, and that the solicitor be instructed accordingly."—Mr. Judge objected to this, and proposed that they should not yet apply for a provisional order, but ask the Board of Trade whether they would consent to dispense with any application for a license or provisional order during the present year, and in the meantime he would oppose all applications of companies, &c., pending the decision of the Vestry. He moved as an amendment that the whole question of electric lighting, together with the reply of the Board of Trade, be referred to the Electric Lighting Joint Committee for consideration and report.—Sir George Harris seconded this.—The amendment was put and was carried by 15 to 13.

Personal Experience of a Shock.—"Thinking some of the readers of the *Electrical World*," says Mr. T. D. Bottome, "might be interested in a personal experience of a shock by an intermittent current, I will give an account of one that occurred to me. On touching two terminals to close a circuit on some experimental apparatus, I thought, of course, I had grasped the insulation, but the bare end of a flexible wire managed to touch my right-hand fingers while I held the binding screw in the other hand. I was instantly thrown down and held perfectly rigid, unable to speak, it seemed to me, for two or three minutes, but probably twenty or thirty seconds would be nearer the actual truth. I felt unconsciousness coming on, when suddenly I became loosened, and I lay perfectly limp a moment or so. I got up, but was scarcely able to walk, the pains being greatest in the hips. However, I got a voltmeter, and found 140 volts on the circuit, and the alternations or intermittances were 150 per second, while I found my resistance, under the same conditions, to be 4,500 ohms. The wire that slipped out of my hand left a burn on my forefinger in the shape of an elliptical hole about $\frac{5}{32}$ inch deep, and scarred the flesh about the hole at a radius of ¼ inch. During the contact I felt difficulty in breathing, but five minutes afterwards my skin was all aglow, as if a bath brush and Turkish towel had been used vigorously, while the respiration became full and a trifle quickened. Two days afterwards I was all right, except a little soreness all over."

Electric Transmission of Energy in the Comstock Mines.—The *Mining Industry* (an American journal) says that the Brush Electric Light Company has shipped to the Nevada mill two dynamos and motors of an improved pattern, and it assures the Nevada mill people that it will be able to put upon the stamps 80 per cent. of the power generated at the bottom of the shaft. There are to be six dynamos, one always to be held in reserve, and six Pelton wheels 40 inches diameter, instead of one of 11 feet diameter, to be made of phosphor-bronze, to drive them, each attached to the dynamo shaft directly. As already explained, these wheels will be set up at the Sutro tunnel level of the Chollar mine, in a large chamber already prepared to receive them. A column of water brought down the side of Mount Davidson in a wrought-iron pipe will be delivered through a proper nozzle upon the surface Pelton, which stands in the mill, under a perpendicular pressure of about 460ft. This wheel is 10ft. 10in. in diameter. After the water leaves the wheel it is piped to the main shaft of the Chollar mine. Down this shaft (and the incline at its bottom) the water is conveyed in two pipes to the electric chamber on the Sutro tunnel level. The water will be put upon the wheels under a perpendicular pressure of 1,630ft. In no place in the world has water been used on a Pelton wheel under such a tremendous head. The water will be delivered upon each wheel through a nozzle somewhat less than half an inch in diameter. Each wheel is intended to develop about 125 horse-power. This will make a total of some 750 horse-power delivered by the six wheels. As this is the first attempt in the history of mechanics to operate water-wheels under such an enormous pressure (as well as the fact of the utilisation of the power by electrical transmission), the result of the experiment will everywhere be anxiously awaited.

Electrical Lifts for the Eiffel Tower.—Two lifts are suspended at the two ends of eight steel cables passing over a pulley, and move up and down in two cylindrical adjacent cages, being kept vertical by the aid of guides. Each lift is divided into three compartments, one over the other. The two upper compartments are designed to hold one hundred passengers; and the lower compartment contains a dynamo of 25 to 30 horse-power, to which the electricity is conveyed by a wire from generators on the ground. The dynamo gives a rotating motion to a truck connected axially with the bottom of the lift, which rolls, by means of four projecting wheels placed radially, along a helicoidal rail winding round the side of the cage. There are two of these helicoidal rails placed slightly further apart than the diameter of the wheels, so that the wheels roll on the top of the lower one when the lift is descending, and revolve on the bottom of the upper one during its ascent. The suspending cables are exactly counterpoised by similar cables, attached to the bottom of both trucks, and rolling round two pulleys below the base of the cages. It is assumed that in practice the utmost difference between the load of the two lifts will be fifty passengers, or a weight of $3\frac{1}{2}$ tons, whereas the resistance of the system to motion is calculated at 4 tons, so that the lifts will not be liable to move of themselves; and though the machines are furnished with a brake, the stopping of the dynamos will stop the lifts. The descending truck, revolving under the action of its dynamo, will draw down its lift, and draw up the other lift, which will be lightened by the action of the dynamo in the truck below it. For a speed of $1\frac{2}{3}$ foot per second, the power required when the lifts are equally loaded will be 27 horse-power; when the descending lift has the maximum excess of fifty passengers, it will be 5 horse-power, and in the reverse case, 48 horse-power. Under the ordinary conditions of traction there will always be a space between the lift and its revolving truck; but if the cable broke, the lift falling freely on the connecting axle would overtake the revolving truck, and thereby arrest its rotation and prevent any further movement, thus securing the safety of the lift in the event of a fracture. A telephone will place the two men working the lifts in communication, so that they can always work in concert. The lift is to take passengers from the second to the third floor of the tower, a vertical height of 492ft., without a stoppage, in about five minutes.

New Technical Schools at the People's Palace.—Another addition to the number of technical schools in the metropolis was made by the opening, on Friday evening last, of the new technical schools at the People's Palace, Mile End, which have been built and fitted at the expense of the Drapers' Company, at a cost of £20,000. The building, which has been erected at the side of the Queen's Hall, from which it is separated by a wide corridor, comprises, in the basement, the engine and boiler room, engineer's shop, pattern making and moulding shop, brickwork and masonry shop, and the electric laboratory. The ground floor is occupied by the lecture room, trustees' and school offices, mechanical drawing room, and two class rooms. On the first floor are the building construction drawing room, head master's room, teacher's room, and two class rooms. The second floor is occupied by the chemical laboratory and three class rooms, whilst above this is the photographic studio. The power for both the engineer's shop and the electrical laboratory is taken from a 6-horse nominal Tangye engine, with air pump and condenser, the engine being fitted with the Tangye-Johnston automatic expansion gearing. Steam is supplied from a Cornish boiler, tested to a pressure of 120lb. per square inch; the working pressure, however will not exceed about 40lb. In the engine room there are three forges, one being fitted with a Roots blower. The engineers' shop contains a screw-cutting lathe with 8-foot bed and 5-inch centre, a screw-cutting gap lathe, 5-foot bed 5-inch centre, a shaping machine, a small planing machine, eight lathes for general work, and twenty vices. A special lathe is also being laid down with 18-foot bed and 6-inch centre, fitted with four headstocks. The pattern-making and moulding shop contains four vices, two moulding troughs, and a lathe for wood turning. The electrical laboratory contains a Victoria dynamo, running at 1,500 revolutions per minute, specially designed for educational purposes, to give 3,000 watts (4 horse-power), self-regulating for constant electromotive force, and having a rotary drum commutator by which the fields can be arranged on the shunt, series, or compound system in various combinations; also provided with a separate search coil, connected to special collector rings and brushes. There are also a 2 horse-power electric motor, an alternator, and two Mordey transformers. The laboratory also contains a complete installation of arc and incandescent lamps and sets of testing apparatus, comprising a Wheatstone bridge, tangent, Thomson's reflecting and astatic galvanometers, &c. The course of instruction is arranged to extend over a period of two years, and will embrace the study of mathematics, mechanical and industrial drawing, science, with laboratory practice and handicraft work and the use of tools. Particular attention will be paid to giving students a thorough technical and practical knowledge of the nature of tools, of setting out working drawings, of the uses of chemistry in various trades, of electricity, and of the nature and use of steam. The engineering course will include drawing, pattern-making from drawings and to measurement, metal turning and lathe work, and the construction of models from drawings of the students' own execution.

REMARKS ON SOME OF OUR TELEPHONIC SYSTEMS.

BY J. MUNRO.

I have recently had an opportunity of seeing some of the Provincial as well as the Metropolitan systems of telephony, and it may be interesting if I give your readers an account of these, especially as there seems to be some misapprehension on the subject.

The centres I shall speak of are some of the most important in the country, namely, Manchester, Liverpool, Glasgow, Edinburgh, Dundee and London. I shall treat them in that order, taking first the overhead work, and, second, the exchanges in each place.

The overhead system of Manchester has recently undergone a change. In place of several small exchanges in different parts of the town, there is now one large central exchange situated in the Royal Exchange-buildings. No. 11 galvanised iron wire was formerly used, but No. 16 B.W.G. copper has been substituted both for trunk and subscribers' lines. These are supported chiefly on strong wooden standards by means of cross-arms. Shackles are employed for the over-house work; but these, I understand, are to be replaced by insulators. The trunk lines to Liverpool and elsewhere are single, the wire running on insulators supported by tall wooden poles. There is a good deal of "cross-talk" or "over-hearing" upon them, which, however, is somewhat reduced by cross-connections at the poles.

Several aerial cables are used in Manchester, especially as leads to clear away from the roof of the Exchange-buildings; but none of them are over half a mile in length. They are of different types, the more recent being Glover's "Anti-Induction" cable, and to diminish the "cross-talking" the metallic sheathing of the cable is connected to earth at intervals. The indoor leads are carefully boxed in on their way to the board.

The new switch room, opened this year, is a long, handsome apartment, well lighted from the roof. An older form of board has been replaced by a "multiple" switch-board of the small pattern, at present fitted for 1,600 subscribers, but capable of taking 4,200. There are now some 1,400 subscribers on the service. The practical advantage of the multiple board is that each operator has within reach the wire of every subscriber on the exchange, so that she (or he) can make the cross-connection which is required herself, without moving from her place, or asking any other operator in the exchange to assist. This convenience not only saves time, but prevents noise in the room. This new board is fitted with polarised "ring-off" indicators, forming "tap" connections to earth when any two subscribers are talking. This arrangement enables a subscriber to ring up his correspondent direct should a conversation be temporarily dropped, without calling the exchange. Moreover, when the conversation is quite finished, either of the two subscribers can notify the exchange of the fact. It is a question, however, whether this advantage is not counterbalanced by the tap connection to earth lowering the talk, especially on long lines. The company's electrician has introduced some improvements in the arrangement of the wires. The test-board admits of the tests being very readily made. The multiple board at New York is arranged in the form of the letter U; at Manchester like the letter L. A separate table, situated in front of the base of the L helps to work the trunk lines. Each local call for a trunk connection is transferred to the operator at this table, who makes out a ticket, stamped with the time, and hands it to an operator on the trunk-board immediately behind her. The latter thereupon completes the connection.

The subscribers' calls at Manchester are made with battery currents. In Liverpool the lines are constructed as at Manchester. Insulators are used, however, on the new line to Bootle, by the docks; and a Felten-Guilleaume cable runs through the Mersey Tunnel to Birkenhead.

In Liverpool the majority of the subscribers are concentrated in one central exchange in the Royal Exchange-buildings. The switch-board here is the first of the Western Electric multiple type fitted up in England; but it is to the credit of the United Telephone Company that prior to this they had introduced into their Chancery-lane Exchange another multiple switch-board on the same principle originally invented by one of their *employés*. The Western Electric Company subsequently claimed that their patents covered this board; but a friendly arrangement was made, and the board has continued in use till now, when it is being replaced by a new multiple of the latest pattern. The subscribers' calls at Liverpool are given with magneto currents; and the ringing currents are generated at the exchange by small magneto-electric machines, driven off a "Thirlmere" water motor by the pressure in the supply pipes.

The system in Glasgow has recently been so fully described in your columns by the company's engineer that I need only refer to it very briefly. The lines are of No. 18 B.W.G. bronze, carried by brown earthenware insulators, and supported on tubular standards of wrought iron by channel-iron cross-arms. At the Royal Exchange, where the central exchange is situated, several large standards are braced together, and carry several hundred wires. These bronze wires are said to give no trouble from the "singing" noise made at the poles. The trunk wires at Glasgow are of No. 14 B.W.G. copper; they are double, and run on white ware insulators, supported by creosoted wooden poles. They are worked with induction coils in the loops. A few cables are used to clear away from the roof of the Exchange—one being of the Paterson type, as supplied by the Western Electric Company. Besides the large central exchange there are several small ones in Glasgow. The central switch-board is of the ordinary multiple type and large pattern, but more modern in make than that of Liverpool. It comprises some 1,500 subscribers, but additional boards have been fitted in another room to take more subscribers eventually. The ringing and call system is the same as in Liverpool. Altogether the Glasgow system appears to be very well carried out.

In Edinburgh No. 18 B.W.G. bronze wires are also used. They are run on white insulators, supported on wooden standards. The trunks are double, crossed at intervals, and worked with induction coils. That to Glasgow is "crossed" for a part of the way and "twisted" for the remainder. There is no large central exchange in Edinburgh, the lines being distributed amongst five small exchanges, comprising in all about 600 subscribers. The largest is in George-street, and has about 150 subscribers. The switch-board is of a very old type.

In Dundee the wires are also of No. 18 B.W.G. bronze, and supported as in Edinburgh. There is one central exchange in the town, with smaller ones in the suburbs. Some 450 subscribers are connected on the central. The switching is performed by a modification of the Law system, each subscriber, besides his ordinary wire, having the means of calling the exchange on a special circuit wire common to 50 or 100 subscribers, at which an operator in the exchange is constantly listening for a call from any of the group. In the Law system the group of subscribers are joined in series on the common wire. In the Dundee modification each subscriber is connected to the common wire by a tap to earth. Each subscriber after being connected at the exchange rings up his correspondent direct, no ringing being done at the exchange. A subscriber can leave his telephone, discontinuing his conversation for a space, and return to it without any fear of the exchange meanwhile disconnecting him. When he has quite finished he can, by the special circuit wire, instruct the exchange operator to that effect. The ringing at Dundee is done by magneto-currents.

The board is of the old Bell type; the indicators not being used unless any of the special circuit wires, above described, are out of order. All the operators are continually listening at their telephones on the circuit wire for calls, and each is provided with a set of keys, enabling her to connect her own instrument with that of any other operator in the exchange. In this way cross-connections are effected between the various sections of the board without speaking *viva voce* across the room.

Subscribers in Dundee are connected by name, not by adopted numbers as in other towns. The custom has grown up since the beginning of the service, and has not yet been changed. It may be feasible in a comparatively small town like Dundee, but it would, evidently, be not merely wasteful of

Digitized by Google

time, but quite impracticable in London or other large cities. The switching system of Dundee, too, though apparently well adapted to the town, would be extremely difficult of application in a large city with several big exchanges.

At all the places mentioned the exchanges are kept open night and day. Public call-offices, where any person, whether a subscriber or not, can speak to a subscriber, have been introduced in all these towns. At Glasgow and Manchester automatic call-boxes, requiring no attendant, and serving the purpose of a public call-office, are also in use, there being about a hundred in operation. I am unable to speak personally as to their efficiency.

In the metropolis the conditions of working are very different from those in the provincial towns I have referred to. This remark applies not only to the overhead lines, but to the exchange system. To begin with, the work has to be carried out on a much vaster scale in London, which must be regarded as a congregation of cities. The difficulties of the overhead work are greatly enhanced by the irregularity of the streets and the rickety character of many of the roofs. The regular streets and solid buildings of Edinburgh and Glasgow, for example, offer facilities for running wires which the huddled rookeries, so common in London, with their broken-backed, red-tiled roofs and infirm brick chimneys do not afford. It is impossible to fix or stay a pole on many of these roofs; moreover, the difficulty of getting way-leaves is exceptionally great. At the principal exchanges large wrought-iron structures, called derricks, are erected, which are so made as to require no stays, and are capable of taking an enormous number of wires. Most of them are at present fitted to accommodate from 1,000 to 1,200 wires, and provision is made for the attachment of cross-bars to take at least as many more. They are built in stories, and admit of the easy manipulation of the wires from platforms inside. The single poles erected on housetops are of tubular wrought-iron, similar to those of Glasgow. This class of pole was first introduced for telephonic purposes, by the United Telephone Company, in the year 1880. Where they are used as junction poles—that is, for wires radiating in all directions, they are mostly without cross-arms; but where they form part of a line carrying a number of wires in one direction, they are provided with cross-arms. In many instances two of these tubular poles are erected side by side, and braced together by means of the cross-arms. All the ground poles are of wood. Whenever possible creosoted poles are used; but where, owing to their unsightliness, these are objected to, as, for instance, in private gardens, English larch is employed, and the poles are painted.

The wires in London are either iron or copper. I have seen it stated in a recent article that they are of No. 8 *steel*, but the blunder is so egregious that, though it did not stand alone, I presume it may have been an inadvertence. Where iron is used for overhouse work it is in the form of a strand, composed of three No. 16 B.W.G. galvanised iron wires twisted together. Where it is run on ground poles it is a single conductor of No. 11 gauge. Where copper is used for overhouse work it is a strand of three No. 18 B.W.G. wires twisted together, and where it is used on ground poles it is either single No. 17 or No. 14 B.W.G. The trunk line which is now being constructed by the United Telephone Company is of No. 12½ copper. Copper, in fact, is gradually superseding iron wire in London, the relative amounts at present being about equal. For overhouse work in London strand wire has almost always been employed, both by private companies and the Post Office, in consequence of its freedom from the "singing" which generally accompanies single wires, and which in the residential districts of London, as well as in the City, where many caretakers live, renders the use of single wire impracticable. When bronze wire was first introduced into England some years ago a considerable quantity of it was erected by the United Telephone Company in London; but it proved to be of such inferior manufacture that it had to be abandoned in favour of the more reliable iron and copper. Whilst insulators are used on ground poles, shackles are mostly employed for overhouse work, on account of their mechanical strength and, having regard to the enormous number of crowded streets which have to be crossed, their safety. Aerial cables of various types are much used in London wherever way-leave difficulties prevent large numbers of open wires being carried. Some of these cables are several miles in length, whilst the longest I am aware of in the provincial towns is only about half a mile.

With regard to what I may call the indoor work, there are a number of large local exchanges in London, each of which should be regarded as the central exchange of a separate town. Just as it would be impracticable to run all the subscribers' lines from the various outlying smaller towns around Manchester or Glasgow into the central exchanges in those cities, so it is impracticable to concentrate all the subscribers' lines from the various districts of London into any one central exchange; in fact, most of the London branch exchanges are, practically, central exchanges connected by trunk lines. The United Telephone Company have, however, for some years, been working in the direction of concentrating their lines, and several minor exchanges which formerly existed have been closed, the wires being carried to the nearest larger exchange, and arrangements are well advanced for merging several of these large exchanges into one.

To secure, however, as far as possible, the advantages of a single central exchange, each branch exchange is provided with trunk wires, not only to its neighbouring exchanges, but also to a common central trunk exchange, where, as the exigencies of the service require it, the branch exchanges are directly connected together. This is a special arrangement peculiar to the metropolis, and due to the conditions existing there. It minimises the number of trunk wires, and secures the maximum of use from each. In most cases the trunks between any two exchanges are divided into two distinct groups, one for the up, and the other for the down traffic—an arrangement which has been adopted in New York. Judging from a Paper read by Mr. Sherwood at the recent Telephone Convention in America, there are many other striking similarities between the New York system in general and that of London.

I may mention in passing that there are some 550 trunk wires in London, some of them being eight or ten miles long. There are some 8,000 miles of wire in the system altogether, of which from 1,200 to 1,300 miles are in cables. There are in all 4,900 subscribers on the exchanges, and from 1,300 to 1,400 private wires.

In seven of the principal London exchanges multiple boards are used, and at four others are in course of erection. Whereas the battery method of ringing was formerly employed, it is gradually being superseded by the magneto system, a process which necessarily takes some time in a system so extensive as that of London. At present about half the subscribers have been provided with the magneto. All private wires have the magneto only. At the exchanges small magneto-electric machines, driven by a Koerber hot-air motor, are also adopted.

At the provincial towns above mentioned lady operators are employed; in London most of the exchanges are worked by the same means, and one or two of them by youths.

There is a night service in London as in other towns, but here, owing to the custom of residing in the suburbs and deserting the "city" at night, it is found needless to keep all the exchanges open. The exchanges in the residential portion of the metropolis are always open; and any subscriber in the business part who desires it is connected at night by a trunk wire to one of these.

It was in London that the first public call-offices were opened, and there are now a large number in operation. Subscribers have the use of these free of charge, but non-subscribers pay a small fee.

In conclusion, I may remark that the work in the different towns referred to is highly creditable to the respective engineers concerned. It is not my intention to make a critical comparison of the different systems, more especially as it appears to me that the conditions under which the work has to be carried out are different in each place. On the whole there seems little to choose between the systems; each is apparently the outcome of the peculiar circumstances obtaining in the locality.

HERTZ'S RESEARCHES ON ELECTRICAL OSCILLATIONS.

BY G. W. DE TUNZELMANN, B.SC.

(*Continued from page 726.*)

Dr. Hertz's next Paper in order of publication in Wiedemann's *Annalen*, "On Some Induction Phenomena arising from Electrical Actions in Dielectrics" (Wiedemann's *Annalen*, Vol. XXXIV., p. 273), contains an account of some researches undertaken with a view of obtaining direct experimental confirmation of the assumption involved in the most suggestive theory of electrical actions, viz., that of Faraday and Maxwell, that the well-known electrostatic phenomena observed in dielectrics are accompanied by corresponding electro-dynamic actions. The method of observation consisted in placing a secondary conductor adjusted to unison, as regards electrical oscillations, with the primary, as near as possible to the former, and in such a relative position that the sparks in the primary produced no sparking in the secondary. As the equilibrium could be disturbed and sparking induced in the secondary by the approach of conductors, it formed a kind of induction balance; but the point of special interest in connection with it was that a similar effect was produced when the conductors were replaced by insulators, provided the latter were of comparatively large size. The observed rapidity of the oscillations induced in the dielectrics showed

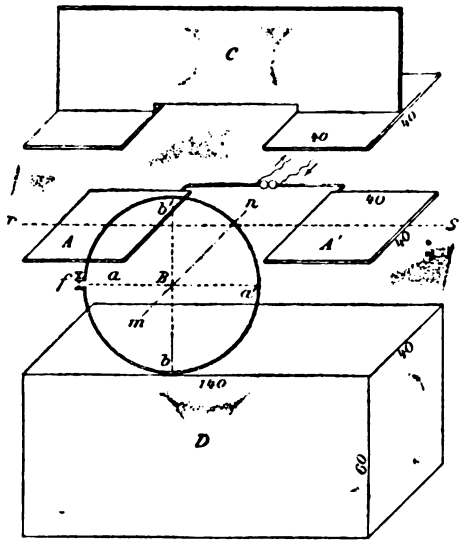

FIG. 10.

that the quantities of electricity in motion under the influence of dielectric polarisation were of the same order of magnitude as in the case of metallic conductors.

The apparatus employed is shown diagrammatically in Fig. 10, and was supported on a light wooden framework, not shown in the illustration. The primary conductor consisted of two brass plates, A A', with sides 40 centimetres in length, joined by a copper wire 70 centimetres long and half a centimetre in diameter, containing an air space of three-quarters of a centimetre, with terminals formed of polished brass spheres. When placed in connection with a powerful induction coil, oscillations are set up, the period of which, determined by the dimensions of the primary, can be determined to within a hundred millionth of a second. The secondary conductor consisted of a circle, 35 centimetres in radius, of copper wire two millimetres in diameter, containing an air space, the length of which could be varied by means of a screw from a few hundredths of a millimetre, up to several millimetres. The dimensions stated were such as to bring the two conductors into unison, and secondary sparks up to six or seven millimetres in length could be obtained.

The circle was movable about an axis through its centre perpendicular to its plane, to enable the position of the air space to be varied. The axis was fixed in the position *m n* in the plane of A and A', and halfway between them. The centre of the circle was at a distance of 12 centimetres from the nearest points of A and A'.

When *f* was in either of the positions *a* or *a'* lying in the plane of A A' no sparking occurred in the secondary, while maximum sparking took place at *b* and *b'* 90° from the former positions. The E.M.F. giving rise to the secondary sparks is, as in previous experiments, partly electrostatic and partly electromagnetic, and the former being the greater will determine the sign of the resultant E.M.F. The oscillations must, for the reason previously explained, be considered as produced in the part of the secondary most remote from the air space. Assuming the E.M.F. and the amplitude of the resulting oscillation to be positive when *f* is in the position *b'*, they will both be negative when *f* is at *b*.

When the circle was slightly lowered in its own plane the sparking distance was increased at *b'* and diminished at *b*, and the null points lay at a certain distance below *a* and *a'*. The electrostatic E.M.F. is scarcely affected by such a displacement, but the integral of the E.M.F. of induction taken round the circle is no longer zero, and therefore gives rise to an oscillation which will be of positive sign whatever be the position of *f*, for the direction of the resultant E.M.F. of induction is opposite to that of the electrostatic E.M.F. in the upper half of the circle, and coincides with it in the lower half where the electrostatic E.M.F. has been assumed to be positive. Since the new oscillation so produced is in the same phase as the previously existing one their amplitudes must be added to give the resultant amplitude, which explains the phenomena.

Effects of the Approach of Conductors.—In making these observations it was found necessary to remove all conductors to a considerable distance from the apparatus, in order to obtain a complete disappearance of sparking at the points *a* and *a'*. Even the neighbourhood of the observer was sufficient to set up sparking when the air space *f* was in either of these positions, and the sparks had therefore to be observed from a distance. The conductors used for the experiments was of the form shown at C (Fig. 10), and consisted of thin metal foil. The objects kept in view in selecting the material and dimensions were to obtain a conductor which would give a moderately large effect, and having an oscillation period less than that of the primary.

When the conductor C was brought near to A A', it was found that the sparking distance decreased at *b* and increased at *b'*, and the null points were displaced upwards—that is, in the direction of C.

From the results of experiments already described it is evident that the effect of displacing A A' upwards would be the same, qualitatively, as that of a current in the same direction as that in A A' directly above it. The effect produced by the approach of C was the reverse of this, and could be explained by an inductive action, supposing there were a current in C in the opposite direction to that in A A', which is exactly what must occur; for the electrostatic E.M.F. would give rise to such a current, and since the oscillations in C are more rapid than those of this E.M.F., the current must be in the same phase as the inducing E.M.F. The truth of this explanation was confirmed by the following experiments. The horizontal plates of the conductor C being left in the same position as before, the vertical plate was removed, and successively replaced by wires of increasing length and fineness, in order to lengthen the oscillation period of C. The effect of this was to displace the null points more and more in an upward direction, while at the same time they became less sharply defined, a minimum sparking taking the place of the previous absolute disappearance. The sparking distance at the highest point had previously been much less than at the lowest point, but after the disappearance of the null points it began to increase. At a certain stage the sparking distance at the two positions became equal, and then no definite minimum points could be found, but sparking took place freely at all positions of *f*. Beyond this stage the sparking distance at the lowest point diminished, and very soon two minimum points made their appearance close to it, not clearly defined at first, but gradually becoming more distinct, and at the same time

Digitized by Google

approaching the points $a\,a'$, with which they ultimately coincided, when the minimum points again became absolute null points. These results are in agreement with the conclusion drawn from the former observations, for as the oscillation period of C approaches that of A A', the intensity of the current in the former increases, but a difference of phase arises between it and the exciting E.M.F. When the two are in unison the current in C attains its maximum, and, as in other cases of resonance, the difference of phase gives rise to a slightly damped oscillation, having a period of about a quarter that of the original one, which makes any interference between the oscillations excited in the circle B by A A' and C respectively impossible. These conditions clearly correspond to the stage at which the sparking distances at b and b' were equal. When the oscillation period of C becomes decidedly greater than that of A A', the amplitude of the oscillation in the former will again diminish, so that the difference in phase between it and the exciting E.M.F. will approach half of the original period. The current in C will therefore always be in the same direction as that in A A', so that interference between the two oscillations excited in B will again become possible, and the effect of C will then be opposite to its original effect. When the conductor C was made to approach A A' the sparks in B became much smaller, which is explained by the fact that its effect will be to increase the oscillation period of A A', and therefore to throw it out of unison with B.

Effects of the Approach of Dielectrics.—A very rough estimate shows that when a dielectric of large mass is brought near to the apparatus, the quantities of electricity set in motion by dielectric polarisation are at least as large as in metallic wires or thin rods. If, therefore, the action of the apparatus were unaffected by the approach of such masses it would show that, in contradiction to the theories of Faraday and Maxwell, no electro-dynamic actions are called into play by means of dielectric polarisation, or, as Maxwell calls it, electric displacement. The experiments, however, showed an effect similar to that which would be produced if the dielectric were replaced by a conductor with a very small oscillation period. In the first experiment made, the mass of dielectric consisted of a pile of books, 1·5 metre long, 0·5 metre broad, and 1 metre high, placed under the plates A A'. Its effect was to displace the null points through about 10° towards the pile. A block of asphalt (D, in Fig. 10), weighing 800 kilogrammes, and measuring 1·4 metre in length, 0·4 metre in breadth, and 0·6 metre in height, was then used in place of the books, the plates being allowed to rest upon it.

The following results were then obtained :—

(1.) The spark at the highest point of the circle was now decidedly stronger than that at the lowest point, which was nearer to the asphalt.

(2.) The null points were displaced through about 23° downwards—that is, in the direction of the block—and at the same time were transformed into mere points of minimum sparking, a complete disappearance being no longer obtainable.

(3.) When the plates A A' rested on the asphalt block the oscillation period of the primary was increased, as shown by the fact that the period of B had to be slightly increased in order to obtain the maximum sparking distance.

(4.) When the apparatus was moved gradually away from the block its action steadily diminished without changing its character.

(5.) The action of the block could be compensated by bringing the conductor C over the plates A A', while they rested on the block, the null points being brought back to a and a' when C was at a height of 11 centimetres above the plates. When the upper surface of the asphalt was 5 centimetres below the plates compensation was obtained when C was placed at a height of 17 centimetres above them, showing that the action of the dielectric was of the order of magnitude which had been anticipated.

The asphalte contained about 5 per cent. of aluminium and iron compounds, 40 per cent. of calcium compounds, and 17 per cent. of quartz sand. In order to make sure that the observed effects were not due to the conductivity of some of these substances, a number of further experiments were made.

In the first place the asphalte was replaced by a mass of the same dimensions of the so-called artificial pitch prepared from coal, and effects of a similar kind were observed, but slightly weaker, the greatest displacement of the null points amounting to 19°. Unfortunately this pitch contains free carbon, the amount of which it is difficult to determine, and this would have some conductivity.

The experiments were then repeated with a conductor, C, of half the linear dimensions of the former one, and smaller blocks of various substances, on account of the great cost of obtaining large blocks of pure materials. The substances used were asphalt, coal-pitch, paper, wood, sandstone, sulphur, paraffin, and also a fluid dielectric, namely petroleum. With the smaller apparatus it was not possible to obtain quantitative results of the same accuracy as before, but the effects were of an exactly similar character, and left little room for doubt of the reality of the action of the dielectric.

The results might possibly be supposed to be due to a change in the distribution of the electrostatic E.M.F. in the neighbourhood of the dielectric, but in the first place Dr. Hertz states that he has been unable to explain the details of the observations on this hypothesis, and in the second place it is disproved by the following experiment :—

The smaller apparatus was placed with the line $r\,s$ on the upper near corner of one of the large blocks, in which position the dielectric was bounded by the plane of the plates A A' and the perpendicular plane through $r\,s$, both of which are equipotential surfaces, so that if the action were electrostatic no effect should be produced by the dielectric. It was found, however, to produce the same effect as in other positions. It might also be supposed that the effects were due to a slight conductivity, but this could hardly be the case with such good insulators as sulphur and paraffin. Suppose, moreover, that the conductivity of the dielectric is sufficient to discharge the plate A in the ten-thousandth of a second, but not much more rapidly. Then, during one oscillation, the plates would lose only the ten-thousandth part of their charge, and the conduction current in the substance experimented on would not exceed the ten-thousandth part of the primary current in A A', so that the effect would be quite insensible.

(To be continued.)

REVIEWS.

Traite Elementaire de l'Accumulateur Voltaique. By EMILE REYNIER. (Paris : Baudry and Co., 1888).

Taken as a whole this book may be pronounced to be well worth the attention of all who are interested in the construction or the management of accumulators. The work is divided into four parts, dealing respectively with elementary principles, a description of various types of cells, technological data, and practical applications. In each section much useful matter is to be found, but in the author's desire to serve the *l'intérêt superieur de la vérité* by discriminating between real inventions and mere adaptations, some curious omissions result. Of course, a book written by a Frenchman for Frenchmen is necessarily French ; and it is no matter for surprise that the principal part is occupied with Gallic inventions. But, judging from the rate at which accumulators are being made both in England and Belgium, it seems strange that only a few pages should be given to the "foreign" manufacturer. We are disposed to attribute this to the patriotism of the author.

Chapter IV. contains sketches of some plates perhaps not generally known in England to the ordinary electrician, though most of them have been tried in approximately the same form by more than one manufacturer in this country. The Faure-Sellon-Volckmar type is briefly discussed, and some comparative tables are given, showing weights, outputs, &c., for lighting and traction cells. The use of oxygenated water with the electrolyte, according to the author, gives an increased rate of discharge, a higher voltage, and a greater capacity. Non-oxidisable sulphates are also mentioned as possessing the same virtue. But, unfortunately, we are told that this increase of activity results in damage to the plate, as ordinarily made.

Digitized by Google

This matter is now being treated experimentally by M. C. Philippart.

Chapter VI. briefly discusses the best known couples, and will be found very instructive from the historical point of view. A careful study of this chapter may save a good deal of useless experimenting.

M. Reynier has himself invented a plate which seems to have some novelty of design. The plate consists of a fluted sheet of lead, with the active material laid in the grooves, and held tight by the subsequent expansion of the plate. The whole is surrounded by a strong casting of lead, which makes metallic connection with the conducting part of the plate proper. This framing is sufficiently strong to resist to some extent the tendency to lateral expansion, and the active material is said to make close contact with the conducting part, and thus give a larger useful effect. This may be so; but we should like to know whether buckling is also prevented.

The application of accumulators to tractive purposes is fairly discussed, and the difficulties of weight, &c., are by no means glossed over. The losses to be expected in batteries, motor, and gearing are fairly estimated, and agree well with figures obtained in this country.

The difference between applying accumulators to traction purposes on land and to the propulsion of boats is very clearly put, much to the advantage of the former.

We extract the following tabular summary :—

Comparison of Electric Traction with Electric Navigation.

Electric Tramcar.	Electric Launch.
Torque is independent of speed.	Torque is proportional *to square of speed.*
The power exerted is proportional to speed.	The power exerted is proportional *to cube of speed.*
For a given distance run work done is theoretically independent of speed.	For a given distance run work done is proportional *to square of speed.*

The use of accumulators for electric lighting, telegraphy, &c., is also briefly touched. As we anticipated, the secondary battery is mentioned as a regulator for lighting circuits. In this country we rely on more efficient and less expensive types of regulators. The author claims, however, to have designed for this purpose a cheap cell, having a high rate of discharge with small capacity. He installed in March, 1877, at the Hotel de Ville, Paris, eleven tons of lead and 4,500 litres of electrolyte for this purpose. This enormous battery is of the Planté type, and is capable of working at the rate of 100 horse-power. This is probably the largest battery in daily use yet brought into existence.

Electric Lighting; its Present Position and Future Prospects. By Hammond and Co. (London: Whitehead, Morris and Lowe).

This little pamphlet contains, within less than 100 pages, concise explanation of practically everything which those who are interested in electric lighting from a consumer's point of view are likely to wish to understand. It is well written and well printed, and we have no doubt that its circulation will tend to the promotion of an intelligent interest in the electric light. We may add that although the authors are well-known exponents of a particular system of electrical distribution, yet they have taken evident pains to present a fair and impartial account of all the practicable methods of central station distribution now in use.

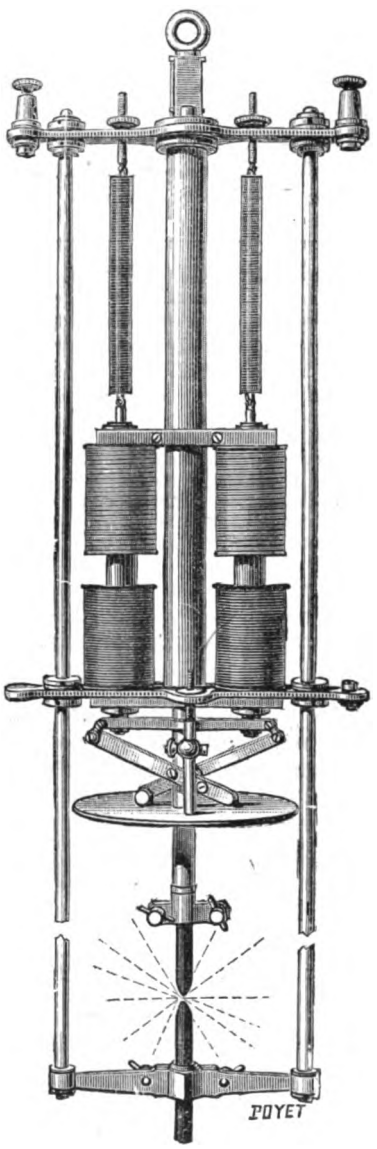
THE GERARD ARC LAMP.*

We illustrate below one of the latest forms of arc lamps devised by M. Anatole Gérard. The most striking part of the mechanism is the brake, which consists of two arms crossed in the shape of an X, and carrying two steel gudgeons, which press against the upper carbon-holder. These arms are connected by two small cranks to a cross piece placed underneath a double solenoid, joined in parallel with the main circuit. The soft-iron cores of the solenoids rest on this cross piece, their other ends being attached to two strong springs. When the circuit is closed the carbons are apart, and the whole of the current passes through the shunt; the solenoids attract the armatures, lowering the X shaped brake, which presses its arms upon the plate beneath, and unlocks the upper carbon-holder;



The Gerard Arc Lamp.

the latter consequently descends and brings the two rods into contact. But at this moment the current in the shunt decreases, the springs act upon the cores, lifting them up, and causing the brake to clutch the upper carbon-holder, and lift it also; the carbons are thus separated, and the arc is struck. When the consumption of the carbons causes the arc to lengthen unduly, the current in the shunt again predominates, and allows the upper carbon to feed down slightly. The central tube is an air-tight cylinder, the piston of which forms part of the upper carbon-holder. When the carbon-holder descends a partial vacuum is formed in the cylinder, and prevents irregular feeding. An external screw allows the admission of air into the cylinder to be regulated to a nicety.

All Communications to be addressed to "THE ELECTRICIAN," 1, Salisbury-court, Fleet-street, London, E.C. Cheques and Money Orders should be made payable to "THE ELECTRICIAN."

All letters intended for insertion in "THE ELECTRICIAN," or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.

"THE ELECTRICIAN" is published every Friday morning, in time for the morning mails. Subscribers should receive their copies by the first post on Friday morning.

"THE ELECTRICIAN" is on sale at the railway bookstalls throughout the United Kingdom on Friday morning, and can be obtained at all Booksellers and Newsvendors; or direct from the office as above.

SPECIAL NOTICE.

Owing to the increase in the number of pages of "THE ELECTRICIAN," in order to partly cover the increased postage, we have been compelled to revise the rates for Foreign Subscriptions, which are now as follows:—

	3 months.	6 months.	12 months.
For Foreign Parts and Colonies:—	s. d.	s. d.	s. d.
Within Postal Union	6 6	... 12 6	... 24 0
,, Aden, Borneo, Ceylon, China, India, Japan, Java, Labuan, Mozambique, New Caledonia, Persia, Philippine Islands, Siam, Transvaal, and Zanzibar	7 6	... 14 6	... 28 0
The rates for the United Kingdom remain as follows:—	5 0	... 10 0	... 19 6

TO ADVERTISERS.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers.* **It has the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application to this office.

TRADE ADVERTISEMENTS *intended for the current issue must be handed in not later than First Post on Thursday morning.*

SMALL PREPAID ADVERTISEMENTS *(for Rates see page XI.) are accepted up to 4 p.m. on Thursday.*

TECHNICAL PRINTING.

"THE ELECTRICIAN" PRINTING AND PUBLISHING COMPANY (LIMITED) *beg to inform Electricians and Electric Light Engineers that they make a specialty of Technical Printing, and have a Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electrical Catalogues and Electro-Technical Literature generally.*

The Electricians' Directory.

Royal 8vo. Cloth Boards, 3s. 6d. Boards, 3s.

At the end of December in each year is issued THE ELECTRICIANS' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and has now attained considerable proportions. Every care is taken to make the names and addresses of all persons engaged in the Electrical Industries absolutely accurate. Useful Tables and Electrical Formulæ are given, together with popularly-written Biographical Notices of the leading Electricians, accompanied in many cases by Portraits.*

THE DIRECTORY FOR 1889 IS IN PREPARATION

ANSWER TO CORRESPONDENT.

A. T.—*In answer to your inquiry as to "what clubs there are in London of which the members are chiefly persons interested in electrical engineering and engineering generally," it must be confessed that the only club which at all answers to this description is the "Whitehall Club," in Parliament-street, but the number of electrical members is not great. The "Dynamicables" are only a dining club, meeting at somewhat irregular intervals. Mr. F. H. Webb, jun., 4, The Sanctuary, Westminster, is the Secretary. The formation of an electrical club has frequently been the subject of discussion, but the difficulties in the way are of a serious character.*

THE AUSTRALASIAN CABLES.

There is generally something of interest to be heard at a meeting of shareholders presided over by Sir JOHN PENDER; and the meeting of the Eastern Extension, Australasia and China Telegraph Company (Limited), of which a full report appeared in our columns last week, was no exception to the rule. That the Company's receipts should show an increase during the half-year of over £20,000, while affording matter for gratification to the shareholders, is interesting to the general public as indicating an improvement in trade generally, of the state of which the telegraph is admitted to be a reliable barometer. Some degree of influence must, perhaps, be allowed to the fact that an important exhibition is now open at Melbourne; but, on the other hand, it may be confidently believed that, as a result of the exhibition, some permanent extension of commerce will ensue.

Digitized by Google

In these days of rapid communication a considerable amount of inconvenience and loss is caused to commercial communities when they are cut off from electrical connection with the rest of the world; and a feeling of profound uneasiness seems to seize upon our distant dependencies when, by any accident, the electrical bond uniting them with the mother country is severed. The record of the Eastern Extension Company is, however, remarkably good in this respect. Since direct telegraphic communication with Australia was established in 1872, until 1880, when the duplicate cable was laid, we learn that the total interruptions averaged seven days per annum, while the average of interruption since the duplication has been less than four days a year.

An interruption occurred on 30th June last, when both the Java-Australia sections were broken simultaneously in deep water by volcanic action, of the violence of which some indication is afforded us when we are told that on picking up the cables roots of trees and other things not usually found at the bottom of the ocean were attached to them. As the effect of this rupture was to isolate the Australasian Colonies telegraphically, the company, recognising that this method of communication should, above everything, be reliable, and in order to have three strings to their bow, promptly gave orders for a new cable to be manufactured and laid from Java to Western Australia, thus not only avoiding the volcanic region which proved fatal to the other cables, but also affording an alternate land system to the existing South Australian overland line. This cable, which we are told will shortly be laid, besides giving satisfaction to the telegraphing public, has, it appears, checkmated the opposition, which threatened to lay a line from India to Western Australia.

Communication having been restored by the repair of the interrupted lines, it was further interrupted between Banjoewangie and the Lombok Strait, where extensive renewals were being carried out by the company's ss. "Sherard Osborn," on the very day that the shareholders' meeting took place, again depriving Australia of the use of the submarine telegraph. Naturally enough these interruptions have from time to time provoked a good deal of discussion in the Colonies, and occasioned some rather wild talking as to the security to be afforded by a cable from San Francisco to Australia and the advantage to be derived from a competition in the rates.

It is frequently the case that those least entitled to complain make the loudest outcry, and this seems to apply to Governments as well as to individuals. Most of the Australasian Colonies contribute a proportion of the subsidy which is paid to the telegraph company for laying the duplicate cable. Queensland, we understand, is the principal exception, and this Colony is at the same time the strongest advocate of a competing line. It is, of course, quite easy to understand how the idea of completing the girdle of the earth and of uniting Australia eastward with Canada should exercise at first sight a certain fascination over many minds; but the question is not, however, in the last resort one of sentiment, but of simple hard matter-of-fact commercial speculation.

Now it has several times been authoritatively pointed out that a Pacific cable, consisting, as it would, of "long stretches of single cable across enormous and unsurveyed depths, terminating in coral reefs," would be of slight value as an alternative route; its existence would always be of a precarious character, and the expense of keeping a sufficiently large repairing fleet in the Pacific Ocean would be enormous, while, again, the large amount of capital required, and the war of rates which could not fail to follow, would make it difficult for either company to maintain their lines efficiently. The inevitable result in the end would be either that one company would buy up the other, or that an arrangement would be come to. In either case the capital, upon which a dividend would have to be paid, being largely increased, high rates would consequently have to be maintained.

If the Colonies wish for low rates the proposition of the Eastern Extension Company seems to us to be fair and reasonable. In effect they say to the Colonies: "You tell us you require low telegraphic rates to develop your resources and your business, and that our traffic would largely increase if the tariffs were reduced. As, however, we are not getting more than a fair return upon our outlay, and the low rates will be for your benefit, the greater part of the risk should also be yours. If you, the Australian Colonies, jointly guarantee us three-fourths of our present revenue, you may reduce the tariff to 4s. per word, or even lower if you please. You would in this way, at a minimum of risk, secure the undoubted advantage of cheap rates."

Up to the present, however, this evidently reasonable proposal has met with no acceptance in the Colonies concerned, where there appears to be a section which considers it preferable to advocate an opposition line which will cost it nothing, in the hope that those who have sunk their money at the bottom of the sea, in order to provide Australia with the magnificent system of submarine telegraphy which she enjoys, should have their profits reduced or altogether destroyed. The spirit of the closing words of the Chairman's address to the Company's shareholders ought to meet with a more generous response in Australasia, and one which we believe would better serve the interests of our Antipodean friends than a costly and uncertain alternate communication *vid* the Pacific. "Occupying the position we do," said Sir JOHN PENDER, on the occasion referred to, "we must not assume the position of monopolists, but must conduct our business on such broad and liberal principles as will satisfy you with the dividends and the general telegraphing public with a cheap, efficient, secure and expeditious system of telegraphy."

OBITUARY.

G. CABANELLAS.

We regret to learn that M. Cabanellas, whose labours in connection with dynamo-electric machinery have brought his name a good deal before the scientific world, died a few days since from inflammation of the lungs. M. Cabanellas began life in the French navy, and rose to the rank of captain. In the war of 1870-71 he greatly distinguished himself while acting as aide-de-camp to Admiral Saisset. On his retirement from the service M. Cabanellas devoted himself entirely to scientific research, and especially to electricity. His works on the theory of the dynamo and on transmission of power, although somewhat abstruse and of comparatively little practical value, yet show considerable penetration and knowledge of detail. Many ideas which are now common property were ten years ago only to be found in M. Cabanellas's works. The name of M. Cabanellas will also be associated with the electric transmission of power to a distance, in which matter he came somewhat into conflict with M. Marcel Deprez—not altogether to the advantage of the latter. For the last few months he appears to have given up his favourite studies and retired to Dieppe, where he held a post under the Government. M. Cabanellas was an officer of the Legion of Honour and a member of the *Institut.*

ON THE TRANSFERENCE OF ELECTRICITY WITHIN A HOMOGENEOUS SOLID CONDUCTOR.*

BY SIR WILLIAM THOMSON.

Adopting the notation and formulæ of my previous Paper, and taking ρ to denote 4π times the electric density at time t, and place (x, y, z), we have

$$\rho = \nabla^2 \psi = -\text{“}v\text{”}^2 \int \left(\frac{du}{dx} + \frac{dv}{dy} + \frac{dw}{dz} \right) dt \quad . \quad (17)$$

and, eliminating u, v, w, ψ by this and (16) from (10), we find, on the assumption of κ constant,

$$\kappa \frac{d}{dt} \nabla^2 \rho = \frac{d^2\rho}{dt^2} - \text{“}v\text{”}^2 \nabla^2 \rho \quad . \quad . \quad . \quad . \quad (18)$$

The settlement of boundary conditions, when a finite piece of solid conductor, involves consideration of u, v, w, and for it, therefore, equations (17) and (12) must be taken into account; but when the subject is an infinite homogeneous solid, which, for simplicity, we now suppose it to be, (18) suffices. It is interesting and helpful to remark that this agrees with the equation for the density of a viscous elastic fluid, found from Stokes's equations for sound in air with viscosity taken into account; and that the values of u, v, w, given by (17) and (10), when ρ has been determined, agree with the velocity components of the elastic fluid if the simple and natural-enough supposition be made that viscous resistance acts only against change of shape, and not against change of volume without change of shape.

For a type-solution assume

$$\rho = A E^{-qt} \cos \frac{2\pi x}{a} \cos \frac{2\pi y}{b} \cos \frac{2\pi z}{c} \quad . \quad (19)$$

and we find, by substitution in (18)

$$q^2 - \frac{\kappa}{L^2} q + \frac{\text{“}v\text{”}^2}{L^2} = 0. \quad . \quad . \quad . \quad . \quad (20)$$

where

$$L^2 = 1 \Big| 4\pi^2 \left(\frac{1}{a^2} + \frac{1}{b^2} + \frac{1}{c^2} \right) \quad . \quad . \quad (21)$$

Hence, by solution of the quadratic (20) for q

$$q = \tfrac{1}{2} \frac{\kappa}{L^2} \left\{ 1 \pm \sqrt{\left(1 - \frac{4 \text{“}v\text{”}^2 L^2}{\kappa^2} \right)} \right\} \quad . \quad . \quad (22)$$

[In the communication to the section numerical illustrations of non-oscillatory and of oscillatory discharge were given.]

MULTIPOLAR MACHINES AND THE DESROZIERS DYNAMO.†

BY M. E. DESROZIERS.

In the present state of our knowledge, Faraday's disc is the prototype of the ideal dynamo. A thin armature without iron, A B (Fig. 1), revolving round an axis O O, between the poles of the magnets C D. One can see at a glance that a machine of this kind possesses several important advantages: 1st. The reaction of the armature is small. 2nd. The armature being light and well balanced, high speeds are permissible. 3rd. The ventilation of the armature is excellent. 4th. Foucault currents are done away with. Numerous attempts have naturally been made to realise all these manifest advantages in actual practice, and it was whilst studying this question that I designed the dynamo which I am about to describe.

It is easy to see that a machine of the Faraday disc type lends itself preferably to multipolar construction. There are two forms of winding suitable to multipolar dynamos: first, that of the Gramme pattern, and, secondly, that in which the coils follow the sides of a star-shaped polygon. The simple regular polygon winding presents several inconveniences in the case of multipolar machines, not least of which is the constructive complexity. From a geometrical point of view, for a given machine and a given uniformity of current, the number of non-synchronous, non-identical coils is practically given *a priori*. The number of collector bars is also in some degree a fixed quantity. But with the simple regular polygon winding it is necessary that there should be at any moment as many groups of coils symmetrically situated and acting synchronously as there are magnetic fields. Consequently, the number of coils is proportional, not only, as in the case of two-pole machines, to the number of commutator sections which are necessary to secure a current of a certain degree of steadiness, but to the product of this number multipled by the number of magnetic fields. This fact introduces, therefore, a grievous complication. Another defect of the simple regular polygon winding is the necessity for placing the different synchronous coils in parallel. In a two-pole machine, owing to the continuity of the magnetic field and the approximate symmetry obtained by the placing of so many coils in series, the equilibrium of the two halves of the armature is an easy matter. But in multipolar machines, especially in those of the Faraday disc type, these conditions no longer hold to the same degree. Owing to the inevitable structural differences, the magnetic fields will be neither symmetrical nor equal, even for identical exciting power; the air-gaps will not be identical; the magnetic circuits will not be identical. Hence the various groups of coils will not be in equilibrium, and as the self-induction of this type of machine is but small, important disturbances will result. True, we can connect identical coils in series in lieu of placing them in parallel, but that does not mend matters much.

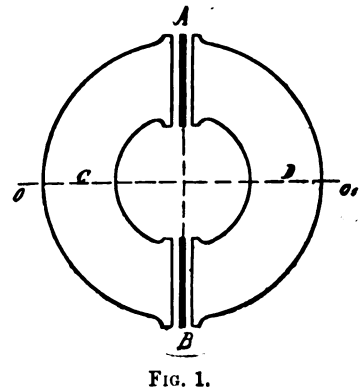

FIG. 1.

The star-shaped polygon winding, on the other hand, assures the independence of each successive group of coils, which need no longer be arranged symmetrically around the circumference. If we follow the winding shown in Fig. 2, we see that the apexes of each triangle advance one division in each similar magnetic field. Hence the coils corresponding to these apexes do not cut the same number of lines of force and will therefore produce different E.M.F's. We are, therefore, no longer obliged to have equal, symmetrical, and synchronously-acting coils. Secondly, as these coils are naturally connected up in series, the magnetic fields need not be symmetrical or identical. These obvious advantages of the star-shaped polygon winding attracted my attention. On studying Fig. 2, however, one is struck by the complex nature of the arrangement, a complexity which practical necessities would add to. This complexity is, fortunately, more apparent than real, and I shall show that it can be avoided by using a certain class of star-shaped polygon, by winding the coils in involutes and radial prejections, and by the rational grouping of the coils in two equal and distinct series.

Let us now consider the class of star-shaped polygon, the number of whose sides is given by the formula $n\,P \pm 1$; where n = number of magnetic fields and P = a certain parameter, which will evidently always be prime with regard to $n\,P \pm 1$. For instance, let $n = 3$ and let $P = 11$; then $n\,P - 1 = 32$. If we join 1 to 12 to 23, and so on, as below,

we get the arrangement shown in Fig. 4. The chords 1 – 12, &c., are however broken up (Fig. 3) into the zigzags R*c d h t*, &c., one such zigzag representing a complete element or section of the armature, and in the case of six-pole machines (to which what follows more especially refers) three of these sections complete the circumference. These three sections make one loop, and it is easy to see that in a certain position they embrace the three positions where the number of positive lines is a maximum; while at a distance of 60° from this they embrace the maximum number of negative lines. Commutation must naturally take place at these points, the neutral lines in disc machines corresponding to the polar lines. However, as the three sections are never exactly symmetrically situated with respect to the poles, being each one division ahead of one another, simultaneous commutation is, as we shall presently see, avoided. In performing the winding of one of these sections, we cross the circle twice —that is to say, the number of radial lines will be either 2 (n P ± 1) or 4 ($n p \pm 1$), according to the number of poles, p and P being arbitrary. It is, however, easy to multiply these radial lines by multiplying the sections. For instance, on reaching *t* (12), instead of going on to 18 we can effect a certain number of backward turns, as shown in Fig. 4, where the sections are trebled. If m denote this multiplying factor, the number of radial lines will be 2 m (n P ± 1) or 4 m ($n p \pm 1$). With a given speed and strength of field, by varying m and p, we possess every facility for obtaining any required E.M.F., whilst satisfying the condition of having a sufficient number of separate sections.

As there are two layers of conductors, they must necessarily cut one another; it is easy to see, however, that they can be arranged in two different planes, it being only necessary that the number of sections in each should be equal. In fact, if we look at Fig. 3, we see that the windings, which begin at an odd number, as 1—7—12, follow on quite naturally, so that they can all be arranged on a single disc. This disc is pierced by holes through which the wires are passed. The same applies to the sections, starting from even numbers, which are wound on a second and identical disc. Then these discs are placed side by side, the ends of the sections are soldered together, and the armature is complete. The two centre portions of the discs are cut away for the sake of lightness, and to give sufficient mechanical strength the two discs are bolted together at the rims and keyed to a German-silver hub with six projecting arms.

This winding, which characterises the Desroziers dynamo, is shown in Figs. 4 and 5 arranged for an armature divided into 52 divisions. By this arrangement the space between the poles is fully utilised; each section has a well-defined position, and an armature so constructed affords every facility for repairs and for inspection whilst at work.

Let us now consider the collector, which forms one of the most distinctive features of the machine. If the ends of each coil were joined to a collector bar, we should have 32 bars, and in a complete revolution there would take place under each brush 32 short circuits of each triple coil. We should therefore have $\frac{2 \times 3}{n p \pm 1}$ of the armature short-circuited each time, so that to obtain continuity of E.M.F. it would be necessary to increase either p or the number of coils. By a modification of the collector and its connections, I have avoided an increase in the number of coils. I connect each triple coil, not to a single bar, but to three, 120° apart in the case of a six-pole machine. The brushes, in lieu of uniting the ends of a triple coil, only unite the ends of a single coil, and each single coil is short-circuited n ($n p \pm 1$) times under each brush at every revolution. This method of connecting up will be understood on examining Fig. 6, where 14 coils are shown connected up. In this figure I have distinguished the two discs which together form the complete armature; the wires of the upper half are shown in full; and dotted as they would appear with the centre of the disc taken away; those of the lower half are shown by disconnected dashes. The method of joining up to the collector bars is clearly shown. The single arrows indicate the path which the current would take in a short-circuited coil if the number of bars on the

collector were not increased; the double arrows show the path taken when each coil is connected to three bars. The connections would be inextricable if I had not made use of the

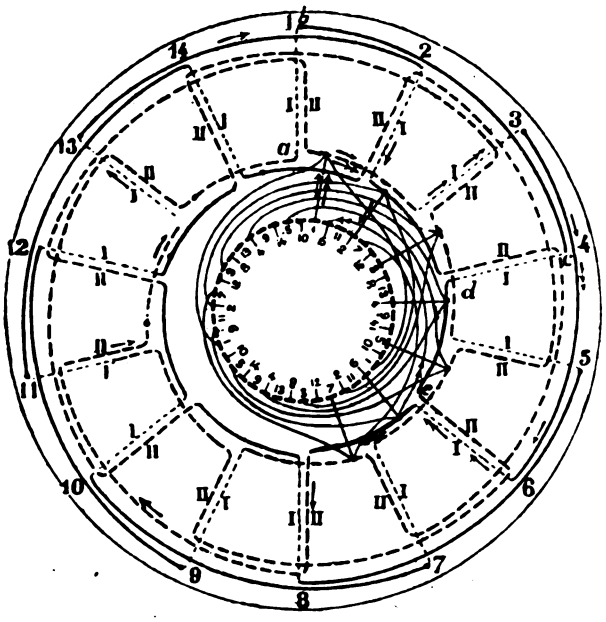

Fig. 6.

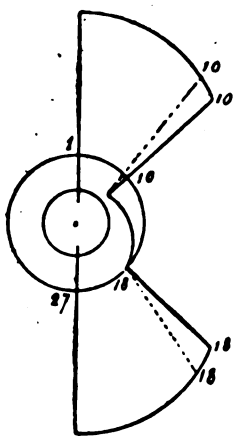

Fig. 7.

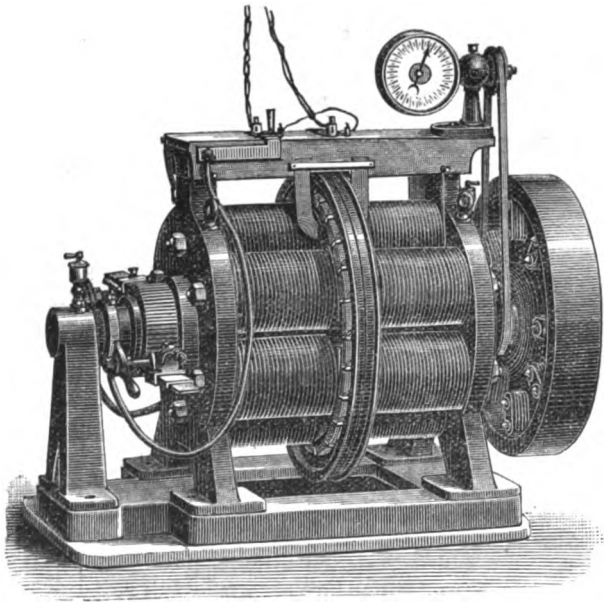

Fig. 8.

properties of the involute. The wires are, therefore, all united to a special piece of apparatus, which I call the analyser, and which is placed between the disc and the collector. The three wires of each coil come from the centre of the armature to an insulated disc; wire 1 passes on straight to the collector bar; wire 1′ is wound in involute on one side of the disc and runs thence to bar 1′; wire 1″ passes through the disc, is wound backwards through 120° and terminates at bar 1″. In this way all the wires are arranged side by side on either face of the analyser, and no mistakes are to be feared. It is not necessary to enlarge further upon the practical advantages of these arrangements, allowing as they do very satisfactory working of the collector. It would be impossible otherwise to stop sparking without increasing the number of coils or increasing the distance between the successive poles. I have, moreover, slightly modified my armature winding in the manner shown in Fig. 7, with a view to still further decrease the number of lines of force cut by the short-circuited coil.

Four Desrozier's machines (Fig. 8) have already been built by the firm of Bréguet, and placed on board the "Formidable" at Lorient. These machines weigh 1,200 klgs. each, run at 350 revolutions, and have an output of 175 amperes at 70 volts; their electrical efficiency is 82 per cent., and their commercial efficiency is 79 per cent., and varies very little with the work. "It is very probable," says the author, in conclusion, "that the efficiency of the Desroziers dynamo would be considerably higher if constructed to meet ordinary commercial requirements."

Section II.—Electro-Magnetic Fields.

(Continued from page 735.)

132. *Sir William Thomson's Graded Galvanometer.*—This instrument (represented in elevation at G, Fig. 112, and in plan in Fig. 113) has a wide range of sensitiveness, effected by varying the distance between the coil and needle. The coil, shown at B, is fixed in position and wound with six turns of copper strip 1·2 centimetre wide and 1·5 millimetre thick, each turn being insulated from its neighbour by winding on, side by side

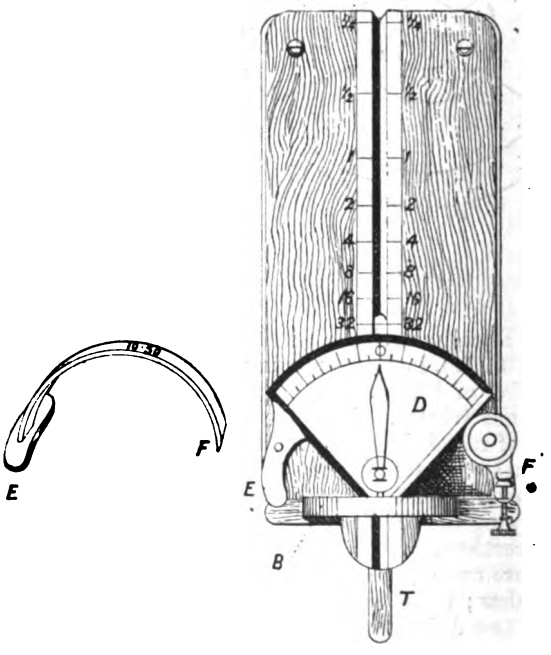

Fig. 113.

with the copper strip, a ribbon of asbestos paper. The two ends of the copper strip are brought out at T, side by side, being kept apart by a wood strip about ¼in. thick, gradually

Digitized by Google

tapered down towards the end, to admit of sliding on the connecting clip A, from which two twisted leading wires connect the coil to the rest of the circuit. The advantage of this mode of connection is that the instrument may be introduced into or withdrawn from a circuit without causing any temporary interruption. The quadrant-shaped box D, with glass cover, contains the pivoted system of needles and pointer, and is fitted with a mirror and tangentially divided scale. The instrument being tangential, the deflections on the scale are proportional to the currents. There are four little magnets, two of which are seen in the figure; the other two are beneath these, and the whole are fixed in an aluminum frame which is prolonged to form a looped pointer. The needle-box may be moved to any position, the V groove cut in the platform guiding it so that the needle is always in a line with the centre of the coil. The two ends E and F of the controlling magnet can be fitted into the side arms E and F of the needle-box, so producing an additional controlling field on the needle in the direction of the meridian, the value of which and the date when measured are usually painted on the magnet. This value cannot, however, be depended on in practice, unless the greatest care is taken to keep the magnet from getting knocked or being placed within range of the influence of foreign magnetic fields, and it is therefore advisable to measure it before or after use. A pin on the underside of the magnet at E fits into a hole in the arm E, and the point of the magnet at F fits in the grooved wheel carried by the adjustable screw at the end of the arm F, by means of which screw the magnet may be accurately adjusted to the plane of the meridian. The arm F also carries a spirit level. Fixed to the outside of the quadrant, opposite the zero point of the scale, is a little prolongation with a horizontal cut in it, the use of which is to enable the observer to bring the needle-box exactly into a given position of sensitiveness by observing that the cut and the given mark on the platform coincide. In the figure this is placed at position 32. At position 1, without the controlling magnet, the needle is at such a distance from the coil that the current producing one division deflection is exactly equal numerically to the intensity of the earth's horizontal field H at the place where the instrument is used, which, in London, is ·18 C.-G.-S. units—that is,

$$\text{Current} = \cdot 18 \text{ ampere per division.}$$

Hence, for D divisions,

$$\text{Current} = \text{D} \cdot 18 \text{ amperes.}$$

Now, at positions 2, 4, 8, 16 and 32 the sensitiveness of the instrument is increased twice, four, eight, sixteen and thirty-two times respectively; that is, a current deflecting the needle say 10 divisions at position 1 will deflect it 20 divisions at position 2, 40 divisions at position 4, and so on. Or if we put currents through the instrument, to cause equal deflections when the needle-box is at positions 1, 2, and 4, these currents would be in the proportion of 4, 2 and 1 respectively. Hence the currents vary inversely as the position P of the needle-box on the platform for a constant deflection, and we may write—

$$\text{Current} = \cdot 18 \frac{\text{D}}{\text{P}} \text{ amperes.}$$

The field F produced at the centre of the needles by the controlling magnet, when this is used, must be added to that of the earth H, as the two fields are in the same direction. To find this field it is necessary to pass a current through the instrument, and note first the deflection without the magnet, then notice how many times the deflection is reduced, say n times, by adding the magnet. This is best done by having the needle-box much nearer the coil when the magnet is on; for example, a constant current is kept on, and at position ½, without the magnet, the needle is deflected, say, 22·5 divisions; the current is then

$$\cdot 18 \frac{22 \cdot 5}{\cdot 5} \text{ amperes.}$$

Now, at position 32, with the magnet on, the needle is deflected, say, 30 divisions, the current is then

$$\cdot 18 \frac{30 n}{32} \text{ amperes,}$$

where n is the number of times the sensitiveness is reduced by adding the magnet. The current being the same the above two expressions are equal, and

$$\frac{22 \cdot 5}{\cdot 5} = \frac{30 n}{32}, \text{ whence } n = 48.$$

The value of the resultant controlling field is then 48 or n times H, and we have seen above that it is also equal to H + F, where F is the field due to the magnet; therefore

$$\text{H} + \text{F} = n \text{ H}$$
$$\text{F} = \text{H} (n - 1)$$
$$= \cdot 18 \times 47 = 8 \cdot 46 \text{ C.-G.-S. units.}$$

It is the value of F thus measured which is usually painted on the magnet, together with the date when measured.

Now, it will be seen in the figure that the needle is not within the coil at position 32; there is still a position of higher sensitiveness, which does not usually fall in the same geometrical series as the previous grades. Its value in some instruments is over 40. If we take it as 45, and suppose the needle-box placed there, without the controlling magnet, we should have

$$\frac{\cdot 18}{45} = \frac{1}{250} \text{ of an ampere per division.}$$

And, using the above magnet with the needle-box at position ¼, we should have

$$\frac{(\cdot 18 + 8 \cdot 46)}{\cdot 25} = 34 \cdot 5 \text{ amperes per division.}$$

This shows the very wide range of sensitiveness obtained.

133. *The Demagnetising Force set up by a Magnetised Rod.*—A bar or rod which has been magnetised sets up by the action of its own poles a reverse magnetising force—that is, it tends to demagnetise itself. To study this phenomenon we must consider the quantity of lines of force issuing from a pole of

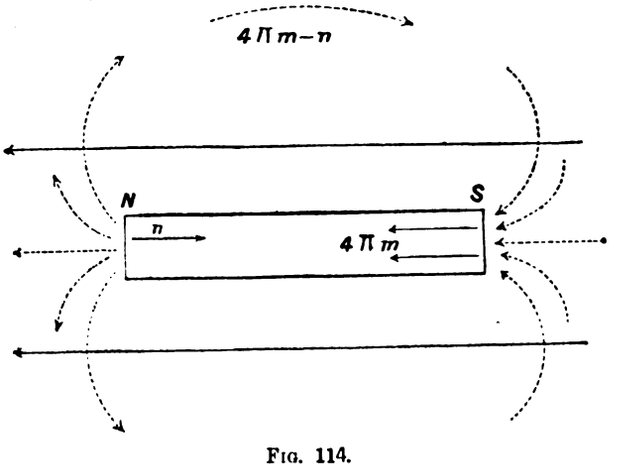

Fig. 114.

strength m (the action of the complementary pole being considered negligible). At a distance of r centimetres from the given pole in *all directions* the magnetic field is equal to

$$\frac{m}{r^2} \text{ C.-G.-S. units}$$

(*see* paras. 108, 109, and 113)—that is to say, the above number of lines of force pierce every square centimetre of surface of a sphere of radius r centimetres whose centre is the pole m. But on the surface of such a sphere there are $4 \pi r^2$ square centimetres area, through each of which, as we have seen, pass the above number of lines of force. Therefore, the total number of lines issuing from the pole m is equal to

$$4 \pi r^2 \times \frac{m}{r^2} = 4 \pi m \text{ lines.}$$

(The Greek letter π (*pi*) is always used as the ratio of the circumference of a circle to its diameter, which is 3·14159.)

Now take an iron bar (Fig. 114) to which is applied a certain magnetising force, the *direction* of which is indicated by the straight arrows on each side of the bar. Suppose that the iron acquires m C.-G.-S. units strength of pole.

Digitized by Google

Lines of force will issue from the N pole and pass in curves through the air to the S pole (para. 104); but these are not all the lines issuing from the pole. They issue radially in all directions, and therefore some pass through the metal to the S pole. It is precisely these lines within the metal which tend to demagnetise the bar. Say there are n demagnetising lines running from N to S through the metal; we shall then have $4\pi m - n$ lines issuing from the N pole into the air, $4\pi m$ being the total number. Both the lines through the air and the demagnetising lines through the metal form closed circuits, and therefore at the S pole the two return circuits of lines are in the same direction and run back through the metal from S to N. These are respectively $4\pi m - n$ and n. Adding them together, because they are in the same direction, we have $4\pi m$ as the number of lines through the metal in the same direction as the magnetising force applied to the bar. This phenomenon is all-important in magnetisation experiments. We wrap a bar of iron round with a certain number of turns of insulated wire, pass a known current through the wire, and from these data can calculate exactly what number of magnetising lines of force are produced by the coil, viz.—

$$\frac{4\pi C n}{l} \text{ lines per square centimetre}$$

(*see* para. 130). But as soon as the iron becomes magnetised, the action of its own poles causes n *demagnetising* lines to pass through the metal and weaken the above magnetising field. Now if the sectional area of the bar is a square centimetres, the demagnetising lines are

$$\frac{n}{a} \text{ lines per square centimetre,}$$

and therefore the resultant, or actual magnetising force **H**, acting on the bar is equal to

$$\frac{4\pi C n}{l} - \frac{n}{a} \text{ lines per square centimetre.}$$

The demagnetising field is greater in proportion as the poles are stronger and nearer to each other. In the case of bars we can only, with strict theoretical exactness, get rid of the effect by using rods of infinite length. Practically, however, by using rods whose length is many times their diameter, the demagnetising effect may be neglected. Prof. J. A. Ewing, of University College, Dundee, who is a high authority on the electro-magnetisation of iron, says in his Paper, entitled "Researches in Magnetism" (*Phil. Trans.*, 1885):—"My own observations show that it is only when the length of the rod (if of iron) is about 300 or 400 times its diameter that the effect of length becomes insensible."

The same authority also states that the demagnetising force due to the ends is unequal along the bar, being much greater at the ends. The demagnetising effect is entirely got rid of if the iron is employed in the form of a ring, since, in this form, there is a complete magnetic circuit, and therefore no poles. The intensity of magnetisation can be found indirectly this way from the value of the magnetic induction **B**, and the magnetising force **H**; but what we are considering now is the *direct* measurement of the magnetisation by the action of the poles on the magnetometer. We shall select two instances from a number of experiments to illustrate the difference between these conditions, and shall take first a short, thick iron rod, in which there is considerable demagnetising effect. When the demagnetising action of the poles is got rid of by employing either very thin iron wires or iron rings, the condition is technically spoken of as that of "endlessness."

(*To be continued.*)

Tempering Steel by Electricity.—Electricity, says *Engineering*, is used in a most successful manner for tempering watch springs and other forms of spring steel, whether in the form of ribbon or wire. The steel is wound upon a spool, from whence it passes down through a bath of oil. The wire is made a conductor in an electric circuit, carrying sufficient current to maintain the wire at a proper degree of redness to answer the desired requirements of temper.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *October 6th*, 1888.

A very interesting Paper was presented a few weeks ago by Prof. J. P. Barnett, of Chicago, before the National Association of Fire Engineers. Much of the Paper was in the form of an explanation as to the method and systems of electric lighting, but the valuable part so far as his hearers were concerned in practical work was that which contained his suggestions as to the manner of dealing with electrical conductors of all kinds. Prof. Barnett has charge of the electrical department of the City of Chicago, and is well-known for his energetic advocacy of electric lighting for city purposes, and his remarks appear to have been accepted with favour. This is a good sign, for there have been only too many endeavours in certain quarters to cultivate a spirit of enmity and opposition on the part of firemen against electric wires of all kinds. Prof. Barnett reminded his hearers of the fact, however, that electric light and power wires were already to be found everywhere, and that the number would certainly not decrease, but largely increase, and that the proper thing to do was to meet the new condition of things, and to acquire as much experience and information as possible in regard to such developments of modern science. He made a good point in recommending the fire department to co-operate with the insurance people in this matter, and said: "While insurance rates are less in some portions of New England, where electric lighting has displaced gas, these lower rates cannot be obtained except on the certificate of an inspector, and I am satisfied that this view of the subject is spreading amongst the sensible insurance people." This is practical, as is also the following passage: "You will all do well to keep your eyes on wires which are cotton-covered and then painted with common paint. The electric lightman will tell you it is underwriters' wire, and therefore good. Tell him you have heard it called undertakers' wire. He will tell you it is asbestos painted; contradict him, make him prove it. He will tell you it is waterproof. Tell him Barnett says it is not, and make him put up a decent wire out of doors, something that with the first rain will not water-soak and endanger the life of everybody who stumbles over it or the property it happens to swing against." Such talks as these are in every way useful.

The subject of the electrical utilisation of water-power is assuming more and more importance, and is attracting considerable attention in circles other than electrical. Some of the new plants which have been installed by the motor companies are of no mean magnitude, while the results obtained have been extremely encouraging. I do not refer to the numerous cases in which electric-light plants, already run by water-power, have been utilised to furnish current for motors during the day, but to installations where the first and only object has been to transmit water-power long distances to drive motors. One instance of this is a plant you have already noted, that of the Sprague Company in the Feather River, Cal., where 14 motors are distributed along a circuit 18 miles in length, for pumping, hoisting, and other operations, utilising the water-power of the river itself, conveyed by tunnel and canal to a point where a fall of 300 feet is obtained. Another instance to which attention has just been directed is the installation prepared by the Brush Company for the famous Sutro tunnel. In this instance there are six Brush dynamos, each to be driven by a 40-inch Pelton wheel. This plant will be set up at the Sutro tunnel level of the Chollar mine, and water brought down the side of Mount Davidson in a wrought iron pipe will be delivered at the wheels, it is said, at a perpendicular pressure of 1,630 feet, the stream acting upon each wheel coming from a nozzle somewhat less than half an inch in diameter. Each wheel is intended to develop about 125 horse-power, or 750 horse-power in all. The current thus generated will be transmitted to drive stamping-mills. The first shipment of machinery for this remarkable plant has already been made, and we shall soon know what results are obtained. It may perhaps be worth

Digitized by Google

mentioning here, as indicative of the size of this field, that the water-power of the country is estimated to average about 200,000,000 horse-power, of which only one and a half million horse-power is utilised. A large proportion of the whole probably will never be utilisable. Of Niagara, with its six million horse-power, for example, only about 5,000 horse-power is utilised to-day, and there are many instances where the waste, if we may give it such a name, is inevitable, and must continue. But even after all deductions have been made it will be seen that in working up water-power for general distribution and consumption electricity has much to do in our country.

An interesting electrical railway patent has just been issued to Messrs. J. D. Nicholson, T. J. M'Tighe and W. J. M'Elroy, the last of whom has Westinghouse affiliations, for an ingenious form of electric railway, not unlike in its main idea that which was brought out by Pollak and Binswanger some little while ago in Europe. There is an insulated underground main conductor connecting with a series of boxes, each of which contains a pivoted magnet, over which is a metallic cap to be operated inductively. As the car passes over the conductor and boxes it becomes energised through a contact bar with a magnet, which is capable of spanning and touching two of the metallic caps at once, so that the current passes from the line through the magnets to the motor, and out to line again. The object and recommendation of the system is the avoidance of exposed conductors or conduits, as such a road would be, so far as its outward signs are concerned, an ordinary street railway, with a number of metallic knobs showing at regular distances apart between the tracks.

You have probably seen accounts in the English daily papers of the extent to which Jacksonville, one of our favourite southern resorts, has been visited by yellow fever. Of course, whenever an epidemic of this kind occurs there is always endless discussion as to the best means of preventing or stopping the spread of the disease, and various odd remedies are sure to be proposed. In the present instance Mr. Edison is given credit for one original preventive. Accepting the theory that yellow fever is a parasitic disease, he asserts, from experiments made, that rhigoline or gasoline and caustic soda combined, distributed over the soil, so as to soak in for some little distance, will effectually eradicate the germs, or at least would arrest their spread. It seems to be admitted that gasoline, wherever it comes in contact with the germs would certainly destroy them, but the idea is not new, it is said; but it happens that a genuine electric cure has also been proposed and introduced. It is described as follows:—"It is a small cylindrical nickel box, containing several steel rods, and connected by 6ft. of wire to an arrangement resembling a garter, or a bracelet. This garter is placed around the wrist of the patient, and the nickel box immersed in a vessel containing hot water. Immediately the microbes begin to perish, and in a few hours the patient sinks into a calm refreshing slumber, and all symptoms of fever disappear." The description is deliciously vague, and I have still to learn that this method of cure is successful, or is looked upon favourably by any person of the medical profession. Times of plague and pestilence always produce their charlatans and nostrums, and in days when electricity is supposed to be able to do everything, I suppose some people are ready to believe that it will cure yellow fever.

I have occasionally commented on the progress made in the agitation for improvements in our patent system. The movement started by the National Electrical Light Association two or three years ago has been steadily maintained, and now the Bill proposing to establish a court of patent appeals has been favourably reported to the National House of Representatives by its judiciary committee. The report of the committee states that the expenses of the court will not exceed $30,000 per annum, and that, moreover, there is a balance in the treasury to the credit of the patent fund of over $3,000,000. Besides, the small sum of money required to carry on the court is absurdly insignificant compared to the amount which would be saved by the speedy adjudication of patent cases. There is another point for consideration, and that is the saving of the time of the Supreme Court, a body which is at present sadly over-loaded with work. At the last term of the Supreme Court, before which all such cases now go, on appeal, 325 various cases were disposed of on oral arguments or submitted on printed briefs. But the docket of the court at the beginning of the term included considerably more than 1,000 cases, so that all the judges worked as many days as possible, and one of them practically killed himself under the pressure, 700 cases went over till the next term; and thus the work accumulates. Evidently the establishment of this court of patent appeals is a desirable reform, and it appears to meet the approval not only of the judges, patentees, and patent attorneys, but of all laymen who have given the subject the slightest attention.

The dispute between the Board of Electrical Control and the local United States Company reached another crisis last week in a somewhat unexpected way. The *employés* of the Board began removing poles on 6th Avenue here, from which the wires of the telephone company had been stripped, and in the course of the work it became necessary to cut the wires of the United States Company. The result was that some 40 or 50 lights were extinguished, and there is a big row, as the United States Company has not been allowed to re-establish its connections. Just what the Company will do in the premises is not easy to say, as the wires were cut by an order of the Board, and cannot be restored in any way without a breach of the law. Meantime the disgusted customers have been deprived of their light, and the company of their revenue. Relations between the Board and the other companies seem to be more pleasant. The East River Company, for instance, have recently completed their new circuit, which runs up and down town a distance of some five or six miles, carrying already about 100 lights; but this is on the east route, where subways have not been provided. An amusing instance of the lessons taught by all this public discussion as to the danger and safety of electric light wires has just been given here in the political campaign. A big banner was hoisted on Broadway by the partisans of General Fisk, the temperance candidate for the Presidency. It was complained of as a nuisance, and threats were made to remove it. The persons in charge, however, have taken measures to secure their banner from disturbance by passing live electric light wires all round the pole which carries it. The result is that it has since been very respectfully let alone.

The Centennial Exposition, which is now being held at Cincinnati, Ohio, is noteworthy as embracing a remarkably fine electrical display. Not only is the electric light used with considerable effect for general purposes of illumination and decoration, but electric motors are also shown doing a variety of work. One of the most remarkable exhibits is that made by the Edison Lamp Company, which has built up over 15,000 Edison lamps into a mammoth pedestal, socket and lamp. The large lamp represents an ordinary sixteen candle-power lamp, magnified over twenty thousand times, with a capacity of 100,000 candle-power. Across the front slope of the pedestal is the name of Edison spelt in lamps, which can be flashed letter by letter all together. This unique piece of work as well as some other novel effects has been carried out by Mr. W. J. Hammer.

In closing a series of articles in *The Electrical World* on telegraphy with superposed pulsatory and undulatory currents, Mr. William Maver, jun., takes occasion to mention the fact that over 13,000 miles of wire in Europe are used for the Van Rysselberghe system of simultaneous telegraphy and telephony, while there are no such wires in Great Britain or in this country. He then proceeds to look for the reason of such a state of affairs. In England as he points out, the Wheatstone automatic system is extensively used, almost to the practical exclusion of the quadruplex; and the insertion of a "graduator" in circuits assigned to rapid automatic work is, of course, out of the question. In this country the quadruplex is undoubtedly a main reliance of the telegraph companies, and the introduction of the "graduators," even when radically modified, would reduce the efficiency of that system. As to the 13,000 miles on the Continent of Europe, Mr. Maver appears to think that there is some question as to the success-

Digitized by Google

ful work obtained there. The reports from Belgium are favourable, but those from other quarters not so optimistic.

An important application has been made through the Inter-State Commerce Commission by the Postal Telegraph Company, for proceedings against the Pacific Railroads, compelling those comporations to perform the obligations imposed upon them by law in respect of telegraph service. Over these railroads up to the present, the Western Union Company has had exclusive rights, but now the Postal Telegraph Company desires to use the railway wire facilities as a means of reaching numerous points now rapidly growing up between the Missouri River and the Pacific, to which it desires to extend the advantages of competition. It already has connections over the Canadian Pacific, but these are not sufficient for its purpose. The company states in its request that it does not ask for any special concession or for anything it will not pay for, but "we insist," says the appeal, "that they shall carry out their obligations to the Government and its citizens by maintaining and operating their telegraph lines, and by accepting from us both through and local business at rates which shall be no greater than those of the Western Union Company, and to which they shall be entitled to their share *pro rata* in proportion." It will be remembered that Mr. Robt. Garrett began this agitation on behalf of the Baltimore and Ohio Company, and that it has now gone on for some time without results, the alliance between the Western Union and the railroads having proved too strong to be broken. It is thought probable however, that the Commission will use its power on behalf of the Postal Company. By the way, having mentioned Mr. Garrett's name, I am sorry to have to say that that gentleman is seriously ill, and has to be constantly watched.

Mr. Henry E. Abbey, our great impressario, mentioned this week to one of the papers an interesting illustration of the facility for rapid transaction of business afforded by cables. He was in Germany while Mr. Grau, one of his associates, was in Buenos Ayres, and Mr. Schoeffel, another, was in England. One Monday Mr. Grau transmitted by cable a very large sum of money, the profits of South American business, *viâ* Europe to New York. On Tuesday, at Hamburg, Mr. Abbey received a telegram from a leading artist in London, with whom he was negotiating, asking him to send $12,000 to an agent in Paris to close the contract. While waiting to obtain this gentleman's address by telegraph Mr. Abbey received a telegram from Mr. Schoeffel in New York telling him that the Buenos Ayres remittance was to his credit in this city. The address of the Paris gentleman reached Hamburg on Tuesday night, and on Wednesday morning the $12,000 of the Buenos Ayres remittance to New York was paid in Paris, and the receipt was sent to Mr. Abbey in Hamburg. The question arises, how long would this business have taken to transact under the old conditions of mail service? Six months would not have sufficed, and the business would have been transacted in some other slower and much less satisfactory way. Speaking of this reminds me, too, that during the present week a copy was received in this city from Europe of the German publication, containing the sensational extracts from the Emperor Frederick's diary. The matter was at once put on the wires—over 22,000 words—and sent to the leading German paper in Milwaukee, where it appeared verbatim next morning. This I believe to be the largest telegram sent in German to this city, and it is unquestionably a very fine piece of journalistic enterprise.

NOTES FROM VIENNA.

(FROM OUR OWN CORRESPONDENT.)

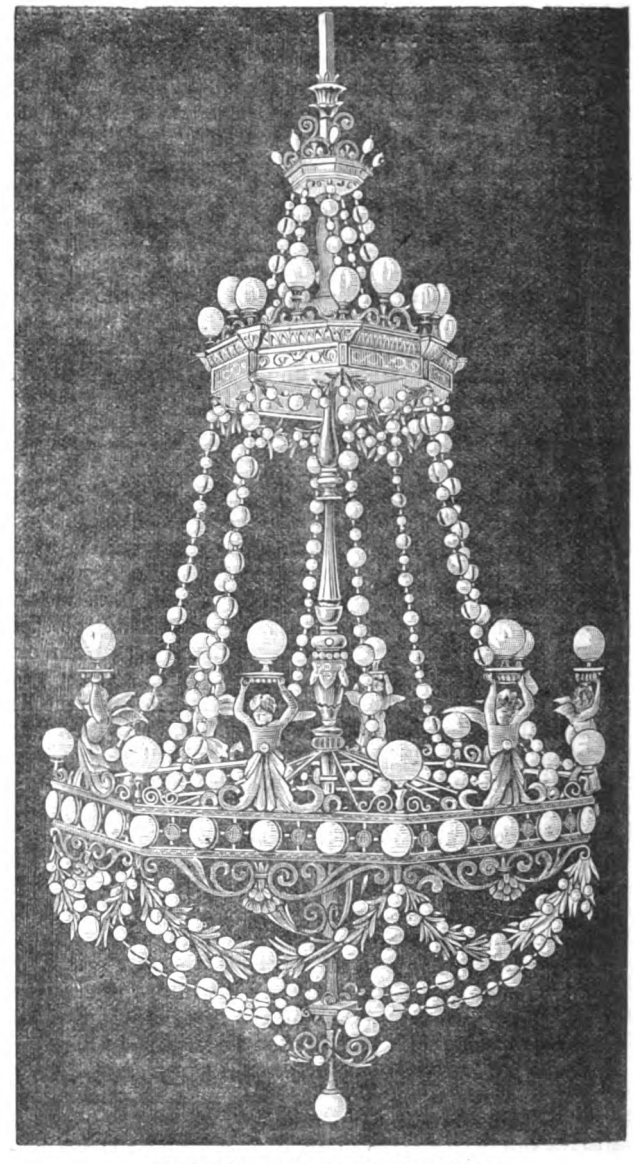
VIENNA, *Oct. 15th.*

THE LIGHTING OF THE NEW COURT THEATRE.

The old Court Theatre was closed last week with great ceremony, and the new magnificent building, which has cost over two millions sterling, was opened with much pomp on Sunday last, the Emperor and many members of the Royal Family being present, also the Prince of Wales.

The contrast between the two buildings can hardly be imagined, considering that the old building was built in 1742, and renovated in 1776. The oldest playbill existing dates from April 8, 1776; since that time more than 30,000 have been issued. Full descriptions of the new building itself, its decorations and splendid paintings have appeared in the daily papers, and this report is, therefore, confined to the electric light installation, as being of special interest to the readers of *The Electrician*.

The installation is, without doubt, the most perfect and substantial that has ever been carried out. It has been made by the Imperial Continental Gas Association, and the current is supplied from their Central Station in the Schenkenstrasse, a description of which appeared in *The Electrician* of September 14th, p. 610. As mentioned then, the company's resident engineer, Mr. T. W. W. Melhuish, A.M.I.C.E., deserves very great credit for his work in connection with the theatre and the Central Station.



Central Electrolier at the Burg Theatre.

The system adopted has been that of accumulators, which are charged during the day from the Central Station. Three batteries of accumulators containing altogether 540 cells of a very large type are placed in the cellars of the theatre. Each cell weighs complete nearly 300 kilos. Two of these batteries are used for lighting the house generally on the three-wire system, and the third is entirely reserved for the stage lighting. The current passes from the accumulators to the regulating room, where charging and discharging regulating switches, having the very extensive range of fourteen cells, are provided for each battery, and from these switches the current goes through wattmeters of Dr. Aron's latest type to the distributing room, thence 94 leads go off to different parts of the house, each circuit being provided with a switch and double safety fuse; the connections are so arranged that any circuit can be put on either battery, thus ensuring equal demands on the latter. Most of the cables in use are made on the Berthoud-Borel principle, and by this means, although the house is damp in many places, and is likely to remain so, an unusually high insulation has been secured.

Digitized by Google

The total length of the cables reaches 110 kilometres, or about 62 miles.

The fittings, such as lustres, standards, brackets, &c., are mostly very fine specimens of this class of workmanship; the engraving of the magnificent lustre in the auditorium carrying 373 lamps will give some idea of these. To such fittings, together with the very tasteful arrangement of lamps, is to a great extent due the magnificent and brilliant effect produced when the house is fully illuminated. It is surprising to see how the effect has been improved by such small means as adopting a suitable shape of lamp, *i.e.*, long pear-shaped globes or rounder ones, and by a judicious mixture of ground, opal, and clear glass lamps. On the stage the coloured effects are most efficiently produced by means of coloured lamps and the different degrees of brilliancy. Darkness is effected by means of a very complete regulating apparatus, designed and manufactured for this theatre; the space occupied by this apparatus is very small. The form of the overhead battens was only determined after a number of experiments had been carried out with a view of determining the most efficient shape; as now made they give every satisfaction. The total number of incandescent lamps installed is 5,300, varying from 10 to 40 candle-power. In addition to these, several arc lamps will be used for stage effects, and for lighting the exterior of the building.

The auditorium is lighted by 720 lamps, including the great lustre; the *foyer*, staircase, corridors, &c., by 1,800; the cloak rooms, stores, cellars, &c., by 800; and the stage by 1,970 lamps; these latter develop a light equal to 50,000 candles.

THE OPERA HOUSE INSTALLATION.

After 15 months lighting of the Opera House (during which time no disturbances whatever due to electrical causes have taken place) the I.C.G.A. have no doubt as to the success of this new installation, and certainly the absolute steadiness of the light, which is so agreeable to the eye, the impossibility of sudden darkness, and consequent panic which might be caused by stopping of machinery, are very strong points in favour of the system which has been adopted. The work in the theatre has been carried out under the personal superintendence of Mr. E. Sechcharge, who has gained golden opinions for his work. To his ability and great industry the success of the work is in no small measure due.

He is now leaving for London to undertake the electric light installation in the new Lyric Theatre, Shaftesbury Avenue, and some other large buildings. It will certainly not be his fault if the lighting of this theatre is not a decided advance on anything that has as yet been seen in a London theatre, and I hear that the enterprising management of the Lyric intend to afford every facility for making their installation a first-rate one.

THE SIEMENS AND HALSKE CENTRAL STATION.

As reported some time ago, this firm had made all arrangements for a large central station in the Neubadgasse. At the time *The Electrician* expressed a doubt as to the hopes of commencing lighting by December being realised, owing to the inevitable interference of the Vienna Town Council, who are known to dearly love a "dog in the manger" policy. This prophecy has now come true. Messrs. Siemens and Halske have stopped the work, owing to the difficulties made by the Town Council and the neighbours, and it is quite uncertain when the work will be recommenced, if ever it will be.

NOTES FROM PARIS.

(FROM OUR OWN CORRESPONDENT.)

PARIS, *Oct. 19th.*

It is probable, and certainly very desirable, that the present stagnation in electric light circles will soon come to an end. The contract for the Municipal Electric Station will be considered on the 22nd of this month, and already no less than 20 tenders have been handed in. These tenders relate to steam boilers for about 800 horse-power, engines for the same power, and electrical plant for 160 arc lights and about 5,000 16 candle-power incandescent lamps. The station will be entirely worked by the Municipality. The light will be used for lighting the Halles Centrales, and will also be distributed to private consumers in the neighbourhood. The Conseil Municipal will meet on the 22nd, and the special committees will have to examine the tenders at once.

It is hoped that the inauguration of this installation will take place by the time of the opening of the Exhibition in May next. At the same time the Conseil Municipal will have to consider the demands for concessions which have been made up to this time for the distribution of electric current to the public in other parts of Paris. The example given by the Municipality has borne fruit, for I am told that the city authorities have received demands for concessions covering a good third of the city.

The Lyons Central Station was opened last week and seems to give the greatest satisfaction. The Théâtre des Célestins, the Café Maderni, the Scala, and many other establishments, are lighted from the station, which is equal to 8,000 sixteen candle-power incandescent lights. All the material, electrical and mechanical, has been manufactured by the Société de Constructions Mécaniques, of Belfort, which has also done the wiring and general fittings. The mains are are all underground, the cables resting on the ground without any tubes or protecting pipes.

I see you have already announced in your columns that a scheme is on foot for lighting Versailles by electricity from a central station at Marly, 10 kilometres off, so that a few details as to the water-power available may prove of interest. The hydraulic station at Marly is situated on a stone bridge spanning the left arm of the Seine at the De la Loge. By a combination of locks and sluices an average fall of 3 metres is always ensured. The plant comprises six enormous water wheels, more than 8 metres in diameter, driving a series of pumps which furnish the town of Versailles with a constant supply of water. Two wheels working day and night suffice for this, so that there are always four out of the six lying idle, representing an annual waste of 650,000fr. As each wheel is capable of working up to 150 horse-power we have no less than 600 horse-power available for electric lighting purposes. It is not astonishing, then, that this scheme has been mooted. No doubt it would have been better to have had the station nearer Versailles; but with a 3-metre fall already available at Marly a station elsewhere is not to be thought of.

THE LONDON CHAMBER OF COMMERCE.

ELECTRICAL AND ALLIED TRADES SECTION.

The following circular has been issued by the Secretary of the London Chamber of Commerce to the members of the Electrical and Allied Trades Section:—

SIR: Your attendance is specially requested at a meeting which will be held at Botolph House, 12, Eastcheap, on Monday, Oct. 22, at 3 p.m., for the purpose of completing the organisation of an Electrical Trade Section of the London Chamber of Commerce on the lines of my circular letter of the 24th of July last. The appended agenda of business will be transacted, and your attention is specially called to the list of members of the section, which, for purposes of ascertaining the representation to which they will be entitled on the general committee, has been divided into sub-sections. The working committee, as a whole, will consist of 33 members, and you are requested to fill up the enclosed voting paper according to the directions given thereon, and return the same to me as early as possible before the meeting takes place, whether you are able to attend or not. To facilitate the scrutiny it has been agreed that no voting papers will be received later than five minutes after the opening of the proceedings.

I am, sir, yours faithfully,

KENRIC B. MURRAY, Secretary.

AGENDA.

1. To receive and adopt the report from the organising committee with reference to the future working of the section.
2. To consider the subjects to be dealt with by the section.
3. Election of the working committee of the section (result of the voting to be announced).
4. Other matters.

REPORT OF THE ORGANISING COMMITTEE.

The committee appointed at the general meeting held on the 27th of July last, "with a view to organising an Electrical Trades Section under the auspices of the London Chamber of Commerce," beg to report that in the interval which has elapsed they have held two meetings to carry out the terms of their reference, irrespective of what has been done by a special sub-committee formed to consider certain details.

The committee recommend that a working or executive committee (elected annually by the general body of the trade in accordance with the bye-laws of the chamber) be charged with the ordinary business of the section, and that in the first instance it consist of 33 members, this number to be increased to 48 at the first annual meeting of the section, if the membership then obtained should warrant a larger representation.

It is proposed that the working committee should meet whenever occasion requires, and that meetings of the whole or part of the section, in addition to the usual annual meeting, should also be called from time to time.

With a view to an equitable representation on the working committee of the various branches of the electrical trade, the organising committee, after preparing a classified list of members,

Digitized by Google

recommend that the committee be divided into the following sub-sections, viz. :—

1. Telegraph companies	5	members.
2. Telephone companies	3	,,
3. Electrical supply companies	6	,,
4. Electrical manufacturers and contractors	13	,,
5. Consulting electrical engineers	4	,,
6. General	2	,,
Total	33	,,

The committee recommend that members of the working committee be elected by ballot, and they have accordingly approved the issue of a voting paper with the circular convening the present meeting. They suggest that the election of the chairman and two deputy chairmen of the section should rest with the working committee.

Having regard to the bye-laws and regulations of the chamber, the committee do not advise the adoption of special rules to govern the section and its committee, as they are of opinion that for the present it will suffice to follow the procedure of other trade sections. As regards applications for admission into the section it is suggested that the working committee should be allowed an opportunity of scrutinising these before presentation to the council of the chamber for election.

The committee further recommend that the questions first dealt with by the section and its working committee should include the most pressing of the matters set forth in the circular letter of the 24th of July last, and that the admission of reporters to all future meetings be determined by the vote of members present.

SIR JOHN PENDER ON SUBMARINE TELEGRAPHY.

On Tuesday last Sir John Pender was presented with the freedom of the Burgh of Dingwall in recognition of his eminent services to the county in connection with the extension of submarine telegraphy throughout the world.

Provost Ross presided, and there was a large attendance. In presenting the freedom of the burgh to Sir John,

Provost ROSS alluded to the distinguished position which he occupied in the work of submarine telegraphy all over the world. During his Parliamentary career Sir John Pender had always evinced a deep interest in the welfare of the northern burghs, and the freedom of the burgh was now conferred upon him, not only on account of his being a prominent and distinguished man, but also as a mark of the people's gratitude for many acts of kindness.

Sir JOHN PENDER, who was received with loud applause, said his audience could well understand the difficulty he had in acknowledging in suitable terms the very eloquent and most kind and generous words which had been put before them by the Provost—words which would touch the heart of any man—words which he had no power or language to thank him sufficiently for (applause). It was indeed a very great honour to receive such a recognition at the hands of old friends, more particularly in a burgh with which he had been associated for so many years. During that time he dared say they had found out the bad parts in his character, and they also had been generous enough to appreciate some of the good parts (applause). He did not accept that honour entirely as a personal honour, but he accepted it in recognition of probably the greatest work that had been done during the greatest and most beneficent reign of any monarch who had reigned in the world ; and the work had been done so silently that even men of distinction could scarcely believe that such a work had been accomplished (applause). There had been a few honest, hard-working men engaged in that work, and one of those distinguished men was kind enough to say to him (Sir J. Pender) that he would like to go to Dingwall, and tell a little of the part that he (Sir J. Pender) played in it. That generosity was displayed on the part of his friend Sir George Elliot, who was now on the platform (applause), and who was, he might tell them, associated with submarine telegraphy before he (Sir John) took any active part in it. He not only made telegraphs, but laid them (applause). He thought he was bound to say a few words to them in justification of the honour they had conferred upon him. In April of this year the jubilee of telegraphy was celebrated. Fifty years ago there were only 2,000 miles of line, whereas the system now extended to 680,000 miles. The income then was *nil*, the income now amounted to many millions sterling (applause). At that time submarine telegraphy was practically unknown. It had been taken up, as he had told them, by himself and his friend Sir George Elliot and others. They had taken a firm grip of it, as they found that science had given them something that would be of universal advantage to the world, and they pushed it on so steadily that at the present moment there were 120,000 miles laid at the bottom of the sea (applause). That 120,000 miles of cable had cost £40,000,000, and still nobody knew where the money had been found, but everyone knew and recognised the enormous advantage it conferred upon humanity (applause). What had telegraphy done? He would enumerate some of the things it had done. That country of theirs was now in touch with all their colonies, it had brought them into touch with their great Indian Empire, with every part of the world where British ships could enter or the British flag could fly (applause). It had done more than that, it had brought about that federation of sentiment, that federation of interest—that which so many statesmen had endeavoured to do by talking, they had done with one great practical act (applause). They had done more in twenty years than Parliament had done during that time with all its talk (laughter and applause). They had done more for the benefit of the world by that one act than Parliament had done during the past twenty years (applause). He asked them not to suppose that he was egotistical in his remarks. He was speaking of a great system which was of vast importance to the world (applause). He would ask them to listen to what other people said on that great subject. At the Jubilee Panquet the following telegram was read from Australia :—"Submarine telegraphy, this offspring of science, has, in the direction of peace, revolutionised the whole world, brought the most distant portions of the British Empire within speaking distance, and rendered federation not only possible, but easy of accomplishment" (applause). America telegraphed : "All rejoice in an anniversary which finds New York as near to London as Camden Town was to Euston-square fifty years ago, and which sees the great name of Wheatstone honoured the world over in connection with inventions that have made nations neighbours, that have broken down prejudice, and provided knowledge, friendship, and peace to the whole universe. God bless Old England!" (applause). He said that he was anxious to read to them those extracts, because it took from him a certain responsibility. It showed them that other nations appreciated these benefits as well as their own. Their policy was not to confine their work to England, they went to the whole world (applause). Another telegram from America, read at the same meeting, said : "While the railroads have been the means of quicker transportation, the telegraph has been, if I may so call it, the nervous intelligence which has informed their movements, enlarged their facilities, and enriched their results. In a few months by these means, towns have sprung up in the virgin forests or on the desolate plains, and in a few years they have, by the same means, developed into opulent cities, giving prosperity and contentment to thousands. Add to this the achievement of submarine telegraphy, and are we not identified with, and, in fact, part and parcel of, one of the greatest powers for good, not only of this marvellous nineteenth century, but of all time? The kinship of nations has been strengthened by the telegraph, and most of all between England and America. The incessant stream of messages across the Atlantic bear silent witness to the bonds of affection, sympathy, and interest which bind the two peoples together" (applause). Could they, he asked, have in words more positive an expression of appreciation of this great work, for which they had done honour to the humble person who was now addressing them (applause)? What said a Minister of the Crown—one who, from his position as Postmaster-General, was entitled to know more than any other person of the benefits conferred on the world by the great work in which he had been engaged? He said, "I make bold to predict for this great science another and much ampler jubilee whenever the next half century enables it to take stock of the marvellous labours which it achieved for the human race, for the development of human enlightenment, and for the propagation of universal peace" (applause). Those were very strong and very emphatic words, and they came from a man whose knowledge of the question was beyond all doubt (applause). Now, he thought he had mentioned to them something of the extent of the work, but when he told them that it had to be carried on from day to day, and from hour to hour, and that the extent of the investment had been on the part of the companies about 90 per cent., and the Governments only 9 per cent., it would give them some idea of what British enterprise was (applause). They had thirty-eight ships that carried a tonnage of 60,000 tons, and it cost £300,000 a-year to maintain the system. When they thought on all that they would have some idea of the work that had been done. Submarine telegraphy had averted wars, and was likely to avert wars in the future. It had promoted social enterprise ; it had sweetened emigration by bringing to those who left the country and went to a country where they could find elbow room, facilities whereby they could converse with their friends, or tell them regarding their surroundings (applause). With regard to emigration, he believed in it very much. He could not see why people would choose to remain in a place where they had no room to turn themselves in ; why should they not go to a country where there is plenty of room and greater opportunities to become prosperous? (applause). Although they were far removed, they were in communication, by the aid of the press, with the home country (applause). The press was the organ which brought that about, but they were the means of giving the press the facilities. A statesman of to-day could not be happy in his position if it were not for the communications he received daily by telegraph. Merchants engaged in enormous export and import traffic, involving thousands of millions sterling, were aided in the most marked way by the telegraph. Prices were daily marked in London from the Indian, China, and other foreign markets of the world, so that merchants at home knew exactly what they were doing. There was scarcely a transaction of any importance in London, Liverpool, or Glasgow that was not either begun or closed by telegram. When the Melbourne Exhibition was opened the other day, he had been asked whether it would be possible to have a communication sent in answer to a message received from Melbourne in a very limited time. The message received from Melbourne to the Queen contained 117 words, and it took only 38 minutes to reach London (applause). The reply contained 13 words from Her Majesty, and it reached Melbourne in 16 minutes (applause). It showed the little time that had been lost when he told them that the distance travelled was 14,000 miles (applause). Indeed, if they took the time as the sun indicated, the message was back before the event took place in Melbourne at all (laughter and applause). He thought that he had said sufficient to satisfy them of the importance of the great work which had been done during the last 22 years. It had only passed its majority, but when it attained to riper years, they would find that it would continue to go on by leaps and bounds ; for if he had one wish more than another, it was that God would spare him for a few years more to see the advantage derived by humanity, and to see the great

Digitized by Google

system arrive at a state of perfection (applause). All that was done had been accomplished in a very short period—in one half of the reign of the Queen, and he thought that every British subject could not help being proud of Britain when he felt his ability in a short space of time to have his thoughts transmitted to any other part of the world (applause). He hoped that he had justified the Provost, Bailies, and Councillors for the honour they had conferred upon him as a representative of the great telegraph system, an honour he could not have accepted simply for the work he had done while he was their member in Parliament. But in those days he had many pleasant associations with these burghs (applause). He might tell them that some of the young men who went from those burghs—those whom, he might say, he had taken by the hand—were part of the organisation of the great telegraph system (applause). He hoped that there were still many coming who were looking forward to take part in it. There was a great field before them, and he would counsel them to look carefully to their education, work hard, incessantly, and earnestly, and their satisfaction in the end would be much the same as he had that day in receiving such a high honour (applause). They had entered his name on the record of an ancient and Royal Burgh, which dated back to a period when such work as he had been representing to them was little known (laughter), but their burgh had held together in a wonderful degree during these long years, and he thought he could associate that with the management of the able men who had filled the positions which were entrusted to them by their townsmen. When his record was written, he desired that he should be remembered as one of the band of earnest workers who had made the nations of the world more united, more in harmony, and more progressive than they found them, and who also desired that peace and goodwill might be promoted by the great agency of submarine telegraphy, which it had been the object of his life to establish and develop (loud applause).

LINES TO THE ELECTRIC LIGHT AT THE GREAT WESTERN RAILWAY TERMINUS.

(By a Misanthropic Gas-holder.)

Twinkle, twinkle, little Arc,
Sickly, blue, uncertain spark;
Up above my head you swing,
Ugly, strange, expensive thing!

Now the flaring gas is gone
From the realms of Paddington,
You must show your quivering light,
Twinkle, blinkle, left and right.

When across the foggy air
Streams the lightning's purple glare,
Does the traveller in the dark
Bless your radiance, little Arc?

When you fade with modest blush,
Scarce more bright than farthing rush,
Would he know which way to go
If you always twinkled so?

Cold, unlovely, blinding star,
I've no notion what you are,
How your wondrous "system" works,
Who controls its jumps and jerks.

Your's a lustre like the day!
Ghastly, green, inconstant ray!
No; where'er they worship you,
All the world is black or blue.

Though your light perchance surpass
Homely oil or vulgar gas,
Still (I close with this remark)
I detest you, little Arc!

—*St. James's Gazette.*

LEGAL INTELLIGENCE.

King, Brown and Co. v. The Anglo American Brush Electric Light Corporation.

In the Edinburgh Court on the 16th inst., before Lord Trayner, his lordship closed the record and ordered proof in an action at the instance of King, Brown and Co., Rosebank Electric Works, Broughton-road, Edinburgh, against the Anglo-American Brush Electric Light Corporation (Limited), 6, York-place, Edinburgh, for the reduction of letters patents obtained by the defenders in October, 1878, and other papers, for "improvements in apparatus for the generation and application of electricity for lighting, plating, and other purposes," material parts of the alleged invention not being new or original. The defenders have threatened the pursuers with legal preceedings and liability in respect of manufacture, use or sale of the alleged invention said to be covered by the letters patent, and in particular of compound-wound dynamo machines. This, the pursuers state, has very seriously affected their business. The defenders admit having threatened the pursuers with legal proceedings, and that the proceedings threatened were carried out against the Orient Steam Navigation Company, who were using machines made by the pursuers. An action against the Orient Company is pending in the High Court of Justice, England, and, it is stated, the same questions are raised there as in the present action. The defenders therefore plead that the case ought to be sisted until the issue of the English action is known.

CORRESPONDENCE.

ELECTRIC TRACTION IN CANADA.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: Thinking it might be interesting to your readers, I send the following short account of the St. Catherine's, Merritton, and Thorold Electrical Street Railway, including (by permission of the president, E. A. Smyth, Esq.) some figures as to the cost of working.

The plant consists of one 100 horse-power generator, seven motor cars, and two cars without motors.

The main line is about five miles and a-quarter, and a branch half a mile.

Working expenses, at per diem.

Power Station.		Road.	
Power	$0 83	Oil and waste	$1 00
Oil and waste	0 20	Brushes	0 30
Labour	3 00	Travellers	0 30
Depreciation on generator, at 3 per cent.	1 00	Labour	2 00
Depreciation on turbine, at 10 per cent.	2 70	Material for repairs of cars and line	1 70
		Depreciation on cars, at 15 per cent.	6 30
		Depreciation on line, at 10 per cent.	2 00
	$7 73		$13 60

Power station	$7 73
Road	13 60
	$21 33, equal to about £4. 7s. 6d.

Seven cars at 72 miles per car gives $3.06 (12s. 3d.) per car, or $0.0424 per car-mile (equal to about 2·08d.)

As these figures were made out for comparison with the cost of horse-power the wages of conductors and drivers were not reckoned. These would average about 3 dols. per car, bringing up the total cost per car-mile to about 4d. The motive power is obtained from Lock 12 of the Old Welland Canal, where there are 300 horse-power on a 12ft. 6in. fall. The rent paid to the Government for this is 300 dols. per annum, and as the turbine is only 125 horse-power, a balance of 175 horse-power remains. This is expected to be in use at no distant period, thus bringing the cost down very considerably. The generator is 100 horse-power separately excited; E.M.F. 500 volts, and is situated within a few yards of the middle of the main line. There are seven motor cars, four closed 10ft. long, which have the motor at the front, and three open 16ft. with the motor in the middle. The motors are all 15 horse-power. Besides these there are two without motors, which are towed by the closed cars whenever there is any increase of traffic, as on market days, &c. When full the closed cars weigh six tons and the open seven tons (2,000lb. to the ton).

The road on which the main line runs is a remarkably bad one for such a purpose. For about three-quarters of a mile from the St. Catherine's Terminus it is level enough, although not straight for more than 300 yards at any one part. It then takes a sudden turn to the right and follows the line of the Old Welland Canal until Thorold is reached, over a succession of hills.

To give an idea of what the cars have to overcome, it will suffice to mention that the end of the track at Thorold is 287ft. higher than at a point four miles distant, and that in this four miles there are several dips that bring up the total height to be mounted to about 370ft. Some of the grades are very bad, the steepest, although not the worst, being 1 in 15. The worst are two of about 1 in 20, these occurring on curves. Many of the curves are very severe, there being eight with radii between 35 and 66ft. in addition to numerous easier. For the greatest part of the distance the line runs on the top of a steep embankment, at the bottom of which is the canal, rendering slow speeds an absolute necessity for safety.

The conductors are two hard-drawn copper wires $\frac{3}{10}$in. diameter, supported on poles where the track is on the side of

Digitized by Google

the road and on cross wires made fast to the houses where it is in the middle. They are about 19ft. from the rails in most parts, although in one or two places they come down to 14ft. to pass beneath bridges. On each wire runs a simple brass or iron wheel, which is connected to the car by a flexible cable to conduct the current. The figures given above are those for the first nine months, namely, from October, 1887, to July, 1888, and looked at in this light, together with the fact that the machinery had at the start to tackle a Canadian winter, they may be considered remarkably good.

Until last October the road was run by horses, and the work was so hard that a pair was required to take a car (10ft. long) to Thorold and back. They made one trip, and had six hours' rest before making a second. It was very seldom that a horse went over the road three times in one day. Even then the conductor used to invite his patrons to walk up the steep hills Since those days, however, matters have altered. Firstly, there is a direct saving of 3 dols. 50 cents. per car per day; secondly, three cars used to be ample for the traffic, and during winter it was a good month when receipts covered working expenses, the last car getting in at 8:40 p.m. Last winter the increased traffic required four cars every day after 12 o'clock, the last one getting home at midnight. Seeing this unexpected increase of business the company had three large open cars built for summer traffic, and since the beginning of June have had to put six on the road as a regular thing. Another advantage is that before it was impossible to take all the passengers that frequently wanted to ride, as the horses could not draw them; now as many as can get a foothold anywhere get on. It may be as well to mention that on this continent they do not trouble about carrying only a certain number in a public vehicle, but let everyone who likes crowd in. On the 1st of July last (a public holiday) a crowd took it into their heads to come from Thorold to St. Catherine's to see a lacrosse match, and piled on to a car to the number of 125, making with conductor and driver 127. As none would get off, and all paid their fares, the conductor had to bring them. The great weight broke the car's back, but it got there all the same. On the 10th August I was riding on a car that was being towed. On the towing car I counted 50, and on the other 61, or 111 all told, plus about a dozen babies. This shows what a thoroughly good motor will do on an emergency. The people who use these cars would not go back to horses for anything. During spring the canal was emptied for a week, and the cars had to be run on the old plan, which resulted in much grumbling, and served as a good guide to public opinion.

A very important item is the matter of repairs to machinery. This has been very satisfactory, the only part that has required much attention being the brakes and the chains that run from the motor to the axle. The electrical part has stood the hard work well, and apart from the trouble that always occurs with new machinery everything has done better than the most sanguine hoped for. Altogether, the proprietors are satisfied that they have made a good investment.

In addition to the main line, which runs from St. Catherine's through Merritton to Thorold, there is a branch wholly in St. Catherine's, about half a mile to the Grand Trunk Railway, Welland Division Station, to which cars run to connect the trains. Another branch, about two miles, will be commenced shortly. This will run to the cemetery.

If any of your readers may happen to be travelling to or from Niagara Falls by the Grand Trunk Railway they will see this road, and pass within a few yards of the power station at Merritton. It will repay them to stay over for a few hours and examine it.—Yours, &c., H. E. DOLAN.

14, King-street West, Toronto, Ontario.
October 1st, 1888.

PRACTICE *VERSUS* THEORY.—ELECTRO-MAGNETIC WAVES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The remarkable leader in your issue of the 12th inst. states very lucidly some of the ways in which theory and practice seem to become antagonistic. There is, however, one point which does not, I think, receive the attention it deserves, which is, that it is the duty of the theorist to try to keep the engineer who has to make the practical applications straight, if the engineer should plainly show that he is behind the age, and has got shunted on to a siding. The engineer should be amenable to criticism.

Another point is this. It might appear from the concluding paragraph of the article to which I have referred that the points at issue between Mr. Preece's views and my own were mere matters of complicated corrections, not affecting the main argument much. But the case is far different. A complete change of type is involved.

Now, I shall have great pleasure, when opportunity offers, in endeavouring to demonstrate that such is the case, and that the despised self-induction is the great moving agent; that although Mr. Preece, in the presence of some distinguished mathematicians, recently boasted that *he* made mathematics his *slave*, yet it is not wholly improbable that he is a very striking and remarkable example of the opposite procedure; that although Mr. Preece, who, as a practical engineer, knows all about electro-magnetic inertia and throttling, does not see the use of inductance, impedance, and all that sort of thing, yet there is not wanting evidence to make it not wholly unbelievable that Mr. Preece is not quite fully acquainted with the subject as generally understood; that, for example, his co-efficient of self-induction is of very different size, and has very different properties, from the theoretical one; and that Mr. Preece's knowledge of the manner of transmission of signals, though it may not be "extensive," is certainly "peculiar."

I may take the opportunity of adding that on account of a certain peculiar concurrence and concatenation of circumstances last year rendering it impossible for me to communicate the practical applications of my theory (based upon Maxwell's views, so far as the higher developments are concerned), either *viâ* the S. T.-E. and E. or four other channels, the resultant effect of which was to screen Mr. Preece from criticism, combined with the fact that Mr. Preece, in his Papers to the Royal Society, British Association, and S. T.-E. and E. has taken his stand upon Sir W. Thomson's celebrated theory of the submarine cable, I have been forced, with great reluctance, to assume what may have appeared to be, superficially, an apparently unnecessarily aggressive attitude towards the said theory. But those who are acquainted with the subject will know that there is no antagonism whatever between the electrostatic theory and the wider theory; and those, further, who may be acquainted with the peculiar concurrence I have mentioned will understand the meaning of the apparent aggressiveness.

In addition, it seems to me to be almost mathematically certain that Sir W. Thomson would emphatically repudiate the very notion of applying his theory of the diffusion of potential to cases to which it does not apply, and to which it was never meant to apply; and I cannot find any evidence in his writings that he ever would have made such a misapplication.—Yours, &c., OLIVER HEAVISIDE.

P.S. Is self-induction played out? I think not. What is played out is what we may call (uniting the expressions of Ayrton, Preece, Thomson and Lodge) the British engineer's self-induction, which stands still, and won't go. But the other self-induction, in spite of strenuous efforts to stop it, goes on moving; nay, more, it is accumulating momentum rapidly, and will, I imagine, never be stopped again. It is, as Sir W. Thomson is reported to have remarked, with a happy union of epigrammatic force and scientific precision, "in the air." Then there are the electro-magnetic waves. Not so long ago they were nowhere; now they are everywhere, even in the Post Office. Mr. Preece has been advising Prof. Lodge to read Prof. Poynting's Paper on the transfer of energy. This is progress, indeed! Now these waves are also in the air, and it is the great "bug" self-induction that keeps them going.

On this question of waves I take the opportunity of referring to a point mentioned at the Bath meeting by Prof. Fitzgerald. That physicist, in directing attention to Hertz's recent experiments, considered that they demonstrated the truth of

Digitized by Google

the propagation of waves in time through the ether; but that, on the other hand, the waves sent along a circuit did not do so, because they might be explained by action at a distance.

It seems to me, however, that the more closely we look at the matter the less distinction there is between the two cases, and that to an unbiassed mind the experiments of Prof. Lodge, sending waves of short length into a miniature telegraph circuit, with consequent "resonance" effects, are equally conclusive to those of Hertz on the point named; in one respect, perhaps, more so, because their theory is simpler, and can be more closely followed.

But, after all, has it been demonstrated that we cannot explain the propagation of electromagnetic waves in time by action at a distance, pure and simple? I suggest the following as evidence to the contrary. Take the case of Maxwell's non-conducting dielectric. Let the electric current element *cause* magnetic force at a distance according to Ampère's law, and let the magnetic current element *cause* electric force at a distance according to the same law with sign reversed. Then

$$\text{curl } \mathbf{H} = \epsilon \dot{\mathbf{E}}, \text{ and } -\text{curl } \mathbf{E} = \mu \dot{\mathbf{H}}$$

follow, and propagation of waves in time follows. That is, by mutual action at a distance between electric current elements, and also between magnetic current elements, we get propagation in time. Of course the currents may be oppositely moving electric or magnetic fluids or particles.

Whether there is any flaw here or not, it is scarcely necessary for me to remark that I do not believe in action at a distance. Not even gravitational.

DUPLEX WORKING.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In *The Electrician* of October 5th, paragraph 5 of the Notes, you remark with regard to an improvement in duplex working by Mr. Melhuish, of the Indian Telegraph Department (quoting, I presume, from the *Indian Engineer*), that "in the ordinary methods of working duplex, the capacity of the wire is only increased so long as no correction is required by either of the receiving clerks; but directly a word misses fire the remaining pair of signallers are reduced to enforced idleness whilst the correction is being made . . . . . Mr. Melhuish's invention is intended to obviate this difficulty, and to enable either pair of clerks to send or receive at will."

En passant, the term "carrying capacity" is preferable to "capacity" in the above paragraph, for obvious reasons.

I am unacquainted with the methods of working duplex employed on the Indian Government lines; but if, because a repetition (or, as it is termed in submarine telegraphy, an "R Q") is required, two of the four clerks are reduced to enforced idleness, it is certainly a good thing for the Indian Government that Mr. Melhuish has come forward with an improvement.

These "R Q's" undoubtedly diminish the "paying-carrying capacity" of the wire or cable, in that they occupy the line for a certain percentage of the time which would otherwise be devoted to paying messages; but this applies also to simplex working, although perhaps in a lesser degree. In our duplex working on submarine cables a constant stream of messages, interpolated with the necessary "R Q's," passes both ways, and there is never any "enforced idleness" on the part of the operators.

If the receiver at station A requires a repetition in a certain message, he writes down the number of the message and the "R Q" required on a slip of paper, and hands it to his sender, who in turn passes it on to station B. The receiver at station B in his turn notes the "R Q" on a slip, and passes it to his sender, who then gives the receiver at A the required information. Thus there is no "enforced idleness," as I have remarked, and also either pair of clerks can and *do* send and receive at will.

In conclusion, if Mr. Melhuish's invention will enable us to weed out these "R Q's," and drop them harmlessly through another instrument without interfering with the paying traffic, then indeed it will be of considerable value; but, as you remark, "an additional instrument or two, and a rearrangement of batteries" is rather vague data to go upon.—Yours, &c.,

F. ALEX. TAYLOR,
Assistant Superintendent and Electrician,
Eastern Telegraph Company.

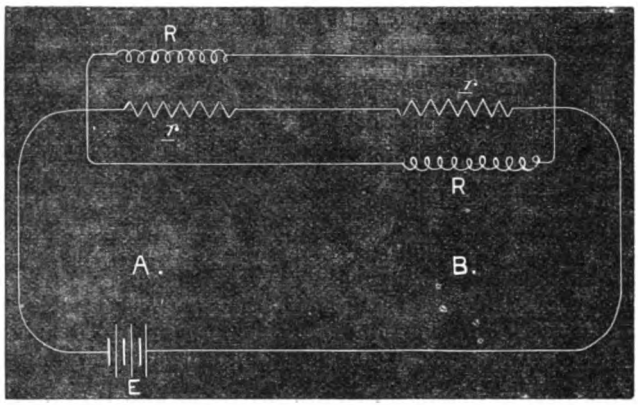
Gibraltar, Oct. 12, 1888.

ELECTRO-CALORIMETRY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Will you allow me to point out that the arrangement employed by Profs. Stroud and Haldane Gee for heating the baths (*Electrician*, p. 705) is electrically in unstable equilibrium, since any difference of temperature between the baths causes less power to be spent in the cooler one, thus tending to increase the difference. With the coils in parallel less power would be spent in the hotter bath, but the method would still be imperfect from the want of equality of heating at different temperatures.

Coils may, however, be so arranged as to completely overcome these defects in an otherwise very simple and convenient



apparatus. In the figure let A and B represent the two baths and the coils therein, each bath being heated partly by a series coil of r ω, partly by a parallel coil of R ω. All four coils should be made of the same metal.

The necessary relation between R and r to secure equal heating may be found by writing

$$\frac{d \text{ watts in A}}{d\theta} = \frac{d \text{ watts in B}}{\theta d},$$

where θ is the difference of temperature between the baths. When worked out this gives $R = 4r$, a result which is obviously true provided the coils have a small temperature coefficient.—Yours, &c.,

SYDNEY EVERSHED.

Westminster, Oct. 17, 1888.

DR. LODGE'S EXPERIMENTS ON LIGHTNING.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: With reference to the phenomena observed by Dr. Lodge in the discharge of Leyden jars, recently described in your journal, perhaps some light would be thrown on their cause if the direction of the secondary discharge were ascertained.

I think it will be found that the induced discharge set up on the passage of the Leyden jar discharge passes through the comparatively good conducting medium afforded by the spark itself and takes the alternative circuit.

In everyday experience I find that induced discharges of no great strength from electro-magnets will pass through a voltaic arc in the opposite direction to the current flowing in the latter; therefore I do not think it impossible that a similar discharge from a curved wire should pass through a conductor which affords it a passage in the manner found by Dr. Lodge.

It does not appear to me that there is in the experiments sufficient resemblance between the circumstances of condenser or Leyden jar discharges and lightning. In the case of the

Digitized by Google

latter we may suppose that the upward movement of masses or layers of moist air oppositely electrified to the surface of the earth, creates with the increase of distance an increasing potential, in the manner of an electrophorus, the air in this case taking the place of the dielectric, and the earth that of the cover.

The discharge occurs when, by the separation of the electrified air or cloud and the earth, the potential is sufficiently increased, and is probably aided and its course determined by the condensed moisture which would be formed by the warm air ascending into upper and colder regions.

The ramifications of a lightning flash show that a number of small streams unite usually into one or more larger discharges, as would occur by removing the cover of an electrophorus to a short distance from the dielectric, and then tilting it slightly to concentrate the charge in the most proximate parts. Whether lightning be formed in this manner or not, it will not have a continuous conducting condenser surface, like that of a Leyden jar, to receive the induced discharge from a conductor, and therefore the induced effects of lightning in a rod will differ from those produced in a conductor by a Leyden jar discharge, and will sooner disappear.

To provide an electrostatic reservoir for the induced discharge, such as the Leyden jar used in the experiments, might cause oscillations similar to those which usually prevent magnetisation being properly carried out by means of condenser discharges.

It is well known that Leyden jar discharges cannot be depended upon, without certain precautions, to magnetise uniformly in one direction, and the reason is to be found in the reception of the induced discharge by the jar until the fall of potential in the conductor allows it to redischarge itself through the helix, when it will demagnetise or even reverse the direction of the magnetism caused by the original discharge.

It can be easily seen that when once a spark has established a conducting path, the induced sparks can pass and repass in a series of oscillations until they are too feeble to overcome the air resistance.

Perhaps another set of experiments with a large electrophorus, and in which the direction of the abnormal discharge, if present, is ascertained, might lead to the elucidation of the apparently paradoxical results obtained.—Yours, &c.,

17, Cornhill, E.C., October 16th, 1888. F. HIGGINS.

LIGHTNING PHOTOGRAPHS.

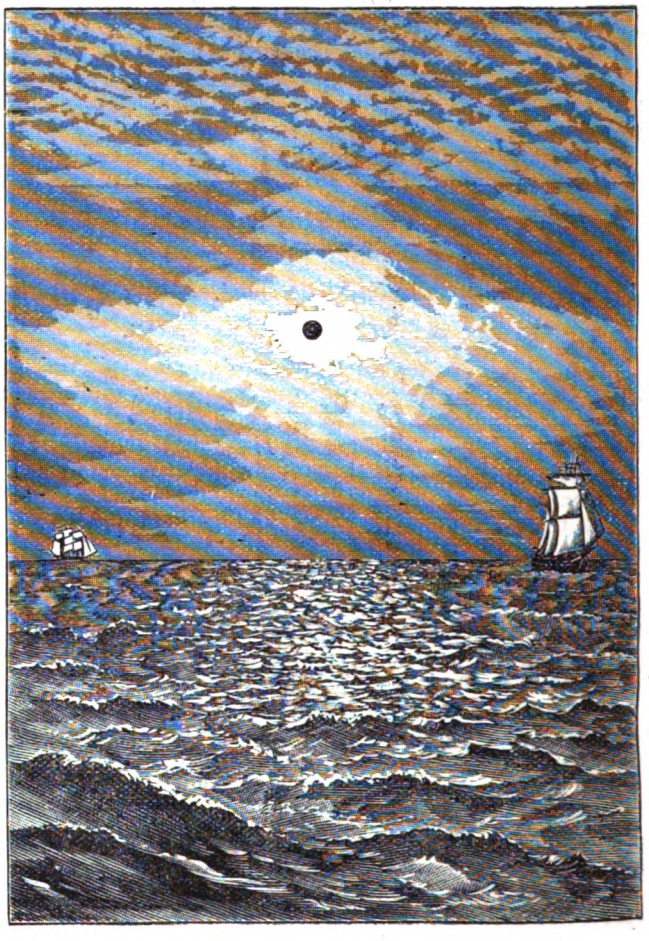
TO THE EDITOR OF THE ELECTRICIAN.

SIR: I have seen with much interest the three engravings in *The Electrician* of the 5th instant. In Fig. 2 is shown what is called a "*dark*" flash. Now, this term, whatever it is intended to signify, is hardly correct, for it is really the result of a very *bright* flash. It is a well-known fact to most photographers that if a dry plate is ever exposed in any way a reversed action takes place when the plate is placed in the developer, and instead of a dense negative being the result, it is found to be thin and flat. If the plate has been very much over-exposed the reversed action is so great that little or no silver is deposited in developing. It is manifest that if only a portion of the plate is thus over-exposed the reversed action takes place on that part alone, while the rest of the plate may be correctly exposed, or even under-exposed.

I enclose two photographs, illustrating this effect; the view has been taken with the sun included, to obtain a moonlight effect, the image of the sun being overpoweringly brilliant, as compared with the light on the rest of the plate. The reversed action necessarily takes place on that part, and in the print the sun comes out black, as in photograph No. 1. No. 2 is a print from the same negative after the sun has been painted out with black. Applying this principle to the photograph in question, the "*dark*" flash would be produced by a very intense flash of light, causing the reversed action on the plate, and, of course, it will come out black in the print. I have not had the opportunity of seeing a negative with a "dark" flash; but should I be correct in my explanation the "*dark*" flash should have "fogged" the plate to some little distance round its course.

With reference to Fig. 3, the ribboned appearance at the edges, spoken of, but not visible on the engraving, is doubtless due to the lens not "covering" the plate, the duplication being caused by astigmatism. Again, you mention that this flash has a tendency to form bright spots at places; this is easily accounted for. If a flash of the meandering type could be taken in two positions at right angles to each other it would be found that these bright spots are produced by the flash striking in a direction perpendicular to the camera, and thus giving a little longer exposure to those parts.

Last year you illustrated a flash of the meandering type, which is strangely similar to a flash I obtained on the same night; it has formed several loops, and several little balls of light at the sudden bends. On examining my negative I came to the conclusion that the loops are caused by the flash striking in a direction perpendicular to the camera, and in doing so forming a turn in a spiral, while the little globes of light are due to the same cause, only the spiral is too small for the convolutions to appear separate.



Engraved from Mr. Adams's Photograph "No. 1."

In the photographic exhibition at Pall Mall last year were a series of lightning photographs taken during the great storm (August 17th, 1887). I think there were at least six taken at short intervals. Amongst these was one which caused me some wonder, as I had not then heard of the oscillatory theory; it was a solid flash, not a meandering one, which was repeated again and again, if I remember right more than six times, each repetition following exactly the same course, and each succeeding one becoming fainter. This photograph, I am inclined to think, is of the utmost importance, as evidence in support of the oscillatory theory, for the flashes were close to each other—in fact, were partly superimposed—and had the camera been moving while the flash was striking, each succeeding flash would be registered by the side of the others, as was the case.

Some mention of a similar flash has been made in the discussion at the B.A., and I believe the cause has been ascribed

Digitized by Google

to reflection from the back of the plate. I hardly think this is possible, as the film is opaque and the light behind the plate is diffused, and what reflection there is will only produce "halation;" also reflection is reduced to a minimum by a dead black backing. Again, why should duplication by reflection take place only in certain cases? I have never seen it in photographs of ordinary subjects, and we have numbers of lightning photographs without a sign of it.

I feel inclined to believe with Prof. Lodge that some flashes are oscillatory and some are not. Those that meander through the air, striking at nothing in particular and vanishing into space, should, I think, be classed as non-oscillatory, while, those which strike direct from the clouds to the earth—thick heavy flashes—probably oscillate until the potential between the points is equalised.

While on this subject I should like to learn if the following phenemena can be accounted for:—One evening last year, after sunset, I was watching a dark black cloud, with clearly defined outline, high above the horizon, when from the top flashes of lightning shot upwards into quite clear atmosphere. There was nothing visible for it to strike at. I understand from a gentleman who has spent some years in India that it is not uncommon for flashes to strike across the clear blue sky in which there is no sign of a cloud.

In conclusion, I should recommend all those who are interested in the study of lightning flashes to refer to negatives or glass positives for their information, as there is much interesting detail lost in silver prints.—Yours, &c.,

W. P. ADAMS, A.K.C., A.S.T.E.

Springwell, Barnes, October 8, 1888.

[Our correspondent's explanation of the "dark flash" is one which is likely to occur to every photographer, and in the discussion on Lightning in Section A at the recent meeting of the British Association it was carefully considered (see *The Electrician*, September 28th, p. 674). But if our correspondent will refer again to the engraving on p. 699 he will notice that a "white" flash lies across the dark one in three several places; and no one has yet shown how this is to be reconciled with the over-exposure theory.—ED. *E.*]

THE LIGHTING OF BARNET.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Since we have obtained the contract and have carried out the lighting at Barnet (the first town in the United Kingdom whose streets are entirely lighted by the electric light) we have been subjected to all manner of abuse from interested opponents in the local papers and elsewhere, chiefly in the shape of anonymous letters (the most contemptible form of criticism), the merest perusal of which is sufficient to show their origin.

The report of a visit to see the electric light at Barnet was published in a Blyth paper as coming from a Blyth man; this report, it is believed, was written by an unfriendly gas shareholder, a resident in Barnet. Of course, it was copied in the *Barnet Press*, and extracts, we regret to say, in some of the electrical papers. The malicious and yet ludicrous nature of that report will be apparent when it is known that the writer states that electric light lamps (of 50 candle-power) gave much less light than an ordinary gas lamp (of about 14 candle-power). The absurdity of this statement is evident by a glance at the two lamps. The writer of the report makes other misleading and erroneous statements.

The editor of the *Luton Times* was, we are so informed, invited to Barnet to write down the electric light, and after spending "a very happy evening" (*vide* report), proceeds to do so in a very amusing, but, of course, totally erroneous and misleading manner.* Many other equally stupid and misleading letters and criticisms have appeared, and perhaps a few facts as a corrective may not be out of place.

Now as to the light. This is the first installation of town lighting by incandescent lamps in series, and we had enormous difficulties in obtaining the novel fittings in the short time at our disposal. Our contract was not signed until July 6th, we did not obtain the official plan showing the position and number of the lamps until some time after, and we found that we had to fit up 71 street lamps, posts, five miles overhead wire, nearly one mile of underground wire, dynamo, engines, &c., in about five weeks. We asked the Local Board for six months in which to do the work permanently. This they were unable to grant, as the gas company's contract expired at the end of August, and we had to light up on the 1st September. Under such circumstances we were compelled to use temporary appliances, which we are now replacing by permanent plant, and we expect shortly to have our duplicate sets of engines, dynamos, &c., in proper working order.

Our contract is for 71 thirty-two candle-power lamps. We have substituted many 50 candle-power lamps in the High-street, &c., in order to make a good display, and the opinion of competent and unbiassed persons is that the light is a success, and we are much gratified at the orders we have received for private lighting and the general good feeling shown towards us by the townspeople of Barnet. The Barnet lighting is, no doubt, the stepping-stone to an immense business in town lighting. We have already had numerous applications from other towns, and we consider the unfair criticism we have received is due to the envy of our opponents, and we take it as a tribute and measure of the success we have already achieved.

* We have deleted a sentence here which possesses no interest of a technical character.—ED. *E.*

COMPANIES' MEETINGS & REPORTS.

Australian Electric Company.

An adjourned special general meeting of the shareholders of the Australian Electric Company (Limited) was held in Melbourne, on Thursday, August 23rd, for the purpose of confirming resolutions passed at a meeting on the 31st of July, winding up the Company, and authorising liquidators to transfer its business to a new company having extended powers. Mr. Levien, M.L.A., occupied the chair.

Mr. S. J. WALKER said that he must object to the winding up of the Company, as it appeared from the last report which had been brought up that its business was in a flourishing condition. The buildings had been enlarged and the plant increased, so that there was no need to merge the Company into a new one.

The CHAIRMAN explained that the reason why the Company was being wound up was not because there was any scarcity of funds, but because the present Articles of Association did not allow of such an expansion of operations as was desirable.

The resolutions of the former meeting, that the Company should be wound up voluntarily, and that liquidators should be appointed to transfer its business, property, and goodwill to a company registered under the Company's Statute 1864, were confirmed.

It was also resolved that Messrs. Levien, M.L.A., H. Fink, and Captain Rowan should be the liquidators of the Company, the fee of each being fixed at 50 guineas.

The Western and Brazilian Telegraph Company (Limited).

Report of the Directors to be presented at the sixteenth ordinary general meeting of the Company, held at Winchester House, 50, Old Broad-street, on Thursday, the 25th October, at 12 o'clock :—

2. The total earnings amount to £86,874. 7s. 11d., as against £81,419. 13s. 1d., an increase of £5,454. 14s. 10d. compared with the half-year to 30th June, 1887.

3. The working expenses, exclusive of renewals of cable, amount to £32,813. 7s. 10d., as against £33,412. 17s. 11d., a decrease of £599. 10s. 1d.

4. Including the amount brought forward from 1887 (£3,464. 8s. 7d.) the balance to the credit of the revenue account is £57,526 8s. 8l., from which has to be deducted £13,500 for debenture interest, leaving £44,025. 8s. 8d., of which £7,500 has been placed to the renewal fund, and £6,000 to the debenture redemption fund. This leaves £30,525. 8s. 8l. The Directors recommend the payment of a dividend on the Ordinary Shares for the half-year of 2 per cent., or at the rate of 4 per cent. per annum, carrying forward £3,293. 16s. 8d. At the corresponding period last year the dividend was at the rate of 2½ per cent. per annum.

5. In the case of shares which have been divided into Preferred and deferred, the whole of the dividend now recommended will be payable to the Preferred shareholders, who are entitled to the payment in each year of 5 per cent. "in priority to any payments to the holders of Deferred Ordinary Shares." This matter will, of course, adjust itself at the end of the year.

6. The agreement between this Company and the London Platino-Brazilian Telegraph Company, referred to in the last report and since ratified by the shareholders, has been carried out, and up to date 34,770 shares have been transferred by shareholders in exchange for 20,862 shares of this Company, and numerous further exchanges are in progress.

7. In the accounts now submitted no credit has been taken for moneys due on account of the half-year from the Platino Company, that company's accounts having hitherto been made up in November and May, owing to their later arrival in this country.

8. The lines of the Company are in good working order, and reference to the figures will show an increasee in the revenue with a slightly diminished expenditure.

9. The dividend will be paid on the 1st November.

CITY NOTES, &c.

ANGLO-AMERICAN TELEGRAPH COMPANY.—At a meeting of the Board of Directors of this company, held on Friday last, it was resolved to declare an interim dividend for the quarter ended September 30th, 1888, of 7s. 6d. per cent. on the Ordinary stock, and 15s. per cent. on the Preferred stock, less income-tax, payable on the 1st November to the stockholders registered in the books of the company on the 9th October.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended October 12th, 1888, amounted to £5,061.

DIRECT UNITED STATES CABLE COMPANY.—The Board of Directors of this company have resolved upon the payment of an interim dividend of 2s. per share, free of income-tax, being at the rate of 2 per cent. per annum, for the quarter ended September 30th, 1888, such dividend to be payable on and after the 24th inst.

EASTERN TELEGRAPH COMPANY.—This company announces the payment by interest warrants, on the 1st November prox., of interest for the half-year ened October 31st, on their Four per Cent. Mortgage Debenture Stock. The books will be closed from October 27th to November 1st, both days inclusive.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended October 12th, 1888, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company, were £4,215.

THE NON-CONDUCTOR OF ELECTRICITY.

WAREHOUSE.

VULCANISED FIBRE,

PATENTED.

This new material is supplied in two qualities, Flexible and Hard.

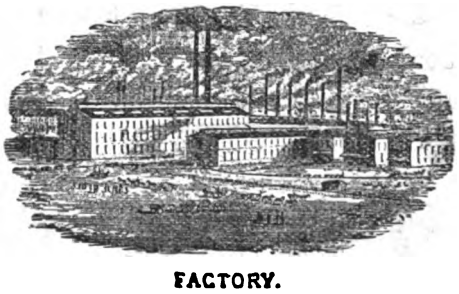
The FLEXIBLE is a substitute for Leather, Rubber, Gutta Percha, &c., and is extensively used by Brass Founders, Axle Makers, Hydraulic, Sanitary, and other Engineers, Pump Makers, Carriage Builders, &c.

It makes the best Hot and Cold Water Packings, and for Axle Washers of all kinds it is unequalled.

The HARD is a substitute for Metals, Hard Wood, Ivory, Vulcanite, Ebonite, &c., and is a good Insulator.

Sold in sheets, 5ft. 6in. by 3ft. 6in., varying in thickness from 1-50in. to 1in.

FLEXIBLE, 2/- per lb.; HARD, 2/3 per lb.



FACTORY.

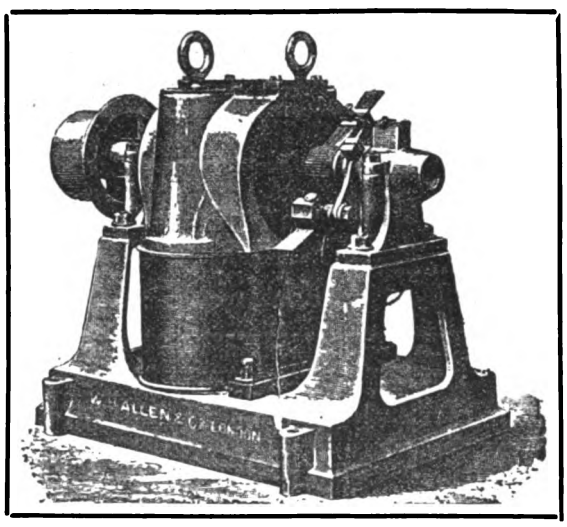
W. H. ALLEN & CO., York Street Works, Lambeth, S.E.

MAKERS AND PATENTEES OF THE

"KAPP DYNAMO."

The only Dynamo that has the following combined advantages: Perfect Ventilation, Positive Driving, No Wasteful Internal Currents, No Heating, Self-Regulation, Slow Speed, and Good Workmanship.



The most reliable for Arc or Incandescent Lighting, Electro-deposition of Metals, Charging Accumulators, and Transmission of Power.

Made direct acting with Allen's High-speed Engine, for long and continuous runs and constant use, without break-down or repairs.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL SCIENCE, INDUSTRY AND ENGINEERING.

No. 545.—Vol. XXI. FRIDAY, OCTOBER 26, 1888. Price 4d.

NOTES.

By the courtesy of Dr. Oliver Lodge we are enabled this week to publish an interesting letter from Dr. Hertz on lightning conductors. This will be found in our correspondence columns.

The members of the technical press who were invited to visit the works of the London Electric Supply Corporation at Deptford on Wednesday last came away with a vivid impression, not only of the magnitude of the undertaking, but also of the sheer audacity—there is no other word for it—of the promoters. We need not repeat here the details which we give in a later column, but we venture to assert that in the whole range of engineering enterprise there is nothing which has demanded more skill, ingenuity and daring than the project, now well under weigh, for the lighting of central London from the Deptford station. The remarkable character of the enterprise is not lessened by the fact that the entire credit of the designs, from the beginning to the end, is due to Mr. S. Z. de Ferranti, and to him alone. Later on we shall of course go at full length into a technical description and discussion of the arrangements. At this moment the only approach to criticism which we think it necessary to make is this: that the plan of relying upon a single engine and dynamo—however perfect—is one which must depend for its justification upon the actual success which it achieves in practice.

Our readers will generally be aware that the "London Electric Supply Corporation" is the lineal descendant of the Sir Coutts Lindsay Electric Light Company, of Grosvenor Gallery fame. The following account of the origin of the latter company, with which we have been supplied, will therefore be read with interest:—

"It is now some four years ago that Sir Coutts Lindsay made up his mind to light the Grosvenor Gallery by electricity, and made arrangements to that effect. On mentioning the fact to a neighbour, that gentleman at once said, 'Put down twice the necessary machinery and produce twice the current you require, and let me have what you can spare.' Very soon other neighbours joined in this request, and Sir Coutts Lindsay began a moderate installation; but, long before it could be completed, the demand became larger and larger, and additions were made to the original intention. At length Sir Coutts Lindsay associated a few gentlemen with himself, among them the Earl of Crawford and Lord Wantage, and a small private company was formed with the title of 'Sir Coutts Lindsay and Co. (Limited),' but, owing to its origin, familiarly known as the Grosvenor Gallery Company. However, although thus enlarged to a company, the demand for electric supply increased so steadily and rapidly that the originators of the undertaking soon found that they must enter into a wider field, and the development resulted in the formation of the London Electric Supply Corporation. The corporation, while constructing their great central station at Deptford, have carried on and developed the original undertaking, until at the present time they are supplying from their Grosvenor Station some 33,000 lamps."

The formation of the Electrical and Allied Trades Section of the London Chamber of Commerce is now an accomplished fact, and in another column will be found the names of the thirty-three members of the permanent committee whose election took place on Monday last. We think that it will be generally admitted that the organising committee—whose most important duty was the determination of the number of members to be apportioned to the representation of each class of trade—discharged their labours in a satisfactory manner. It was undoubtedly a wise arrangement to defer the election of the fifteen members which are required to bring up the committee to the full total of forty-eight, until the numerical strength of the section shall have further increased. We also think that the list of names already chosen is such as will command a general feeling of confidence.

Turning to the proceedings of the meeting on Monday last, it must be confessed that the differences of opinion which were disclosed—or, rather, were emphasised, for their existence was already well known—are of a serious character. We have never hesitated in our conviction that any attempt to control prices would be a mistake, and would, moreover, be foredoomed, sooner or later, to failure. No individual manufacturer, whether a member of the Section or not, could be bound by any resolutions of this character, and the attempt would not conduce to that harmony of feeling which it is one of the objects of the movement to promote, and which is so especially desirable in the *quasi*-scientific industries. With regard to the regulation of wages, although our views are less pronounced, yet we are inclined to think that similar considerations may be applied. We are confident that the Section will find abundance of useful and necessary work lying ready to its hand, and we trust that—at any rate, so long as this is the case—no attempt will be made to force on the consideration of questions whose discussion is repugnant to so many of the members, and which can well await further developments.

Digitized by Google

THE following is a copy of a circular with which the house holders in the Camden Town district have recently been inundated :—

"THE SUBURBAN ELECTRIC SUPPLY COMPANY.

"Temporary Offices—96, Camden Road, N.W.

"The above Company is prepared to receive applications for Electric Current to be supplied at a Yearly Rental per Lamp, payable quarterly, the first payment being due three months after installation. Three months' notice in writing to be given for a discontinuance of the supply. The current will be available from one hour before sundown to 1 a.m. in the first instance, and on a sufficient number of subscribers being obtained the current will be continuous. No less number than 20 lamps of 10 candle-power will be installed, or one arc lamp of 1,000 candle-power. For further information apply to the manager as above."

The tariff is fixed as follows :—£1 per 10 candle-power lamp, £2 per 20 candle-power lamp, £3 per 32 candle-power lamp; arc lamps, £18 per 1000 candle-power. With this is enclosed a "wiring estimate," which reads as follows :—

"WIRING ESTIMATE.

"To supplying and fixing all the necessary cable, flexible cords, switches, cut-outs, holders, lamps, shades, casing, ceiling-roses. The lights to be so arranged as to meet the requirements of each individual consumer, and in accordance with the Phœnix Fire Office Rules. The whole to be carried out in the most workmanlike manner, including all labour and supervision, for the sum of Twenty-two Shillings and Sixpence per light.

"*Terms:* Cash when the light is turned on."

At first sight it strikes one as rather singular that in a document ostensibly emanating from a public company (although it will be observed that the word "Limited" is not employed) no information is given as to the technical, financial or commercial position of the concern, nor is any signature attached or any other guarantee of genuineness vouchsafed. We have therefore deemed it desirable to institute inquiries into the position and prospects of the "Suburban Electric Supply Company," with a view of discovering the whereabouts of their central station, the system adopted, the extent of their financial resources, and the names of the promoters, directors, engineers, &c.

As a result of these inquiries we are now in a position to publish a complete and exhaustive history of the whole undertaking. At the present moment, however, we confine ourselves to the following remarks :—(1) The Suburban Electric Supply Company is a private venture, and has not, up to the present, been placed upon the Register of Public Companies. (2) Our representative was, unfortunately, unable to find the manager himself, but he is able to state, on the authority of the office boy, that the central station is nearly complete and will be ready to start in November—the boy could not recollect its whereabouts. (3) This state of things reflects the highest possible credit upon the contractors whoever they may be for we have the best possible reasons for asserting that less than one month ago the contract had not been signed, nor had the system of operation been determined on. (4) Notwithstanding the forward state of the preparations, the managerial, clerical and technical staff are at the present moment concentrated in one individual, whose name we need not for the present disclose.

THE long and the short of the business is, we believe, simply this. A gentleman having some spare time on his hands, and taking a benevolent interest in electric lighting, conceives the idea of working up a connection in one of the inner suburbs, with the intention of disposing of the business so formed to any electric lighting contractors or others whom he can interest in it. Very well—we have no legal ground for complaint, only we think it a most unfortunate proceeding in respect of the true interests of electric lighting, and we consider it our duty to state the facts as far as we know them.

ONE of the finest specimens of mill lighting which we have come across has recently been carried out by the Schmidt-Douglas Electric Lighting Co., of Bradford, for Messrs. HOLLINGRAKE and CLEGG, worsted spinners, of Halifax. On the occasion of a recent visit we found 500 incandescent lamps and 60 arcs, all of which are run from a single Schuckert dynamo at 110 volts, with a steadiness which leaves nothing to be desired. The dynamo is driven from the mill engine, which is a magnificent machine, capable of developing over 1,000 horse-power. This mill is almost entirely devoted to the spinning of coloured yarns, and the advantage of the light in enabling colours to be dealt with is fully appreciated in the woollen trade, and we have no doubt that a considerable extension of mill lighting in the West Riding may be confidently looked for in the near future. It is, however, an unfortunate fact that a good deal of bad work has been done in the district, and this has had the inevitable effect of retarding progress. In this very mill the present installation is the third which has been put in.

AT Birmingham this week we witnessed a trial run of an electric tramcar which has been built by Elwell-Parker (Limited) for the Birmingham Central Tramways Company. The car is intended for use as a locomotive, to draw a detached train behind it, and since it has not yet wholly emerged from the experimental stage we do not propose at the present moment to describe the arrangements in detail. We may, however, say that the Tramway Company has been well satisfied with the results hitherto obtained, and that, as regards the design of the motor, gearing and equipment, the details are worked out in a manner well calculated to sustain the reputation of the Wolverhampton firm. Although this car is little more than half the size and weight of the steam locomotives in use at Birmingham, yet the dynamometer tests showed that it was able to exert a tractive force 66 per cent. greater. The Birmingham Central Tramways Company are looking into the question of electric traction with perfectly serious intentions. Their experience of steam locomotives - of which they possess no less than 76 - is not of a wholly favourable character. The wear and tear is something enormous. A tyre of 4 inches in thickness is only good for 27,000 miles—that is, about nine months' use—by which time it has been reduced in thickness to 1½ inch, and this is in addition to an equally excessive wear of the axles. What this means in the way of expense and trouble for continual adjustment in case of so complex a machine some of our readers will be able to appreciate. With electric traction the greater part of this trouble will be

Digitized by Google

avoided. The company also find that the public prejudice against the steam cars—"Juggernauts," as they are called in Birmingham—increases rather than diminishes with lapse of time. With regard to cable haulage, which is in use on one part of this company's lines, their experience seems to be only moderately satisfactory. We gather that they do not propose to extend the system beyond the limits at first contracted for, some portion of which has yet to be laid down. Elsewhere we give some detailed figures as to the cost of working per car mile which this company incurs for horse, cable and steam traction respectively. This will be useful for purposes of comparison.

A CORRESPONDENT sends the following, "with best wishes for the learned editor's speedy recovery from temporary insanity, caused by reading 'fairy tales of science'":—

"Etheric force" has found a formidable rival in "carbodium." According to a long extract in the *Globe* from an American source, an inventive mechanic of Cleveland City has been spending a lifetime in solving the profound problem of "generating heat from electricity." The solution of all his difficulties is "carbodium," a composition which "looks like a lump of coke." When connected to two wires this mysterious substance yields a heat, "not dry like a furnace, nor yet damp, but that pleasant warmth felt on a spring day." We much fear, however, all this must be taken *cum grano salis*, for we learn further that this historic interview took place in the inventor's little shop back, "where one feels the very influence of the subtle fluid on the body, and even on the brain," and therefore the narrator can scarcely be held responsible for his actions. The whole conception is too startlingly original, daring and profound for immediate acceptance.

Alpignano.—The central lighting station of Alpignano (Italy) started running on the 23rd September. Cruto lamps are employed.

Personal.—Messrs. Sir W. J. Armstrong, Mitchell and Co., of Elswick, have appointed Mr. A. A. Campbell Swinton their permanent consulting electrical engineer.

Telegraphy and Telephony in Austria-Hungary.—The Hungarian Budget for 1889 contains an item of 60,000fl. to be appropriated to the development of the Telegraph system, and for the construction of a Telephone between Vienna and Pesth.

The Institution of Civil Engineers.—There are now on the books of this society 1,614 members, 2,499 associate members, 458 associates, 19 honorary members, and 939 students, together 5,529, being an increase at the rate of 3¾ per cent. during the past twelve months.

The Electric Light in Mexico.—The last mail from Mexico states that the public electric light service in that capital has been augmented by 300 additional lights, contracted for by the City Council. The city of Tehuacan is shortly to be illuminated with the electric light.

The Electric Light at Suakim.—The Eastern Company's ship "Electra" arrived at Suakim on Tuesday last, and her electrical and engineering staff has been placed at the disposal of the Government for the repairing of the electric light on the Shata Gate, which operation is expected to take about a week.

India Rubber, Gutta Percha and Telegraph Works Company (Limited).—The Portuguese *Diario do Governo* contains a decree from the Minister of Marine conceding to this company a prolongation of the period originally fixed for the laying of the submarine telegraph cable between Loanda on the West Coast of Africa and Cape Town.

Interruption of the Australasian Cables.—The Eastern Extension, Australasia and China Telegraph Company announce that telegraphic communication is again interrupted with Australia and New Zealand, owing, it is believed, to the accidental breakage by the company's repairing ship of the duplicate cable whilst renewing a portion of the original cable off the Lombok Straits. The ship is on the spot, and it is hoped that communication will be restored very shortly.

Leeds.—The Leeds Corporation have recently received a number of applications from electric lighting agents and syndicates with a view to the installation of the electric light in certain districts of the borough, and it is probable that the whole subject will shortly be brought before the Town Council. In the meantime the Electric Lighting Committee has instructed the Borough Surveyor to prepare a scheme for lighting a sectional area of the borough, starting with Briggate, Boar-lane, and Commercial-street, with the view of supplying the light to the public. The work is to proceed without delay.

Fleetwood.—A town's meeting was on Monday night held in the Fielden Public Hall, Fleetwood, to hear the report of the deputation appointed several weeks ago to inquire into the cost and methods of lighting in other towns. One conclusion the committee had arrived at was that in a town like Fleetwood, where the cost of gas is over 4s. per thousand cubic feet, the introduction of the electric light would insure a considerable saving. The meeting resolved—"That the Improvement Commissioners be requested to take into consideration the recommendations made in the report, with a view to the introduction of the electric light or other light into Fleetwood."

Palermo.—The following information relating to the present position of electric lighting at Palermo may prove of interest. The principal streets and squares are lit by 100 Thomson-Houston arc lamps. The Bellini Theatre, the Hotel de Ville, and several other buildings are lit by 16 and 32 candle-power Edison incandescent lamps, run off Zipernowski-Déri transformers. The central station is 3 kilometres outside the town, and the insulated copper conductors are all run overhead. The consumers are charged by meter or by contract. The Aubert meter is used for arc lamps and the Cauderay meter for incandescent lamps. The prices charged are 50c. per arc lamp per hour, and 10c. per incandescent lamp per hour.

New Electrolytic Treatment of Copper Solutions.—It is reported that the mining engineer who is at the head of the Official Department of Mining in Spain has invented a new process connected with that employed at Rio Tinto and similar mines, to obtain the metal from weak solutions of sulphate of copper. The object of the process is to obtain the copper in the pure state as electrolytic copper, instead of in the form of precipitates. Laboratory experiments have been made with solutions brought from the Rio Tinto and the Lagunazo mines. These proved successful, the process being exceedingly simple. It is stated that of the copper contained in the solution 78 per cent. is obtained as pure electrolytic copper, and the remainder only has to be refined. The Lagunazo mines are said to be about to employ the process on a large scale.

Liverpool.—The Watch Committee of the Liverpool City Council, at their last meeting, had a letter before them from the Liverpool Electric Supply Company (Limited), applying for the consent of the Corporation to the company making

Digitized by Google

application to the Board of Trade for a provisional order under the Electric Lighting Act, 1888. The committee, after considering the matter, passed a resolution that as the company are only just beginning to work under the Liverpool Electric Lighting License, 1888, which has been granted by the Board of Trade, they be informed that until sufficient time has elapsed to enable the Council to see how they have carried out the provisions of the license, the committee cannot recommend the Council, as the local authority under the Electric Lighting Act, 1888, to consent to the company making an application for a provisional order.

Electrolytic Formation of Aluminium Alloys.—M. Jules Dreyfus has recently devised an apparatus for obtaining aluminium and other metals in the form of alloys. The apparatus consists of a carbon crucible, having a hole at the bottom plugged with carbon. The top of the crucible is closed by the positive electrode, while the bottom is in connection with the negative pole. The process is commenced by placing some copper in the crucible, and passing a current through it. As soon as sufficient copper is deposited to form the negative electrode, aluminium is placed in the crucible. The aluminium dissolves, and is carried to the copper, producing bronze, while the oxygen combines with the carbon. Care must be taken to constantly add copper and aluminium. The carbon crucible consists of thick plates, which can be replaced as they are eaten away.

The Strand District Board of Works.—At a meeting of the Board held on Wednesday, 17th inst., letters were read from the Electric Supply Corporation (Limited) and Messrs. Deacon, Gibson and Co. (the company's solicitors), the former asking for a license to supply the electric light to the district, and the latter urging that the application made by the company be acceded to. The company's letter was accompanied by several memorials, signed by inhabitants of the district, in favour of their application.—Mr. Biggs pointed out that the Board had already passed a resolution in favour of another company, and unless that was rescinded it was impossible to grant the application.—Dr. Sandwell moved that the matter be referred to the Lighting Committee for consideration and report, but, after discussion, the motion was allowed to stand over till the next meeting of the Board, a special meeting to be held during the interim for the purpose of rescinding the previous resolution.

Birmingham.—The annual meeting of the Town Council on the 9th of November will, after the election of the Mayor, be made special to consider the notice given by Messrs. Barlow, Smith and Pinsent, solicitors, on behalf of their clients, Messrs. Arthur Chamberlain and George Hookham, of New Bartholomew-street, Birmingham, electrical engineers, of the intention of the said Arthur Chamberlain and George Hookham to make application to the Board of Trade in pursuance of the Electric Lighting Acts, 1882 and 1888, for a Provisional Order, to be confirmed by Parliament in the next ensuing Session, empowering them to supply electricity for public and private purposes within the area within the jurisdiction of the Council; to determine whether the Council shall consent to or oppose the grant of such Provisional Order; and to authorise the General Purposes Committee to take measures for carrying out the decision of the Council.

Vegetation on Telegraph Wires.—A telegraph wire, says the New York *Electrical Review*, is the last thing one would expect to support vegetation of any kind; yet a traveller in Brazil writes to a German horticultural journal describing a crop of mistletoe which he found clothing the wires not far from Rio Janeiro. At a distance, he says, the wires appeared fringed with what he supposed were the leavings of a recent flood. But a perception of their height soon removed this idea, and upon examination the fringe proved to be composed of thousands of little mistletoes, firmly fixed to the wires from which they depended. Many species of this family flourish in Brazil, and some of them, called "bird-weeds" by the people, thickly infest fruit trees and other cultivated plants and bear large berries, which are greedily devoured by birds. These seeds are deposited on the telegraph wires in the birds' droppings, and quickly take root, and although the plants perish, naturally, before very long, they are succeeded by others, and the curious mistletoe fringe is perpetuated.

Light Batteries for Ballooning.—In the experiments made by Commander Renard and Captain Krebs to propel and steer balloons, the source of energy was a single-fluid battery excited by a liquid composed of chromic acid dissolved in dilute hydrochloric acid. The negative element was platinised silver foil; this foil was shaped into a tube, in the centre of which was placed a pencil of amalgamated zinc. On account of this disposition the current density on the surface of the zinc was 25 to 40 amperes per square decimetre. The elements and liquid were contained in tubes of ebonite or glass, the height being ten times the diameter. A battery of 16 cells, 40 millimetres in diameter, and each composed of six tubes joined in parallel, gave a current of 120 amperes, with a useful potential of 1·2 volt, and fed twenty Gérard 45-watt glow lamps. A battery of 36 tubes, 30 millimetres in diameter, was joined in series, and maintained a Gramme arc lamp of 30 carcels for over two hours. The total weight of the battery was 15 kilogrammes, and the energy expended 200 to 250 watts.

Baudot's Isochronous Regulator.—M. Baudot has devised a new isochronous regulator for his multiple printing telegraph apparatus. The regulator consists of a movable mass of metal, capable of moving between two guide rods fixed transversely to the end of the motor shaft. Two powerful springs, which are also fixed to the motor shaft, pull this mass of metal towards the centre of rotation. When the motor is in motion the strength of the springs is so arranged that if the speed exceeds a certain amount the centrifugal pull of the mass of metal stretches the springs and pulls the shaft against the bearings, and by increasing the friction reduces the speed to its normal value. This arrangement merely constitutes a speed regulator; but it is converted by M. Baudot into an isochronous regulator by establishing a suitable relation between the centre of rotation, the centre of gravity, and the points to which the springs are fixed. The apparatus was specially constructed to maintain the uniformity of speed of the distributor employed in M. Baudot's printing telegraph under variable conditions of power and work. The additional work introduced by friction varies from 5 to 90 gramme-metres. The variations of speed arising from changes of temperature are negligible, amounting as they do to only one-tenth per cent.

Bath.—It will be remembered that some months ago the Bath Town Council passed a resolution accepting the tender of Mr. H. G. Massingham to light 50 of the principal streets of the city by electricity, on the Thomson-Houston system, at £19. 17s. 6d. per lamp per year. A committee was chosen to make arrangements for the introduction of the light, and this committee has drawn up a report which will be presented to a meeting of the urban sanitary authority, to be held on Tuesday next. This report states that the tender of Mr. Massingham stipulated that the Corporation should provide and fix the columns which are necessary; 243 of these will be needed, and the cost of providing and fixing them will be £2,500. The committee recommend that the terms of the proposed contract

Digitized by Google

should be altered, and that £21. 17s. 6d. per lamp per annum be paid to Mr. Massingham upon his furnishing the columns, which will become his property on the expiration of the term of the contract. They also recommend that if a limited liability company, with a capital of £10,000 be formed, the contractor shall have power to assign the contract to them, and that then his and his sureties' liability shall cease. The committee state that Mr. Massingham will be prepared to supply occupiers within the area to be lighted at the rate of £2 per annum for each lamp of 10 candle-power, provided the consumer have his house properly wired and fitted with suitable lamps; or by meter at the rate of 1s. per Board of Trade unit.

The Lighting of the City.—At the meeting of the Court of Common Council, on Thursday in last week, Mr. Pannell (chairman of the Commission of Sewers), in answer to Mr. Stewart, said there were before the Commission six or seven applications from electric lighting companies who were desirous of lighting a portion or the entire area of the City. These applications had been referred to the Streets Committee, and the solicitor and engineer had been instructed, in conference with Mr. Preece, to prepare for the purposes of the committee a scheme on which could be based a form to be advertised, so that they might receive tenders not only from these companies, but from any other corporation that might desire to tender for any area of the City.—At a meeting of the Aldgate Ward Ratepayers' Association, Mr. Marriage said it was quite time that more light was provided for the City. They had recently had an example of the dangerous condition of the streets, owing to the bad lighting. At the present time the streets gave opportunities for all sorts of crimes to be perpetrated. The Chairman said the little town of Barnet put the City of London to the blush by the action it had taken with regard to electric lighting. That it should not be used by the Corporation was to him a marvel, because it must be cheaper than gas. After some further discussion on the subject, the secretary was instructed to communicate with the Streets Committee of the Commissioners of Sewers, calling their attention to the defective lighting of the district.

Filtration of Mercury.—Mercury often becomes contaminated with alloys or other impurities which can be removed by simple filtration. This may be done in glass funnels, the stems of which are drawn out to a fine capillary tube. But this often becomes clogged after a short time, and then ceases to act; besides, it acts very slowly. Prof. C. H. Bohn, of Aschaffenburg, in the *Zeitschrift für Instrumentenkunde*, recommends a method which has long been practised in Bunsen's laboratory. A filter is made of writing paper, and numerous fine holes pricked in it. Instead of making these round with a needle, it is better to use the point of a penknife, which produces narrow triangular holes. The holes should be pricked both vertically in the direction of the radius of the filter, and horizontally, at right angles with the former; some of the holes should be pricked from the outside inwards, and the others in the opposite direction. Even with this arrangement, the filtration sometimes proceeds only very slowly, but it may be accelerated by using a filter-pump. A still better way to purify mercury by filtration, according to the same author, is the following:—Select a glass tube, of about the thickness of a lead-pencil, and about a yard long. Expand one end to the shape of a funnel, and the other to a tulip-shaped bulb, or expand this end in a wave-like form, such as is customary when rubber tubing is to be stretched and tied over the end of a tube. A piece of linen or chamois is firmly tied over the latter end, and the tube then suspended. On pouring the mercury into the funnel, it will be pressed through the pores of the filtering medium with a pressure considerably exceeding that of the atmosphere.

The Wirt Rheostat.—The construction of the Wirt Rheostat is as follows:—The wire, which is covered, is first wound as closely as possible upon a paper tube, which is kept in shape on a mandrel during winding. When the tube is sufficiently covered, the whole wire and tube are well varnished. While the tube and varnish are still soft, the former is pressed flat in a heavy press. The flattened paper covered with wire is then wound round the metal cylinder which forms the body of the instrument, and is attached to it firmly by string, the whole being varnished. The cylinder is then put in a lathe, and the covering of the wires carefully bared at a suitable point for the contact of the brush, which consists of parallel hard copper wires pressed against the cylinder by their natural spring, the two ends of the brush being supported by upright pieces, one of which is connected to one terminal of the instrument. The metal cylinder is attached to one end of the convolutions of wire by solder, and is also connected to the other terminal of the instrument. The convolutions of the wire being vertical, and the brush horizontal, it follows that by the rotation of the cylinder by the handle at the top successive convolutions are cut out of circuit, and so the resistance is altered. The smallest difference of resistance, therefore, that can be made is that of a length of wire equal to the circumference of the paper tube. By means of a pointer attached to the handle, the actual resistance corresponding to any degree of rotation can be tested and marked upon a scale of a dial over which the pointer moves. The compactness of the instrument is much in its favour. The size of instrument principally in use is on a base 5¾in. square, the cylinder being 3⅓in. diameter and 3⅛in. high. The wire can be wound in this size to any resistance between 1,200 and 45 ohms.

Transmission of Power between Thorenberg and Lucerne.—The following data have reference to the transmission of power from hydraulic works at Thorenberg to a flour-mill in Lucerne. Dynamos of Brown's design are employed, the generator and motor being of the same type, but differently wound. The plant has to transmit 120 horse-power, with 1,000 volts, at a speed of 450 revolutions, and 80 amperes. The line, which is partly above and partly underground, has a total resistance of about two ohms. The above-ground portion is 3,040 metres long, and 63 square millimetres in section, and is suspended on porcelain double-bell insulators. In order to prevent the two machines from being injured by short-circuiting caused by any accidental contact of the two line wires, a special electro-magnetic accessory is joined up in the general circuit, so that immediately the current strength becomes abnormal the field-magnets of the dynamos are automatically shunted. This automatic circuit-closer consists of a straight electro-magnet, having each end of its core fixed in a mass of iron. Beneath these prolongations of the core is an armature which works on a hinge, and, in its position of rest, holds up the weighted extremity of an upright lever, the lower end of which turns on an axle held in a frame. At the lowest part of the base-board are two metal springs; as soon as the current attains a strength of about 20 per cent. more than the maximum, the armature of the circuit-closer is drawn upwards and releases the lever, which falls between the contact springs, and thereby short-circuits the field-magnets of the dynamo. A hand cut-out of special form is also used in this installation, so that, in case of necessity, the circuit of a machine in action can be opened without endangering the insulation. This cut-out is composed of a base on which are mounted a carbon rod, held at its lower end between two flat

Digitized by Google

metallic springs that are fixed on an insulating handle, the latter being attached to a bar which can be slid up and down. In order to avoid an abrupt severance of the circuit, the handle is moved slowly downwards; directly the springs and carbon are separated, the space between them is bridged by an arc, which, with careful manipulation, can be made to attain a length of 50 centimetres before the circuit is finally broken.

Electric Lighting in Dublin.—A special meeting of the Municipal Council was held on Monday last in the City Hall, to consider, and, if deemed expedient, to adopt a resolution authorising an application by the Corporation, as Local Authority for the City of Dublin, to the Board of Trade, for a provisional order to authorise the Corporation, as such authority, to supply electricity for any public or private purposes within the area of the City of Dublin. Mr. J. L. Robinson, in moving that the Town Clerk be instructed to issue the necessary advertisements and take all proper steps to obtain a provisional order giving the Corporation power to use electricity for public and private lighting, said this question was before the Council for a considerable time, and although nothing very practicable was done so far, it did not result from any neglect on the part of the special committee to whom the matter had been referred, but from the unreasonable opposition of the Gas Company. The Corporation wished to treat the Gas Company with every consideration, but owing to the factious opposition it was time for the Corporation to see that the Gas Company had not the monopoly of electric lighting as well as the gas lighting. The Gas Company had served notice that they were going in for a provisional order in December next to enable them to use electricity for public as well as private purposes. The Corporation ought to make a determined stand in this matter, and they should remember that they had to look after the interests of the citizens. The committee were also advised that the best and most prominent electric lighting companies would be more likely to tender for the lighting of thoroughfares, and at a cheaper rate, if allowed the option of private lighting; and under those circumstances they recommended that application be made to the Board of Trade for a provisional order to enable the Corporation to supply electricity for private as well as for public purposes. The committee were also of opinion that any further steps which should be taken in the matter should be entrusted to a special committee. Mr. Healy seconded the motion. Mr. Doran was opposed to the additional expenditure that would be involved by using electricity. It was proposed to replace 318 gas lamps by 45 electric lamps, which he believed would not be at all adequate, although the change would cost the citizens £1,500 a year more. Alderman Winstanley thought it should be shown that a profit would be made by the Corporation entering on this enterprise. Mr. Mayne, M.P., denied that the Dublin Electric Light Company was a failure. The motion was put and adopted. Mr. Robinson then moved the appointment of a select committee of fifteen members to take all necessary steps to carry out the object of the resolution. Alderman Byrne seconded the motion. Mr. Doherty moved as an amendment that the appointment of the committee be postponed until the report of the committee of the whole house on the subject of electric lighting be discussed. Mr. Dennehy seconded the amendment, which was lost on a division, 12 voting for and 25 against. The original motion was then adopted.

Tempering Springs by Electricity.—Mr. Frederick Sedgwick, of Chicago, has invented a process of tempering spring wire and ribbon by the introduction of a current of electricity as an agency for raising the temperature of the metal to the required heat. While Mr. Sedgwick's work has thus far been more especially confined to the tempering of watch main springs, he has carried out the plan of putting the finest kind of fire temper into round wire, which can be used to great advantage in numerous articles of which more will be said hereafter. The process by which the inventor tempers steel for watch springs is said to be very simple and inexpensive. He tempers the steel in continuous lengths of any number of feet or yards, instead of cutting it up into the proper length for one watch spring, and treating each separately. The greatest difficulty met with in tempering a fine piece of steel, such as that for a watch spring, by any other process, is the oxidation of the surface of the metal by contact of the heated surface with the air, and also the buckling or twisting of the ribbon on being plunged into the oil-bath. Both of these troublesome points are stated to be effectually eliminated by Mr. Sedgwick's process. In the old method the surface has to be rubbed, dressed down, and polished, piece by piece, with emery, until a smooth surface and uniform gauge are obtained; and where the strip of metal is twisted it has to be straightened out by hand before the temper can be drawn. In the new method the soft steel is wound, like a long, narrow ribbon, on a large spool as it comes from the splitting rolls. The ribbon then passes through a set of very fine but powerful rolls, which give it a perfectly even gauge of the desired thickness of the finished spring. The soft steel is again spooled, and is ready for the hardening process. From the spool the ribbon passes a point of contact of an electric current from a dynamo, the ribbon itself there forming a circuit by extending to a second point of contact. Midway between the two points, and at the place where the ribbon has received the greatest heat (it being raised to a bright red), it passes into and through an oil bath. The second point of contact is in the further end of the bath, so that a greater portion of the current is taken up in the oil. There is a simple device in the bath for preventing the metal from twisting and kinking, and which also effectually eliminates all oil bubbles which would otherwise form on the surface of the steel, and thus make it rough. The ribbon passes through the apparatus continuously at the rate of several yards a minute, and when it emerges from the oil bath it possesses a perfectly uniform temper of great hardness. The fine polished surface given to the ribbon by the finishing rolls is not in the least destroyed, and all that is required is to remove the burned oil by the buffing machine, and smooth the edges by an automatic grinder. The temper is then drawn to the required degree and colour by a current of electricity, and at this point the temper is automatically gauged. It is then ready to be cut into suitable lengths, and coiled ready for market. For coil springs such as are used in the magazines of repeating firearms, and light coils of almost any other kind where a reliable spring must be had, the Bessemer electric-tempered wire can be advantageously employed, as it can be hot set. Mr. Sedgwick has a device for giving the wire its proper temper while in the coil. A spring thus made is said to have a much longer life than any other spring coiled in a cold state. Very superior crinoline wire and piano strings can also be thus made. By a slight change in the application of the principles Mr. Sedgwick has successfully case-hardened common soft iron wire. Experiments showed that with Nos. 8 and 9 wire the case-hardening extended through one-third the thickness of the wire. But the remarkable feature of this was that, while the surface becomes so hard that it can scarcely be touched with a file, the wire itself retains its pliability to a wonderful degree. This wire would enter very successfully into the manufacture of wire cable and rope of all kinds.

NOTES ON ELECTRO-MAGNETIC INDUCTION.*

BY DR. J. A. FLEMING, M.A.

Researches of Prof. Joseph Henry.—An early worker in the field of electro-magnetic discovery opened up by Faraday was Prof. Henry, of Princetown, New Jersey, and his work was fruitful in many new and important investigations. An account of his experiments is to be found in the *Philosophical Magazine*, Vol. XVI., 3rd Ser., 1840. (See also *Transactions* of the *American Philosophical Society*, 1838, Vol. VI.) As this memoir sets before the reader in a very clear manner the chief phenomena of mutual induction, I propose in this Paper to reproduce the main portions of it.

The principal articles of apparatus used in the experiments consisted of a number of flat coils of copper riband, which were designated by the names *Coil No. 1*, *Coil No. 2*, &c., also several long bobbins of wire, and these, to distinguish them from the ribands, were called *Helix No. 1*, *Helix No. 2*, &c.

Coil No. 1 was formed of thirteen pounds of copper plate one inch and a-half wide and ninety-three feet long; it was well covered with two coatings of silk, and was generally used in the form represented in Fig. 1, which is that of a flat spiral sixteen inches in diameter. It was, however, sometimes formed into a ring of larger diameter, as is shown in Fig. 2.

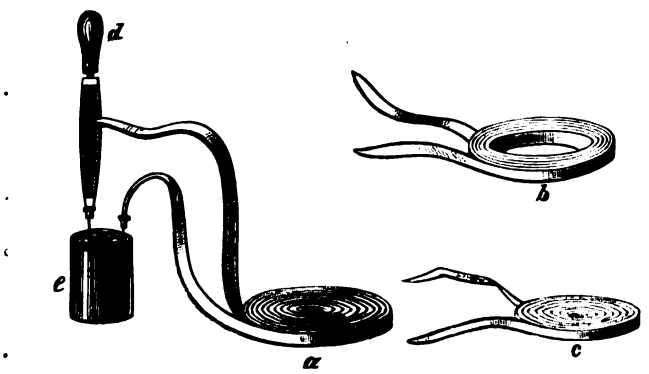

Fig. 1.

Coil No. 2 was also formed of copper plate of the same width and thickness as coil No. 1. It was, however, only sixty feet long. Its form is shown at *b* in Fig. 1. The opening at the centre was sufficient to admit helix No. 1. Coils No. 3, 4, 5, 6, were all about sixty feet long, and of copper plate of the same thickness, but of half the width of coil No. 1.

Helix No. 1 consisted of sixteen hundred and sixty yards of copper wire $\frac{1}{40}$th of an inch in diameter; No. 2 of nine hundred and ninety yards, and No. 3 of three hundred and fifty yards of the same wire. These helices were wound on bobbins of such size as to fit into each other, thus forming one long helix of three thousand yards, or, by using them separately and in different combinations, seven helices of different lengths. The wire was covered with cotton thread saturated with bees' wax, and between each stratum of spires a coating of silk was interposed.

Helix No. 4, shown at *a*, Fig. 2, was formed of five hundred and forty-six yards of wire $\frac{1}{40}$th of an inch in diameter, the several spires of which were insulated by a coating of cement.

Helix No. 5 consisted of fifteen hundred yards of silvered copper wire, $\frac{1}{125}$th of an inch in diameter, covered with cotton, and is of the form of No. 4.

In addition, a long spool of copper wire covered with cotton, $\frac{1}{16}$th of an inch in diameter and five miles long, was provided. It was wound on a small axis of iron, and formed a solid cylinder of wire eighteen inches long and thirteen in diameter.

For determining the direction of the induced currents a magnetising spiral was used, which consisted of about thirty spires of copper wire in the form of a cylinder, and so small as just to admit a sewing needle into the axis.

Also a small horseshoe is frequently referred to, which was formed of a piece of soft iron about three inches long and $\frac{2}{3}$ths of an inch thick; each leg was surrounded with about five feet of copper bell wire. This length was so small that only a current of considerable quantity could develop the magnetism of the iron. This instrument was used for indicating the existence of such a current. The battery which was used was a simple copper-zinc cylinder battery, having about $1\frac{3}{4}$ square feet of zinc surface. In some experiments a series of cells was used, but most experiments were performed with one or two cells of the above kind. The manner of interrupting the circuit of the conductor was by scraping one end of the conductor along a rasp, held in contact with the battery terminal.

Provided with this apparatus, a preliminary series of experiments was made on the self-induction of these various coils. The mode of operating was to close the battery circuit by dipping the ends of a coil or helix into two mercury cups, and then to break the circuit by lifting out one end from its mercury cup, the hands being at the same time in contact with the battery terminal and the end of the conductor which is being raised. In this way the *extra current* or electro-magnetic discharge of the coil passed through the operator's body.

When the electromotive force was small, as in the case of a thermopile or a large single cell, and the circuit is the flat riband coil No. 1, ninety-three feet long, it was found to give brilliant

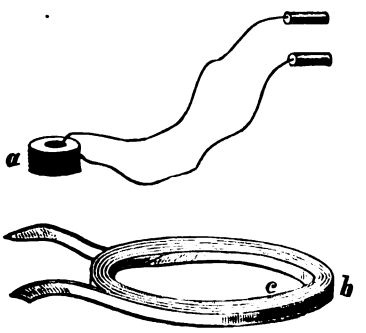

Fig. 2.

snaps at the surface of the mercury when contact was broken, but the shocks were very feeble, and could only be felt in the fingers or through the tongue. The induced current in a short coil, which thus produces deflagration, but not shocks, may, for distinction, be called one of quantity.

When the length of the coil was increased, the battery being the same, the deflagrating power decreased, while the intensity of the shock continually increased. With five riband coils making an aggregate length of three hundred feet and a small battery, the deflagration was less than with coil No. 1, but the shocks are more intense.

There appears to be, however, a limit to this increase of intensity of the shock, and this takes place when the increased resistance or diminished conduction of the lengthened coil begins to counteract the influence of the increasing length of the current. The following experiment illustrates this fact.

A coil of copper wire $\frac{1}{16}$th of an inch in diameter was increased in length by successive additions of about thirty-two feet at a time. After the first two lengths, or sixty-four feet, the brilliancy of the spark began to decline, but the shocks continually increased in intensity until a length of five hundred and seventy feet was obtained, when the shocks also began to decline. This was, then, the proper length to produce the maximum effect with a single battery and a wire of the above diameter. With a battery of sixty cells (Cruickshank's trough), having plates four inches square, scarcely any shock could be obtained when the coil formed a part of the circuit. If the length of the coil was increased, then the inductive effect became very apparent.

When the current from ten cells of the above-mentioned trough was passed through the large spool of copper wire the induced shock was too severe to be taken through the body. Again, when a small battery of twenty-five cells having plates

* These Papers may be regarded as a continuation of Prof. Fleming's articles which appeared under the title of "Notes on Alternate Currents" (see *The Electrician*, Vols. XIX. and XX.).—Ed. *E.*

Digitized by Google

one inch square, which alone would give but a very feeble shock, was used with helix No. 1, an intense shock was received from the induction when the contact was broken. Also a slight shock in this arrangement was given when the contact is formed, but it was very feeble in comparison with the other. The spark, however, with the long wire and compound battery was not as brilliant as with the single battery and short riband coil.

When the shock is produced from a long wire as in the last experiments, the size of the plates of the battery may be very much reduced without a corresponding reduction in the intensity of the shock. A small battery was made, formed of six pieces of copper bell wire, about one inch and a-half long, and an equal number of pieces of zinc of the same size. When the current from this was passed through the five miles of wire of the spool the induced shock was given at once to twenty-six persons joining hands.

With the same spool, and the single battery used in the former experiments, no shock, or at most a very feeble one, could be obtained.

The induced current in these last experiments may be considered as one of *considerable intensity* and *small quantity*.

The energetic action of the flat riband coil in producing self-induction led Prof. Henry to conclude that it would also be the most proper means for the exhibition and study of the phenomena of mutual induction.

Mutual Induction.—Coil No. 1 (*see* Fig. 3) was arranged to receive the current from a small battery of a single cell, and coil No. 2 was placed over it with a plate of glass between to secure perfect insulation. As often as the circuit of No. 1 was interrupted a powerful secondary current was induced in No. 2. When the ends of the secondary were joined to a

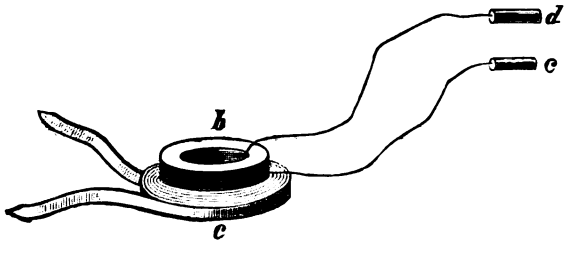

FIG. 3.

magnetising spiral the enclosed needle became strongly magnetic. Also when the ends of the second coil were attached to a small water decomposing apparatus, a stream of gas was given off at each pole, and when the secondary current was passed through the wires of the iron horse-shoe magnetism was developed. The shock, however, from the secondary coil was very feeble, and scarcely felt above the fingers. This secondary current had, therefore, the properties of one of moderate intensity but considerable quantity when developed by the current in one flat riband coil acting on another flat riband coil.

Coil No. 1 remaining as before, a longer coil, formed by uniting Nos. 3, 4, and 5, was substituted for No. 2. With this arrangement as a secondary circuit, the magnetising power of the current and the brilliancy of the spark at breaking contact was less than before, but the shocks were more powerful—in other words, the intensity of the induced current was increased, whilst its quantity was decreased.

A compound helix formed by uniting Nos. 1 and 2 helices, and therefore containing two thousand six hundred and fifty yards of wire, was next placed on coil No. 1. The weight of this helix happened to be precisely the same as that of coil No. 2, and hence the different effects of the same quantity of metal (as secondary circuit) in the two forms of a long and short conductor could be compared. With this arrangement the magnetising effects with the apparatus above-mentioned disappeared. The sparks were much smaller and the decomposition less than with the short coil, but the shock was almost too intense to be received with impunity except through the fingers of one hand. The secondary current in this case was one of small quantity but of great intensity.

The following experiment is important in establishing the fact of a limit to the increase of the intensity of the shock as well as the power of decomposition with a wire of given diameter.

Helix No. 5, consisting of a wire $\frac{1}{125}$th of an inch in diameter, was placed on coil No. 2, and its length increased to about seven hundred yards. With this extent of wire neither decomposition nor magnetism could be obtained, but shocks were given of a peculiarly pungent nature. The wire of the helix was further increased to about fifteen hundred yards; the shock was now found to be scarcely perceptible in the fingers.

As a counterpart to the last experiment coil No. 1 was formed into a ring of sufficient internal diameter to admit the great spool of wire, and with the whole length of this (five miles) the shock was found so intense as to be felt at the shoulder when passed only through the forefinger and thumb. Sparks and decomposition were also produced, and needles rendered magnetic. The wire of this spool was $\frac{1}{16}$th of an inch in diameter; and we therefore see from this experiment that by increasing the diameter of the wire its length may be also increased with increased effect.

The previous experiments were repeated, using a battery of sixty cells (Cruickshank's trough). When the current from this was passed through the riband coil No. 1, no indication, or a very feeble one, was given of a secondary current in any of the coils or helices arranged as in the preceding experiments. But when the long helix No. 1 was placed as a primary, instead of coil No. 1, a powerful inductive action was produced on each of the circuits used as before.

First, helices Nos. 2 and 3 were united into one coil and placed within helix No. 1, which still conducted the battery current. With this disposition a secondary current was produced, which gave intense shocks but feeble decomposition, and no magnetism in the soft iron horse-shoe. It was therefore one of intensity, and was produced by a battery current also of intensity. Instead of the helix used in the last experiment for receiving the induction (secondary) one of the coils, No. 3 (copper riband), was now placed on helix No. 1, the battery remaining as before. With this arrangement the induced current gave no shocks, but it magnetised the small horse-shoe, and when the ends of the coil were rubbed together produced bright sparks. It had, therefore, the properties of a current of quantity, and it was produced by the induction of a current from a battery of intensity.*

This experiment was considered of so much importance that it was varied and repeated many times, but always with the same result; and it therefore established the fact *that an intensity current can induce one of quantity*, and by the preceding experiments the converse has also been shown, *that a quantity current can induce one of intensity*.

(To be continued.)

THE CENTRAL LIGHTING STATION OF THE LONDON ELECTRIC SUPPLY CORPORATION AT DEPTFORD.

The Central Electric Lighting Station at Deptford will very shortly assume a position of absorbing interest in scientific and in engineering circles throughout the civilised world. This enterprise has been conceived, and is now in process of execution, on a scale of such colossal magnitude that our friends over the water will once for all—in their own expressive phraseology—have to take a back seat. In central station electric lighting the banks of the Thames will shortly have a display which, in the mere matter of bigness, will simply "whip creation." We have so often had to suffer under Yankee boasts of this order that we are now disposed to make the most of our opportunity for revenge, and we felicitate ourselves and

* This last experiment is very interesting, as showing that in 1838 Prof. Henry had already realised that which is sometimes called the reverse use of the induction coil. He had employed a current flowing in a fine wire of many turns and moving under a high electromotive force, to induce a current of greater strength in a secondary circuit, consisting of a lesser number of turns of copper riband, and moving under a less electromotive force. In other words, he had constructed *a step-down transformer*.

Digitized by Google

all English electrical engineers accordingly. Regarded merely as an engineering enterprise, a building which is designed ultimately to contain engines and boilers for the production of 140,000 horse-power will become an object of the first importance. When it is added to this that the engines are to drive dynamo machines with armatures of 42ft. in diameter, giving an E.M.F. of 10,000 volts, it will be seen that the electrical and mechanical problems which have had to be solved are upon a scale of magnitude which fully justifies the employment of superlatives. Our sense of the skill and daring with which these problems have been attacked is in no way lessened by the knowledge of the fact that the whole of the arrangements, architectural, mechanical, and electrical, have been designed by Mr. S. Z. de Ferranti, the engineer to the corporation, and are being carried out under his sole superintendence.

The works were commenced in April last, and since then, by the aid of the arc light, they have been pushed forward night and day without intermission. The present stage of their progress is not, however, sufficiently advanced to justify such full and exhaustive details of the arrangements as we hope in due time to supply; in fact, the roofing is not yet commenced, though, on the other hand, some of the Babcock and Wilcox boilers are already *in situ*.

It will therefore be understood that the details which we are now to give are merely of a preliminary character, and are chiefly designed to convey a general idea of the size and character of the undertaking.

The works are situated on the riverside at Deptford, and cover an area of nearly four acres. With the exception of a wharf for unloading coal—for which service it is anticipated that a special line of steamers will be employed—the whole of this space will be covered by the engine and boiler houses. The general plan of the arrangement is as follows:—A central avenue runs from the river right through the middle of the ground up to the external gateway. A second line at right angles to this is then selected, along which a massive partition wall is built, the only opening in it being a lofty arch for the central avenue. On the river side of this the boiler houses are placed, consisting of a basement, taking the flues for the smoke and compressed air, two railways for removing the ashes, and necessary space for the forced draught apparatus. Next comes the ground floor of the boilers and firing platform, above this is a concrete ceiling, which carries a repetition of the basement, with flues, &c. Above this is another floor of boilers, and again under the roof is a sloping floor for storing some 40,000 tons of coal. The tramways for taking the coal from the ships will run at this elevation, and will discharge their coal directly into the store over several lines. The gases before passing to the chimneys go through feed water economisers. There are two chimneys, one on each side of the ground; each chimney is 26ft. on one face and 18ft. on the other, and is divided into four flues. These two chimneys are capable of taking the smoke from boilers which will indicate 40,000 horse-power. The whole of this plant will eventually be repeated three times over when the station attains its maximum capacity.

On the other side of the central partition wall comes the first engine-house, which is 66ft. wide, then a row of columns some 80ft. high, and on the other side of these columns is placed the second engine-house, which again is 66ft. wide, and is finished with another row of columns similar to the first. The floor of these engine-houses is formed of wrought-iron girders and concrete, the foundations for the machinery going through the basement, which is 12ft. deep, on to the gravel. This basement is, therefore, convenient for getting at the foundation bolts and also for placing the steam and water-pipes in.

The first engine-room, on the left-hand side of the central avenue, will contain two Corliss engines and two Ferranti high-tension dynamos of 1,500 horse-power each. These machines will be the first to be started, but will eventually be used only for the day circuits. They will be driven by rope gearing of 40 turns. The armatures are 12ft. 6in. in diameter.

The first engine-house, on the right-hand side of the central avenue, will be entirely devoted to the condensing gear, which will be sufficient for the whole station when completed. The second engine-house is being arranged to take four direct-driven Ferranti dynamos of 10,000 E.H.P. each. To give some idea of the size of these machines it may be here stated that the shafts are 36in. diameter in the centre. The armature measures about 45ft. over all, and the weight of the whole machine, exclusive of the engine, is some 500 tons. They will run at 60 revolutions, with an E.M.F. of 10,000 volts.

The E.M.F. of 10,000 volts may cause some surprise to the electrical world, but the electricians of the corporation, after a number of careful experiments, have arrived at the conclusion that 10,000 volts is no more difficult to manage than 2,400 (the figure at present employed at the Grosvenor Gallery) if suitable precautions are taken.

The first two Ferranti dynamos, of 1,500 horse-power each, are nearly completed, and will shortly be erected. The two dynamos of 10,000 horse-power will probably be completed in about five months.

There are many special features in these machines which will be described later. We may, however, mention here that the insulation of the armature coils is effected by means of sulphur, which yields excellent results mechanically as well as electrically. The machines are being built by Messrs. Hick, Hargreaves, and Co., of Bolton.

Amongst the precautions which are taken in dealing with the high voltage we may refer to the fact that the brushes are completely enclosed in an iron box which is *magnetically locked* by the current of the exciting circuit.

Next to the machinery itself the greatest interest attaches to the method of distribution. This is briefly as follows:—The potential of 10,000 volts will undergo two transformations before the consumers' lamps are reached. A considerable number of secondary transforming stations will be established in different parts of London, whose function will be to reduce the potential from 10,000 to 2,400 volts, and distribution will be effected from these sub-stations on exactly the same lines as are now in use at the Grosvenor Gallery. The current in the consumers' lamps will therefore be of the tertiary order. One of the most far-seeing and admirable arrangements which the company has made is the manner in which they have practically solved the problem of conducting the high-potential mains to their destination.

Agreements have been made with the Chatham and Dover, Brighton and South Coast, and South-Eastern Railways for the use of their lines as main arteries.

From Deptford the primary conductor will be carried along these lines to the London Bridge, Cannon-street, Ludgate Hill, Charing Cross, and Victoria Railway Stations, and it will also enter at several of these points upon the Metropolitan and District lines of railway. From these points of vantage no difficulty will be experienced in reaching the secondary transforming stations in any part of central London. It is, moreover, intended that the network of secondary wires from which the consumers' transformers will obtain current shall always be supplied from at least two separate and independent sub-stations. The primary conductors will consist of two concentric copper tubes, and the method of insulation between these tubes is the subject of one of the most important patents of Mr. Ferranti. The cable will be $2\frac{3}{8}$in. external diameter, the outer tubular conductor being $\frac{3}{16}$in. and the inner $\frac{3}{32}$in. in thickness, leaving a space of $\frac{3}{16}$in. in the centre. It will be uninsulated upon its exterior; in fact, this return conductor will be placed to earth. The current density will be extremely low, not exceeding 170 amperes per square inch, and at 130 alternations per second it will be found that the thickness of the conductor is within the theoretical limit recently indicated by Sir William Thomson.

The Heisler Electric Light Company.—The *St. Louis Globe Democrat* says that the Heisler Electric Light Company has secured patents in Belgium, England, and Italy for its system of lighting, and is expecting the same favour to be accorded it in Germany and Austria at an early date, when it will begin at once to work the foreign field. It has been carrying on an active correspondence for several months with a view of arranging its plans abroad

HERTZ'S RESEARCHES ON ELECTRICAL OSCILLATIONS.

BY G. W. DE TUNZELMANN, B.SC.

(*Continued from page 758.*)

It was shown in the experiments described in my last Paper that when variable electrical forces act in the interior of dielectrics of specific inductive capacity not equal to unity, the corresponding electric displacements produce electro-dynamic effects. In a paper "On the Velocity of Propagation of Electro-Dynamic Actions," in Wiedemann's *Annalen*, Vol. XXXIV., p. 551, Dr. Hertz shows that similar actions take place in the air, which proves, as was previously pointed out, that electro-dynamic action must be propagated with a finite velocity.

The method of investigation was to excite electrical oscillations in a rectilinear conductor in the same manner as in former experiments, and then to produce effects in a secondary conductor by exciting electrical oscillations in it by means of those in the rectilinear conductor, and at the same time by the primary conductor acting through the intervening space. This distance was gradually increased, when it was found that the phase of the vibrations at a distance from the primary lagged behind those in its immediate neighbourhood, showing that the action is propagated with a finite velocity, which was found to be greater than the velocity of propagation of electrical waves in wires in the ratio of about 45 to 28, so that the former is of the same order as the velocity of light. Dr. Hertz was unable to obtain any evidence with respect to the velocity of propagation of electrostatic actions.

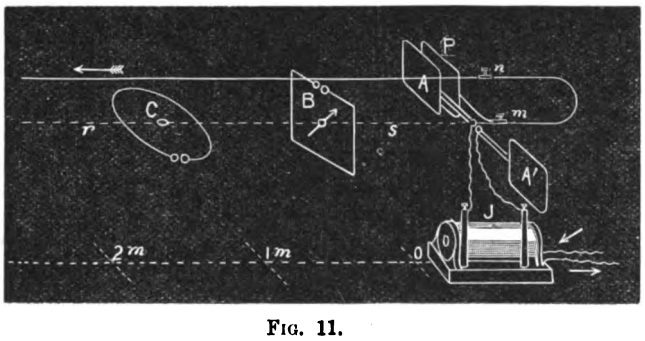

FIG. 11.

The primary conductor A A′ (Fig. 11) consisted of a pair of square brass plates with sides 40 centimetres in length, connected by a copper wire 60 centimetres in length, at the middle point of which was an air space, across which sparks were made to pass by means of powerful discharges from the induction coil J. The conductor was fixed at a height of 1·5 metre above the base-plate of the coil, with its plates vertical, and the connecting wire horizontal. A straight line, *r s*, drawn horizontally through the air space of the primary and perpendicular to the direction of the primary oscillation will be called the base line, and a point in this situated at a distance of 45 centimetres from the air space will be referred to as the null point.

The experiments were made in a large lecture room, with nothing near the base line for a distance of 12 metres from the primary conductor. The room was darkened during the experiments.

The secondary conductor consisted either of a circular wire, C, of 35 centimetres radius, or of a square of wire, B, with sides 60 centimetres long. The primary and secondary air spaces were both capable of adjustment by means of micrometer screws. Both the secondary conductors were in unison with the primary, the (half) vibration period of each being 1·4 hundred-millionth of a second, as calculated from the capacity and coefficient of self-induction. It is doubtful whether the ordinary theory of electrical oscillations would lead to accurate results under the conditions of these experiments, but as it gives correct numerical results in the case of Leyden jar discharges, it may be expected to be correct as far as the order of the results is concerned. When the centre of the secondary lies in the base line, and its plane coincides with the vertical plane through the base line, no sparks are observed in the secondary, the E.M.F. being everywhere perpendicular to the direction of the secondary. This will be referred to as "the first principal position" of the secondary. When the plane of the secondary is vertical and perpendicular to the base line, the centre still lying in the base line, the secondary will be said to be in its "second principal position." Sparking then occurs in the secondary when its air space is either above or below the horizontal plane through the base line, but not when it is in this plane. As the distance from the primary was increased the sparking distance was observed to decrease, rapidly at first, but ultimately very slowly. Sparks were observed throughout the whole distance of 12 metres available for the experiments. The sparking in this position is due essentially to the E.M.F. produced in the portion of the secondary remote from the air space. The total E.M.F. is partly electrostatic and partly electro-dynamic, and the experiments show beyond the possibility of doubt that the former is greater, and therefore determines the direction of the total E.M.F. close to the primary, while at greater distances it is the electro-dynamic E.M.F. which is the greater.

The plane of the secondary was then turned into the horizontal, its centre still lying in the base line. This may be called "the third principal position." When the centre of the circular secondary conductor was kept fixed at the null point, and the air space was made to travel round the circle, vigorous sparking was observed in all positions. The sparking distance attained its maximum length of about six millimetres when its air space was nearest to that of the primary, and its minimum length of about three millimetres when the distance between the two air spaces was greatest. If the secondary had been influenced by the electrostatic force, sparking would only be expected when the air space was close to the base line, and a cessation of sparks in the intermediate positions. The direction of the oscillation would, moreover, be determined by the direction of the E.M.F. in the portion of the secondary furthest from the air space. There is, however, superposed upon the electrostatically excited oscillation a second oscillation due to the E.M.F. of induction, which produces a considerable effect since its integral round the circle (considered as a closed circuit) does not vanish; and the direction of this integral E.M.F. is independent of the position of the air space, opposing the electrostatic E.M.F. in the portion of the secondary next to A A′, and assisting it in the portion furthest from A A′, as explained in a previous Paper.

The electrostatic and electro-dynamic E.M.F.s therefore act in the same direction when the air space is turned towards the primary conductors, and in opposite directions when the air space is turned away from the primary. In the latter position it is the E.M.F. of induction which is the more powerful, as is shown by the fact that there is no disappearance of sparking in any position of the air space, for when this is 90 degrees to the right or left of the base line it coincides with a node with respect to the electrostatic E.M.F. In these positions the inductive action in the neighbourhood of the primary can be observed, independently of the electrostatic action.

Waves in Rectilinear Wires.—In order to produce in a wire by means of the primary oscillations a series of advancing waves of the character required for these experiments, the following arrangements were made:—Behind the plate A was placed a plate, P, of equal size. A copper wire one millimetre in diameter connected P to the point M of the base line. From M the wire was continued in a curve about a metre in length to the point N, situated about 30 centimetres above the air space, and was then further continued in a straight line parallel to the base line for such a distance as to obviate all danger of disturbance from reflected waves. In the present series of experiments the wire passed through a window, and after being carried to a distance of about 60 metres was put to earth, and a special series of experiments showed that this length was sufficient. When a wire, bent so as to form a nearly closed circuit with a small air space, was brought near to this straight wire, a series of fine sparks was seen to accompany the discharges of the induction coil. Their intensity could be varied by varying the distance between the plates P

Digitized by Google

and A. The waves in the rectilinear wire were of the same period as that of the primary oscillations, as was proved by their being shown to be in unison with each of the two secondary conductors previously described. The existence of stationary waves showed that the waves in the rectilinear wire were of a steady character in space as well as in time. The nodal points were determined in the following manner:—The further end of the wire was left free, and the secondary conductor was brought near to it, in such a position that the wire lay in its plane, and had the air space turned towards it. As the secondary was moved along the wire, points of no sparking were observed to recur periodically. The distance from the point n to the first of these was measured, and the length of the wire made equal to a multiple of this distance. The experiments were then repeated, and it was found that the nodal points occurred at approximately equal intervals along the wire.

The nodes could also be distinguished from the loops in other ways. The secondary conductor was brought near to the wire, with its plane perpendicular to it, and with its air space neither directed completely towards the wire nor completely away from it, but in an intermediate position, so as to produce E.M.F.s perpendicular to the wire. Sparks were then observed at the nodes, while they disappeared at the loops. When sparks were taken from the rectilinear wire by means of an insulated conductor, they were found to be stronger at the nodes than at the loops; the difference, however, was small, and was, indeed, scarcely distinguishable unless the position of the nodes and loops was previously known. The reason that this and other similar methods do not give a well-defined result lies in the fact that irregular oscillations are superposed upon the waves considered; the regular waves, however, can be picked out by means of the secondary, just as definite notes are picked out by means of a Helmholtz resonator. If the wire is severed at a node, no effect is produced upon the waves in the portion of wire next to the origin; but if the severed portion of wire is left in its place, the waves continue to be propagated through it, though with somewhat diminished strength.

The possibility of measuring the wave-lengths leads to various applications. If the copper wire hitherto used is replaced by one of different diameter, or by a wire of some other metal, the nodal points retain their position unchanged. It follows from this that the velocity of propagation in a wire has a definite value independent of its dimensions and material. Even iron wires offer no exception to this, showing that the magnetic susceptibility of iron does not play any part in the case of such rapid motions. It would be interesting to investigate the behaviour of electrolytes in this respect. In their case we should expect a smaller velocity of propagation, because the electrical motions are accompanied by motions of the molecules carrying the electric charges. It was found that no propagation of the waves took place through a tube 10 millimetres in diameter, filled with a solution of sulphate of copper; but this may have been due to the resistance being too high. By the measurement of wave-lengths the relative vibration periods of different primary conductors can be determined, and it therefore becomes possible to compare in this manner the vibration periods of plates, spheres, ellipsoids, &c.

In the experiments made by Dr. Hertz nodes were very distinctly produced when the wire was severed at a distance of either 8 metres or 5·5 metres from the null point of the base line. In the first case the nodes occurred at distances from the null point of −0·2 metre, 2·3 metres, 5·1 metres, and 8 metres, and in the latter case at distances of −0·1 metre, 2·8 metres, and 5·5 metres. It appears, therefore, that the (half) wave-length in a free wire cannot differ much from 2·8 metres. The fact that the wave-lengths nearest to P were somewhat smaller was to be expected from the influence of the plates and of the curvature of the wire. This wave-length, with a period of 1·4 hundred millionths of a second, gives 200,000 kilometres per second for the velocity of propagation of electrical waves in wires. Fizeau and Gounelle (Poggendorff's *Annalen*, Vol. LXXX., p. 158, 1850) obtained for the velocity in iron wires 100,000 kilometres per second, and 180,000 in copper wires. W. Siemens (Poggendorff's *Annalen*, Vol. CLVII., p. 309, 1876), by the aid of Leyden jar discharges, obtained a velocity of from 200,000 to 260,000 kilometres per second in iron wires. Dr. Hertz's result is very nearly the mean of these, from which we may conclude that the order at any rate, of the vibration period as calculated by him is correct. The value obtained cannot be regarded, independently of its agreement with experimental results otherwise obtained, as a fresh determination of the velocity, since it rests upon a theory which is open to doubt.

(To be continued.)

THE ELECTROLYTIC PURIFICATION OF ALCOHOL.

M. Ponthière, of the University of Lourain, has published some interesting information with regard to the methods employed in France for purifying the products of the distillation of various substances containing sugar or starch, by means of the electrolytic process of M. Naudin. The alcohol of beetroot, for instance, when subjected to this treatment, and afterwards rectified in the usual manner, is entirely free from the unpleasant smell which characterises the crude product; whilst the alcohol of the Jerusalem artichoke, which is, as a rule, completely useless, yields as good results if treated by the Naudin process as that distilled from maize.

The earliest attempts in this direction were made by M. Eisenmann, who, although he employed electricity, made no use of electrolysis. M. Eisenmann passed a current of ozonised air at 70°C. through the liquid to be purified. To ozonise the air, it was sent through a glass tube placed between the terminals of an inductive coil. This process certainly oxidised some of the deleterious constituents of the liquid, but did not seem to act on the aldelydes which form the principal impurity of crude alcohol.

In the Naudin process the liquid is first hydrogenised by means of a Gladstone and Tribe zinc-copper element. At M. Boulet's works, at Bapaume-lez-Rouen, wood or iron vats are used containing a number of zinc plates which are alternately flat and corrugated. The weight of zinc in a 150-hectolitre (3,300 gals.) vat is 6,200 kg. (6 tons); the number of plates is 105, and the active surface equals 1,800 square metres (19,800 square feet). Sulphate of copper is dissolved in the alcohol to be treated, and the reduced copper is deposited on the zinc plates. Five solutions containing ·5 per cent. of copper sulphate are employed in succession. The total weight of copper deposited is 360 kg. (0·35 tons) in the case of the 150-hectolitre vat. The temperature at which the deposit is made is a matter of supreme importance; it ought to be from 30°C. to 35°C.; five degrees more or less injuriously affect the process. If the temperature is too low, the action ceases; if it is too high, the copper does not adhere firmly to the zinc plates. Each solution requires 24 hours to completely deposit the copper contained in it, so that the entire zinc-copper process requires five days. Owing to the formation of oxidised zinc-hydrate, 5 kg. of hydrochloric acid are added every week for every 150 hectolitres of alcohol treated.

The above process is generally sufficient to completely purify the crude alcohol, but owing to the presence of other impurities it is sometimes necessary to employ electrolysis before rectification. The voltameters in which this latter process takes place are glass cylinders 125mm. in diameter and 60mm. long, furnished with ebonite caps, through which pass the copper electrodes and the supply and overflow pipes. To treat 300 hectolitres in twenty-four hours M. Naudin employs twelve voltameters, two in series and six in parallel, using a total current of 36·65 amperes and an E.M.F. of 113·5 volts. The current is furnished by a four horse-power Siemens shunt-wound dynamo. To neutralise the small quantity of hydrochloric acid employed to acidulate the solution some zinc is placed in the vat supplying the still in which the spirit is rectified.

M. Naudin has furnished the following figures as to the cost of each of the above operations in producing one hectolitre (twenty-two gallons) of pure alcohol.

Treatment of 200 hectolitres of products of the first distillation by the zinc-copper process in twenty-four hours.

Commercial hydrochloric acid, 1·25 kilog., at 6fr. the 100 kilog.	·075fr.
Sulphate of copper, 1·25 kilog., at 56fr. the 100 kilog. zinc consumed	·70 ,,
By the acid or sulphate of copper, 2 kilog. .... / By the liberation of hydrogen, 1·5 kilog., at 60fr. the 100 kilog.	2·10 ,,
Labour, 24 hours	7· ,,
Power	2· ,,
Maintenance and repairs	1·50 ,,
Depreciation, 15,000fr. in ten years	4·50 ,,

The Electrician.

Published every Friday. Price Fourpence; Post Free, Fourpence Halfpenny.
Editorial and Publishing Offices
No. 1, SALISBURY COURT, FLEET STREET, LONDON, E.C.
Telephone No. 2714.

All Communications to be addressed to "The Electrician," 1, Salisbury-court, Fleet-street, London, E.C. Cheques and Money Orders should be made payable to "The Electrician."

All letters intended for insertion in "The Electrician," or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.

"The Electrician" is published every Friday morning, in time for the morning mails. Subscribers should receive their copies by the first post on Friday morning.

"The Electrician" is on sale at the railway bookstalls throughout the United Kingdom on Friday morning, and can be obtained at all Booksellers and Newsvendors; or direct from the office as above.

SPECIAL NOTICE.

Owing to the increase in the number of pages of "The Electrician," in order to partly cover the increased postage, we have been compelled to revise the rates for Foreign Subscriptions, which are now as follows:—

	3 months.	6 months.	12 months.
For Foreign Parts and Colonies:—	s. d.	s. d.	s. d.
Within Postal Union	6 6	... 12 6	... 24 0
„ Aden, Borneo, Ceylon, China, India, Japan, Java, Labuan, Mozambique, New Caledonia, Persia, Philippine Islands, Siam, Transvaal, and Zanzibar	7 6	... 14 6	... 28 0
The rates for the United Kingdom remain as follows:—	5 0	... 10 0	... 19 6

TO ADVERTISERS.

"The Electrician" offers exceptional advantages to Advertisers. **It has the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application to this office.

Trade Advertisements *intended for the current issue must be handed in not later than First Post on Thursday morning.*

Small Prepaid Advertisements *(for Rates see page XI.) are accepted up to 4 p.m. on Thursday.*

TECHNICAL PRINTING.

"The Electrician" Printing and Publishing Company (Limited) *beg to inform Electricians and Electric Light Engineers that they make a specialty of Technical Printing, and have a Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electrical Catalogues and Electro-Technical Literature generally.*

The Electricians' Directory.

Royal 8vo. Cloth Boards, 3s. 6d. Boards, 3s.

At the end of December in each year is issued The Electricians' Directory and Handbook. *The Directory was established in 1883, and has now attained considerable proportions. Every care is taken to make the names and addresses of all persons engaged in the Electrical Industries absolutely accurate. Useful Tables and Electrical Formulæ are given, together with popularly-written Biographical Notices of the leading Electricians, accompanied in many cases by Portraits.*

THE DIRECTORY FOR 1889 IS IN PREPARATION.

"THE ELECTRICAL WORLD" IN THE UNITED KINGDOM.

Arrangements have been made by which "The Electrical World" of New York can be obtained from "The Electrician" Office, 1, Salisbury-court, Fleet-street, London, E.C.

The Rate of Subscription (payable in advance), including postage, is **£1. 1s. 0d.** *per annum to this Country and Abroad.*

Single Copies of "The Electrical World" can also be obtained, **price 6d. each.**

The Rates for Advertisements in "The Electrical World" of New York can be obtained on application to "The Electrician" Printing and Publishing Company, Limited, as above.

"THE ELECTRICIAN" IN THE UNITED STATES.

Similarly, "The Electrician" can be obtained in America at the Offices of "The Electrical World," 168 to 177, Potter-building, New York.

"The Electrician" can also be obtained from D. Van Nostrand, *23, Murray-street, and 27, Warren-street, New York.*

The Rate of Subscription for American Subscribers (payable in advance) is $6 per annum.

THE NEW PATENTS BILL.

In our issue of October 5th we printed the clauses of a Bill which will be introduced in the forthcoming Session of Parliament under the title of "An Act to Amend the Patent Designs and Trade Marks Act," and in the same issue we expressed a general approval of the scope of the measure. At that time a somewhat vigorous opposition was manifesting itself in the columns of one of our engineering contemporaries. We have since been happy to observe, however, that this does not by any means represent the feeling of the entire engineering profession, and a very considerable amount of support has been accorded to the view to which we have given expression. The matter is one of considerable importance to the electrical profession; considering the admittedly unsatisfactory state of the patent law it is perhaps a matter for regret that it *should* assume such importance; but we must, of course, deal with the facts as we find them. It is probably beyond the power of human ingenuity to devise a patent system of an even reasonably perfect character. It would seem as if the securing to the inventor an incontestable right to the results of his invention, without infringement on the equal rights of others,

Digitized by Google

can never be effected in any other than an extremely haphazard and fortuitous manner. There is, therefore, all the more reason that any effort which promises to remove any one of the stumbling blocks with which the path of the inventor is strewn should receive encouragement.

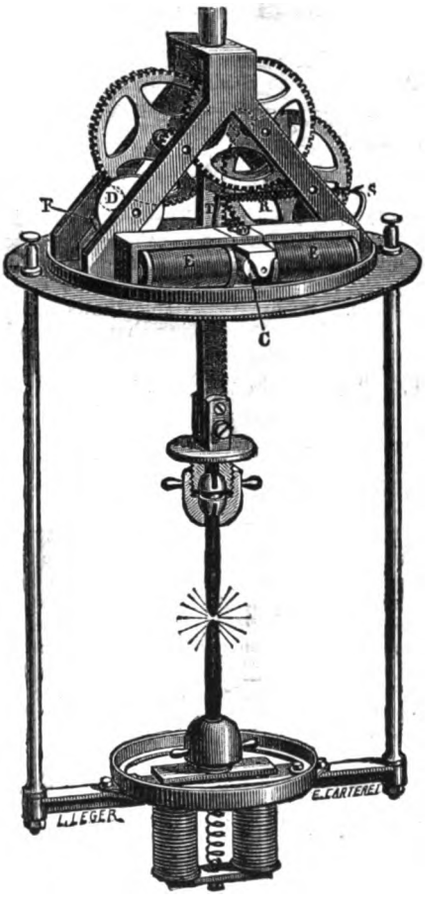
The object of the present Bill is, as we have already explained, to deal with one of the first and most elementary stages in the process of securing a patent. It is, of course, by no means necessary—nor does the Bill propose to make it necessary—for an inventor to seek the services of a patent agent; but seeing that the patent law confessedly aims at securing to the poor, and may be uneducated, inventor the fruits of his ingenuity, it is certainly desirable that the law should take cognizance of the qualifications of those who profess to be the qualified interpreters of its requirements. At the present moment the patent agent has absolutely no legal status whatever; anyone who is so desirous may achieve such success as he can command as a patent agent without any preliminary inquiries or initiation. Now, this state of things is of little consequence to the rich man, who has means of discovering, and will take good care to discover, an agent who is really qualified for the work which he undertakes. Not so the poor man. He is probably incapable of drawing up his specification without the assistance of an agent, and as a rule he is absolutely without means of ascertaining the competency of the individual whom he employs. It is therefore quite as much, or even more, in the interest of the poor inventor as in the interest of the patent agent that we are inclined to support the proposal for effecting compulsory registration.

In fact, the Bill goes but a very little way towards the desired end. Every agent who has been established in practice for twelve months previous to the 1st July last will be entitled to registration without inquiry, and although the Board of Trade are empowered to draw up regulations which new candidates will be required to satisfy, yet it is scarcely to be supposed that they will see their way to making these very *exigeant*. Another point which ought not to be overlooked is that the creation of a roll of patent agents, and the consequent raising of the present admittedly low status of the profession, will of itself have a tendency to attract a better class of men into its ranks. The amount of knowledge demanded of a competent patent agent is by no means inconsiderable; not only is it desirable, to say the least, that he should be an engineer, and still further that he should have special knowledge of as many branches of industrial enterprise as he can contrive to master, but he has over and above all to become acquainted with patent law, and with the voluminous and ever-increasing mass of patent law decisions. This is no light task, and any man who has thoroughly mastered the legal branch of this business would seem to be fairly entitled to the status of a member of a learned profession.

The preparation of a specification which is intended to describe and protect an invention of real value is a matter of no slight difficulty, and involves a responsibility which ought not to be lightly incurred. It is unfortunately a fact well known to those who have made themselves acquainted with the records of patent litigation that owing to the badness of many specifications the most deliberate infringements of important inventions have and do occur, whilst the patentee finds himself without redress, even if he be not saddled with heavy costs incurred in an attempt to defend his claim. Against all these weighty arguments in favour of the Bill we are unable to find any solid contention on the part of its opponents. The idea that the Bill will prevent an inventor from drawing up his own specification, or from getting it drawn up by a friend, simply arises from a total want of acquaintance with the terms of the measure. This exhibits a degree of negligence which we view with surprise and regret in the editorial columns of the oldest engineering journal. The only other argument which we have been able to find is based upon the assertion that it is undesirable to allow the patent agents to become a close corporation. We think that we have already sufficiently exposed the fallacy of this argument, but we may just add that it is not proposed to confer the power of admission to the roll upon the Institute of Patent Agents, but to vest it in the Board of Trade, and it is perfectly gratuitous to suppose that that power will not be fairly and honourably exercised. The subject is one which might well occupy the attention of the Committee of the Electrical and Allied Trades section of the London Chamber of Commerce, and we should be pleased to find that they had decided to take active steps in support of the Bill.

THE GRAVIER ARC LAMP.*

The essential feature of the Gravier arc lamp consists in a train of clockwork supported on a triangular frame, the last wheel D



The Gravier Arc Lamp.

(*see* figure) being clutched by the brake F, which is actuated by the armature C, of the electromagnet E E, placed in shunt upon the main circuit. The spring R, uniting the two levers S and T, brings the armature back to its normal position when the electromagnets cease to act. A thick wire electro-magnet, actuating the

* Translated from M. Hippolyte Fontaine's "Éclairage à l'Electricité," by kind permission of the author.

Digitized by Google

lower carbon holder, causes the arc to be struck when the current passes. The working of the lamp explains itself. The only feature worthy of notice is the method employed in constructing the armature C. A thin copper cylindrical mould is placed vertically between the poles of a powerful electro-magnet, and filled with iron filings. When the filings have arranged themselves under the influence of the poles, melted paraffin is poured into the mould. A cylinder is thus obtained in which the magnetised particles are distributed in a special manner, and which moves between the two poles exactly like an iron excentric. This lamp works tolerably well if all the parts are properly fitted, but it is needless to say the cylinder, with its magnetised molecules, in no way adds to the regularity or fixity of the arc.

UNDERGROUND WORK IN BROOKLYN, N.Y.*

BY W. D. SARGENT.

The extension of underground conduits in Brooklyn has been restricted, since my last observations on the subject, to short sections for the purpose of connecting our new buildings in the Brooklyn and Williamsburgh districts with the underground system. All of the new conduits have been made of the creosoted wood, the ducts 3in. square, inside measure, with the exception of one short section of Macdonald creosoted wood, with round holes 2½in. in diameter. It is fully decided, however, that hereafter no ducts will be laid with an opening of less than 3in. in the clear.

In order to make ample room for the conduits reaching to our principal office, No. 16, Smith-street, we have built a tunnel the whole width of the street, high enough and wide enough to walk through, and it now carries 108 ducts, with room for, perhaps, 60 or 100 more. There are special features in this tunnel and method of bringing the terminals of the cables into the building which it is difficult to describe or to reproduce in a drawing. The *New York Electrical Review* of August 4th, 1888, gives illustrations which will convey some idea of the character of the work, and the members of the Association are cordially invited to visit the office and inspect the arrangements for themselves.

The first sections of our creosoted wooden conduits have now been in service four years. There is no evidence of decay, and the ducts remain clean and dry, enabling us to draw in and withdraw the cables without any difficulty.

So far as conduits are concerned, we think experience has fully sustained our judgment in favour of the creosoted wood.

One of the most important things, after the conduits, in underground work, is the manholes, which should be as large and commodious as possible. Within reasonable limits it is almost impossible to get these manholes or working chambers too large. While we from the start realised the importance of this part of the work, we have in quite a number of instances been compelled to rebuild and enlarge the manholes as first designed. Given a conduit of durable material, connecting with commodious manholes, this part of the underground problem, so far, presents no serious difficulty.

The character of the cables to be drawn into the ducts, and the method of distributing wires from them, are questions that demand our most earnest attention.

Experience has taught us that larger conductors and thicker insulation, together with twisted metallic circuits, are an essential part of perfect service. Conductors of ·035 to ·040 of an inch in diameter, insulated to ·125 of an inch in diameter, and twisted in pairs, with 100 to 104 wires, or 51 or 52 metallic circuits, make up a cable of from 2 to 2¼in. in diameter. Such a cable will weigh between 4 and 4½ pounds per foot, according to the amount of lead; and on account of the tendency of the lead pipe to buckle in bending, we do not believe that it is practicable to handle cables of larger diameter and weight. The consideration of these facts led us to decide that our ducts should hereafter be three inches.

We are using nothing but the lead-covered types of cable, some of which has been in service underground for four years and is still in good condition. Of the cables which were laid four years ago, those covered with pure lead appear to be more than half eaten through. One that has been drawn out during the writing of this article has been underground for two years and is badly corroded, there being holes eaten in it in many places nearly one-sixteenth of an inch in depth. Of the cables furnished by the Western Electric Company at the same time, in which there is a small percentage of tin mixed with the lead, the corrosion is very slight, and we are led to believe that cables covered with this alloy will last from three to four times as long as those covered with pure lead. We believe that if in addition to the tin the cables were drawn through a bath of gas tar or asphaltum, then covered with a good stout braid and run through the gas tar or asphaltum again, the cables would be practically imperishable, so far as the outside covering is concerned, and it is a question whether this additional expense would not be justified by their increased length of life. It is certainly worth the trial.

The air-tight terminals which were put on all our lead cables more than a year ago appear to have removed all the difficulties which we formerly had at that point, and the tests of our cables, making due allowance for temperature, &c., show that there is no deterioration during the past year.

Of the cables mentioned by me last year, one of 7,180ft., containing 100 wires, twisted indiscriminately, manufactured by the Western Electric Company, has been reduced by the change to the new Central Office to 6,344. Tests made Aug. 16, 1888, give the insulation 300 megohms, capacity ·22 microfarads, resistance of the conductors 43½ ohms per mile. The conductors are ·038 of an inch in diameter, insulated to ·088 of an inch. For a time during the past year all the conductors were in service, but recently the trunk lines to Bedford office have been taken out, and there are now thirty wires working through it. The condition of this cable in regard to cross-talk is the same as last year—that is, it is not bad enough to prevent its use.

The cable manufactured by the New York and New Jersey Telephone Company, with 100 wires, twisted in pairs, has been reduced to 6,117 feet. Tests Aug. 19, 1888, give the insulation 39 megohms per mile, capacity ·275 microfarads, and resistance of the conductors 43 ohms per mile—temperature in both these cases being, in the air, 80 degrees, and of the water from the hydrants 73 degrees. We assume that the temperature of the water from the hydrants is the temperature of the air in the conduits. Seventy-four wires are working through this cable, and the cross-talk is no worse than last year, and is not so bad as to prevent its constant use. In both cases all the dead wires are kept grounded at the cable terminals.

The greatest length of cable we have now underground is 11,800 feet, between our Bedford and Williamsburgh offices, consisting of 100 wires, twisted in pairs, the pairs broken up at all the splices, conductors ·025, insulated to ·075. The insulation of this cable is 99 megohms per mile, capacity ·26 microfarads, resistance of the conductors 47 ohms per mile; 17 conductors in this cable are in use for trunk service between the two offices, the rest of the wires being grounded close to the terminals at both ends. The cross-talk in this cable is very slight, and is, indeed, less than in the Western Electric cable of 7,000 feet. We received complaints from both these offices that the talking by subscribers through this cable was difficult and unsatisfactory. A special investigation of these complaints at the points they originated demonstrates that the difficulties complained of are not in the cable, but rather in the condition of the transmitters and instruments in the various offices and carelessness of the subscriber. Considering this cable as a whole, two miles in length, its electrical qualities are—insulation 50 megohms, capacity ·52 microfarads, resistance of conductors 94 ohms. We are inclined to think this is about the limit of good working in that type of cable, and that the complaints we are getting about the service over it are due to the fact that it loads up the circuit so that there is no margin for any deficiency in the subscribers' circuits connected to it; whereas if its efficiency was higher there would be a margin to cover such defects, and complaints would be prevented. There is no doubt that the reduction of the cross-talk and the increase in the capacity is due to the fact that the 83 of the 100 wires are grounded at the terminals, and that when the whole cable is put into service this condition of affairs will be changed more or less; that is, the capacity will diminish and the cross-talk will increase.

It was a consideration of the difficulties to be encountered in the use of greater lengths of this type of cable, which the above experience emphasizes, that decided us during the past year to make a special cable for our trunk lines, doubling the weight of copper and thickness of insulation. This resulted in our ordering three miles of cable, conductors ·052 of an inch in diameter, insulated to ·125 of an inch, sixty wires laid up indiscriminately; and, during the past two months, two miles of this cable, or 10,560ft., have been put upon the elevated railroad structure connecting the Brooklyn Central Office with the Bedford Central Office. The insulation is between 1,200 and 1,500 meghoms per mile, capacity ·27 microfarads, resistance of conductors between 21 and 22 ohms per mile, at a temperature of 74 degrees. This cable, though of the same length as the one between the Bedford and Williamsburgh offices just mentioned, gives surprisingly better results, the cross-talk being very slight, and the volume of sound full and strong. Forty of these wires are grounded at the cable terminals, and twenty are in active service.

There does not seem to be anything in the electrical measurements to indicate what causes the difference in the practical working of the two cables, but the results are gratifying, and seem to plainly indicate that increasing the weight of the copper and thickness of the insulation is a step in the right direction, and I am inclined to think that grounded trunk wires of this last type may

* Paper read before the Telephone Convention in New York.

Digitized by Google

work successfully between our various Brooklyn offices, the distances between which do not exceed two and one-half miles.

All the new cables we have used this year have been of 108 wires, or 51 pairs, twisted, laid up in regular cable form, in alternate reverse directions, conductors ·035 of an inch in diameter and insulated to ·125 of an inch. The insulation of these cables when placed in position underground ranges from 1,500 to 3,000 megohms, capacity from ·17 to ·18 microfarads, and the resistance 52 ohms per mile. We believe that this type of cable will fulfil all the conditions required in our underground work, but at the present time we have no length sufficient to give actual working results.

The transition period between grounded and metallic circuit systems will be very troublesome and annoying, and may last several years. It is our intention, in ordering the type of cable just described, to make provision in the manholes for joining the sections together by devices which will enable the joints to be opened readily without cutting the cable and the pairs broken up in order to prevent cross-talk on grounded circuits; and at the same time allow of access to them for straightening them through when twisted metallic circuits are required. The necessity for getting at the joints in this way from time to time, and the space required to accommodate connecting boxes, is another argument in favour of large and commodious manholes.

The durability of lead pipe, with a slight mixture of tin, the maintenance of a uniform and high insulation, together with uniform resistance of conductors, after four years of service, are indications of length of life that are very encouraging.

Up to the present time we have met with no serious accident in our underground work, either from explosions of gas or the men being overcome with foul air. We believe it quite likely that gas is not as plentiful in the streets of Brooklyn as it is in many other cities, and therefore the accumulation in the ducts and manholes is not so great; but we have been very careful not to spare any precautions that would insure our safety.

The Dorsett conduit, of which we have five miles, with ducts two inches in diameter, has proved to be very unsatisfactory, and the ducts, on account of inequalities at the joints, will only permit of a cable an inch and a quarter in diameter being drawn in. This reduces the capacity enormously, and is therefore a source of inconvenience to us.

It is plainly proved that the use of underground wires reduces the margin of good working very largely, and will therefore require that extraordinary care must be taken to bring the service to its highest efficiency at all other points.

The most fruitful source of our trouble is the transmitter and battery, and while there have been very great improvements during the past year or two, there is still room for much more improvement before we reach perfection. The numerous contacts, in the magneto bells and other apparatus, need especial attention and care, and platinum should be used wherever possible.

Another source of trouble is carelessness in running the wire from the insulator outside the building to the instruments in the building. The writer knows of many cases where the subscriber's wire is run through the window casing with the ordinary cotton-covered wire and but little care taken in the inside of the building to keep it away from possible dampness.

As the mileage of underground wire increases, these and other faults now overlooked will become more and more apparent, and the expense of maintenance and inspection will be largely increased. There is only one way to bring back the easy working margin we have enjoyed on pole wires, and that is by the use of metallic circuits, and the sooner we get down to that basis, the better it will be for the service.

The following shows the actual extent of our underground work on September 1st, 1888:—

Length of conduit	15·17	miles.
,, ,, duct	105·5	,,
,, ,, cable	22·93	,,
,, ,, conductor	2053·3	,,

1,913 subscribers are working through underground wires using 1229·9 miles of wire.

The Indian Telegraphs.—The *Indian Engineer* says:—"A telegraph line has been constructed between Assam and Burma, through Munipur and Tummoo, and, besides connecting the two provinces, it forms an additional link in the telegraphic communication between India on the one side and China and Australia on the other. The telegraph has been already laid to Mansehra from Abbottabad, on the Oghi route. The laying of the line to Darband has been suspended for the present, until the troops have been pushed up in front of the working party.'

CHARLESWORTH'S PORTABLE PROJECTOR APPARATUS.

Messrs. Charlesworth and Co., electrical engineers, of Oldham, have recently designed an improved search-light apparatus, especially adapted for the Suez Canal traffic. The lights required for this purpose are a search light hung in a cage over the ship's bow, for use when under weigh, and an arc lamp hung in the rigging, for use when mooring at the stations.* The current is generated by an engine and dynamo taken on board with the lamps, and supplied with steam from the ship's boilers.

The engine and dynamo made by Messrs. Charlesworth are shown on the engraving (Fig. 1). The engine is of the open frame type, this form having been decided upon in preference

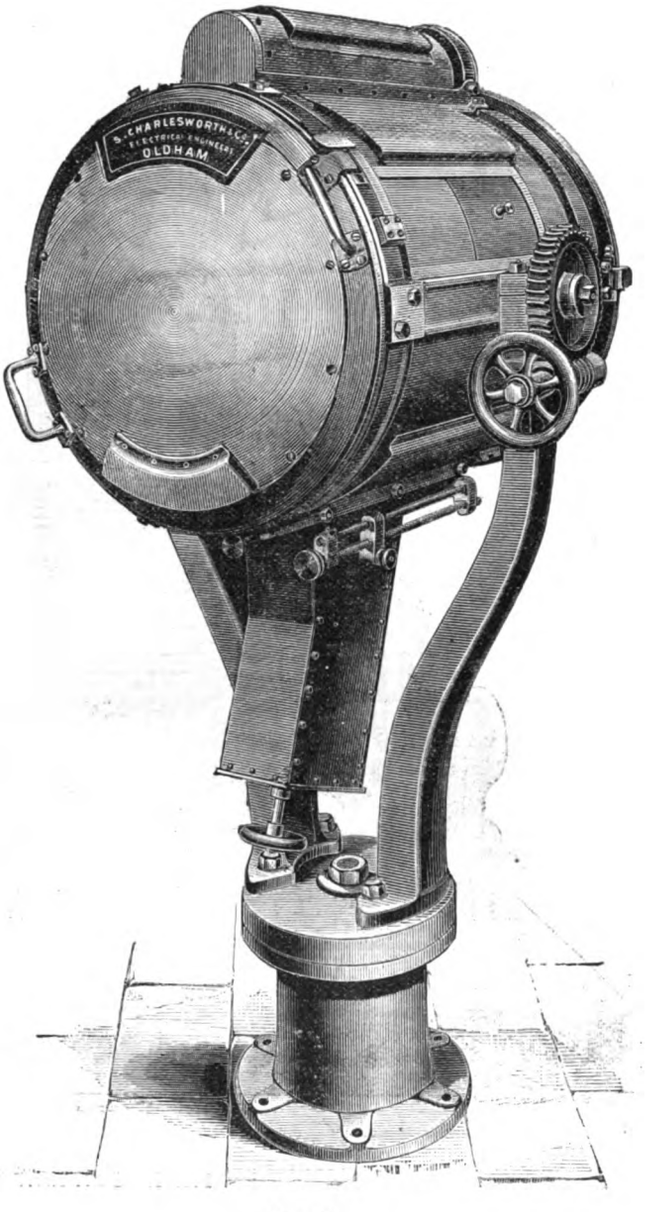


FIG. 2.

to any rotary or closed-in engine. The cylinder is 7in. diameter, stroke 6½in., and speed 425 revolutions per minute. It is usual in passing through the Suez Canal, on account of the slow speed at which the vessels proceed, to allow the pressure in the boiler to fall considerably below the normal, and on this account the engine has been constructed to work at the low-pressure of 40lb. per sq. in. On some vessels, however, this custom is not followed, pressures as high as 120lb. being carried occasionally. A throttle-valve governor does not work efficiently as a reducing valve through such wide limits, and so a hand expansion gear is fitted capable of varying the cut-off from ¼ to ⅞ stroke. By this means

* *See* also *The Electrician*, September 28th, 1888, p. 669.

Digitized by Google

the engineer can set the cut-off to suit the pressure, leaving a reasonable margin for the governors to deal with. In order to reduce wear on the valve gear, a piston valve is used. The crank shaft is of Whitworth steel and has cast-iron balance discs shrunk on the crank webs.

The dynamo, which is one of Messrs. Charlesworth's No. 5, is carried on the engine bedplate, the armature shaft being coupled to the engine shaft by means of a conical interchangeable coupling. It is compound-wound, and gives 65 volts, 55 amperes and 425 revolutions per minute.

The resistances are as follows:—Armature, ·151 ohm; shunt, 39·87 ohms; series, ·037 ohm. The machine is made rather large for its work in order to allow for the extra heating to be expected in the latitude of Suez. In order to protect the engine and dynamo from injury when being lifted on and off the steamers, they are enclosed in a strong steel box, not shown in the engraving, the sides of which can be removed when working. A ring bolt is provided on the top for lifting and rollers on the bottom. The engine has no tendency to walk about when working, so that there is no necessity to bolt it down, a few wedges only being required under the bedplate to take up the round of the deck.

The projector, which is one of Messrs. Charlesworth's Suez Canal type, is shown in Figs. 2 and 3. It is of very strong construction, the barrel being of rolled cast steel, with brass rings, and longitudinal stay bars. It is fitted with best quality Chance mirror and dispensing lens, and has the usual horizontal and vertical movements for directing the beam of light. In order to place the lights under the direct control of the pilot a switch, similar in appearance to an engine-room telegraph, is provided to be fixed on the bridge. Flexible armoured cables are provided for making the connections, and the necessary instruments and cut-outs are in the same box as the engine and dynamo.

The engine, projector, and general arrangement are chiefly the design of Mr. Claude W. Hill, who was engaged for some time on electric light work on the Suez Canal. The apparatus was passed by the Suez Canal Company at the first trial, and Messrs. Charlesworth have received orders for several sets.

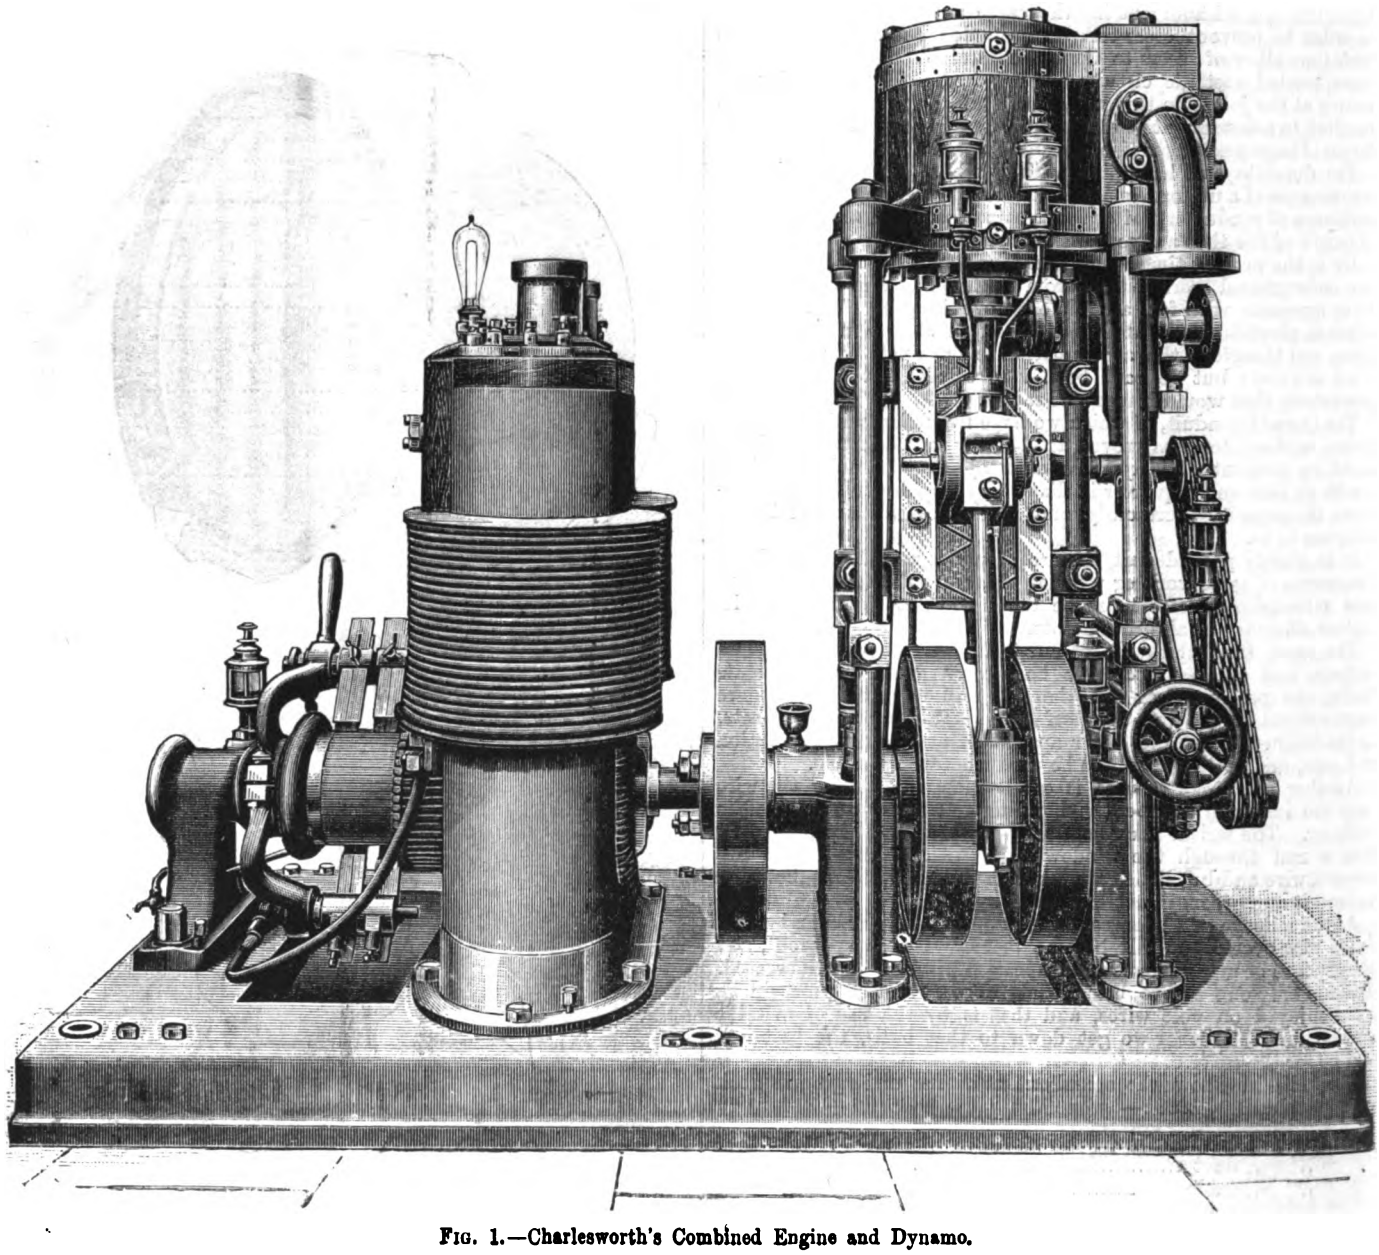

Fig. 1.—Charlesworth's Combined Engine and Dynamo.

THE USE OF MICA AS A DIELECTRIC.*

BY DR. JGNAZ KLEMENCIC.

These investigations were made to determine the specific inductive capacity of mica, and its suitability for the manufacture of condensers, and the following results have been obtained:—The value of the specific inductive capacity is 6·64. The capacity in the case of perfectly dry mica is independent of the charging E.M.F., and was found to increase by only 1·8 per cent. when the time of charge was increased from ·002 second to 20 minutes, the time of discharge

* Abstracted from Exner's "Repertorium der Physik."

Digitized by Google

in each case being ·007 second. The specific resistance is not less than 6×10^{21} times the specific resistance of mercury.

But little is to be found in electrical literature on the subject. Fleeming Jenkin found about a 7 per cent. variation of capacity between a momentary charge and one of five seconds. Colley found that the two best out of a number by Elliot varied 10 per cent. under similar circumstances, and Kägi has also done good work on the subject. There can be no doubt that the discrepancies between the results obtained by different investigations are to some extent due to variation in the mica itself, but the author believes that the great differences between his results and those just referred to are to be ascribed rather to the fact that in his observations the mica was absolutely dry. Temperature has also a great influence on capacity; but this has been left for a future investigation.

Determination of the Specific Inductive Capacity.

Two plates of mica were experimented with, 400 square centimetres area, and 0·00508cm. and 0·0108cm. respectively in thickness. The thickness was determined with great accuracy, and the methods employed are described by the author in detail. Each plate was then made up as a condenser in the following way:—A perfectly true iron plate 18 by 18 centimetres was electro-plated with copper and amalgamated; it was then carefully dried and cleaned, and placed with its amalgamated side upwards. A few drops of mercury were then poured on, which immediately spread over the whole, forming a pasty but at the same time a firm surface. The mica plate was then slid quickly on, pushing all dirt before it, and leaving a perfectly bright surface of mercury amalgam in contact with its under side. Any air bubbles were at once apparent, and could be worked out by moving the plate about. In the thicker plate some small air bubbles were noticed in the plate itself, but none were observed in the thinner one.

The upper covering was also formed of mercury. A strip of sheet iron, ·5 millimetre thick and 1 centimetre wide, was made into a ring about 17 centimetres mean diameter. This was stood on the middle of the mica plate, the lower edge being first tested on a surface plate and made perfectly true, and the upper edge stiffened to prevent deformation. The tube was coppered and amalgamated, as there was otherwise a slight error due to the mercury not touching the iron all round the edge. The diameter was of course measured to the *outside* of the tube. The S.I.C. was determined from the formula

$$\sigma = \frac{4 \pi d k}{S},$$

where σ = the specific inductive capacity of the dielectric, k the capacity of the condenser, d the distance between the coverings, and S their area.

The capacity was measured by discharge throw compared with that of a known air condenser. To avoid errors due to absorption

both the time of charge t_1 and the time between charge and discharge t_2 were made as short as possible. Hiecke's method* with a falling weight was used, t_1 being ·00026sec. and t_2 ·007sec.

Under these conditions two tables of tests are given showing for the thin plate $\sigma = 6·74$ at 14° Cent. and for the thick 6·54 at 14·3°.

When t_1 was made 20 seconds, t_2 still remaining ·007, the values of σ rose to 6·97 and 7·07 respectively. This apparent increase is nearly exactly inversely proportional to the thickness of the plates. At the end of each set of readings one was taken with the battery reversed, but no polarisation effect was obtained. When continuously charged and discharged for two hours by tuning fork the capacity remained absolutely unchanged.

The 3 per cent. difference in the value of σ for the two plates the author attributes to some slight irregularities which were observed in the thicker one, and possibly to a small error in determining the thickness.

The value found is not in accordance with that of the refractive index according to Maxwell's "Electro-Magnetic Theory of Light," the refractive index for mica being, according to Landolt and Börnstein, 1·6; but as has been often pointed out before, in dispersion formulæ there is no certain method of determining the refractive index for waves of infinite length.

THE COST OF STEAM, CABLE, AND HORSE TRACTION ON THE BIRMINGHAM TRAMWAYS.

The working of the Birmingham Tramways at the present moment affords a favourable opportunity for the comparison of the cost of the various systems of traction. Some further information on these points may be found amongst our "Notes" this week. In the above table we give detailed figures as to the cost per average mile run, obtained from the balance-sheet showing the working expenses for the year ended June 30th, 1888.

ASBESTOS-PACKED COCKS.

The disadvantages attending the ordinary method of packing cocks has led to Bell's Asbestos Company taking up a system of asbestos packing,

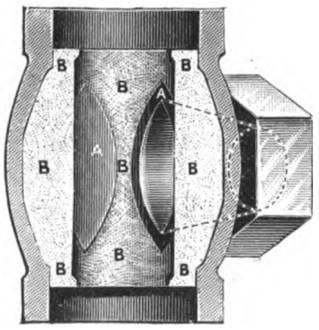

Fig. 1.

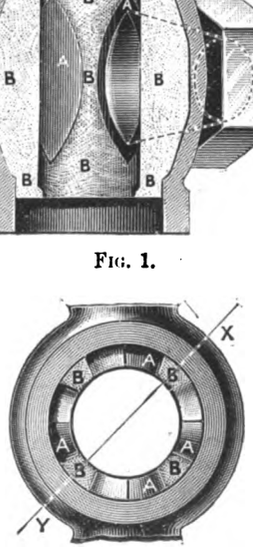

Fig. 3.

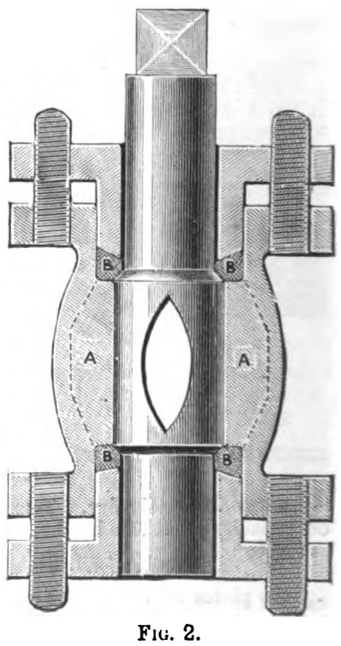

Fig. 2.

the invention of Mr. Baines, which is a marked improvement upon the old system. These asbestos-packed cocks are shown in Figs. 1, 2, 3. Fig. 1 is a section on the line X Y, Fig. 3; Fig. 2 a sectional elevation; and Fig. 3 a plain view of this cock. On the inner circumference of the shell four projecting pieces, A, of oval form are cast, having pointed ends at top and bottom, through two of which the way passes. The grooves B

Digitized by Google

thus formed increase in depth as they decrease in width, so that they are of the same sectional area throughout their length. The packing when acted upon by the glands will flow easily along the grooves B, and owing to the peculiar formation of the grooves (their holding capacity being the same at their greatest and least diameters) the packing cannot become jammed. When further packing is required, it is added at the glands in the usual way, and this can be done while under pressure, no special skill or tools being required. There is no packing between the bottom of the plug and the barrel, so that friction and wear are reduced, and the cock is more easily opened and closed. Screwing down the glands merely affects the packing, tightening it, or, in case of leakage, taking it up. There is no liability of the plug jamming, or of metal to metal contact between the periphery of the plug and the barrel, both being parallel. Cocks thus packed have been in satisfactory use for some time past, being highly spoken of by users. One engineering firm states that it has severely tested them with water at 1,000lb. and steam at 70lb. per square inch for two months, and finds them superior to any packed cock ever seen.

PRACTICAL STANDARDS FOR USE IN ELECTRICAL MEASUREMENTS.

Report of the British Association Committee, consisting of Prof. G. Carey Foster, Sir William Thomson, Prof. Ayrton, Prof. J. Perry, Prof. W. G. Adams, Lord Rayleigh, Dr. O. J. Lodge, Dr. John Hopkinson, Dr. A. Muirhead, Mr. W. H. Preece, Mr. Herbert Taylor, Prof. Everett, Prof. Schuster, Dr. J. A. Fleming, Prof. G. F. Fitzgerald, Mr. R. T. Glazebrook (Secretary), Prof. Chrystal, Mr. H. Tomlinson, Prof. W. Garnett, Prof. J. J. Thomson, Mr. W. N. Shaw, Mr. J. T. Bottomley, and Mr. T. Gray, appointed for the purpose of constructing and issuing practical standards for use in electrical measurements.

The committee report that the work of testing resistance coils has been continued at the Cavendish Laboratory, and a table of the values found for the various coils is given :—

Legal Ohms.

No. of Coil.	Resistance in Legal Ohms.	Temperature.
Elliott 193, C.C.L. 178	·99971	15°·5
Elliott 201, C.C.L. 181	1·00005	14° 8

B.A. Units.

No. of Coil.	Resistance in B.A. U.	Temperature.
Elliott 200, C C.L. 71	1 00049	13° 8
Elliott 43, C.C.L. 72	·99955	14° 7

In conformity with the opinion expressed by the committee in their last report some steps have been taken towards the construction of an air condenser. A meeting was held in London, and Dr. Alex. Muirhead exhibited an air condenser, capacity about ·0035 mf. This condenser consists of a series of concentric cylinders of brass, insulated from each other by glass rods. Dr. Muirhead expressed his willingness to lend this condenser to the committee, with two others of similar construction, and it was agreed that the secretary should be requested to test them and to make a determination of their absolute capacity. Some delay in sending the instruments to Cambridge unavoidably took place, but the experiments requisite are now in progress. So far, of the £80 granted last year for the purpose only £2. 10s. has been expended.

During the year the original resistance standards of the Association have been compared with each other by the secretary and Mr. T.. C. Fitzpatrick ; an account of the experiments is given in the appendix to the report, together with a chart giving the values of their resistance between 10° and 20°. The general result of the comparison is that, with perhaps one exception, the relative values of the standards between the temperature of 10° and 20° have not changed since they were constructed in 1865 until June, 1888. A change of about ·0002 B.A.U. has been observed in the coil F since the end of June, 1888.

The attention of the committee has been directed by several practical electricians to the desirability of a redetermination of the value of the specific resistance of copper. It is known that copper wire is now made having a resistance three or four per cent. less than Matthiessen's standard. In view of the importance of copper to electricians the committee have undertaken to make experiments on the specific resistance of copper, and wish to thank the various gentlemen who have brought the matter forward for their offers of help.

At the last meeting of the committee it was resolved on the motion of Mr. W. H. Preece to adopt the name "therm" for the gramme water degree Centigrade unity of heat. Thus, one "therm" is the quantity of heat required to raise one gramme of water at its maximum density 1° Centigrade. It was also agreed to adopt the name "joule" for 10^7 C.-G.-S. units of work. Thus, a joule is equal to 10^7 ergs. It is the work done in one second by the power of 1 watt, or, again, the work done when a current of 1 ampere flows for one second between two points between which the difference of potential is one volt, and hence a power of 1 watt is 1 joule per second.

Hence, also, if we take the value of the mechanical equivalent of heat as $4{\cdot}2 \times 10^7$ ergs, we have 1 therm is equivalent to 4·2 joules.

In accordance with a suggestion made at the Manchester meeting, the value of the resistance of mercury in terms of the B.A. unit has been again determined by the Secretary and Mr. Fitzpatrick. They find that a column of mercury, 1 metre long, 1 square millimetre in section, has at 0° C. a resistance of ·95352 B.A. units, and that the value of the ohm in centimetre of mercury is 106·29. The committee are of opinion that they should be appointed, with the addition of a name of Mr. T. C. Fitzpatrick, to continue the experiments already referred to, and with a grant of £100. They propose that Prof. G. Carey Foster should be the chairman, and Mr. R. T. Glazebrook the secretary.

THE JASPAR ARC LAMP.*

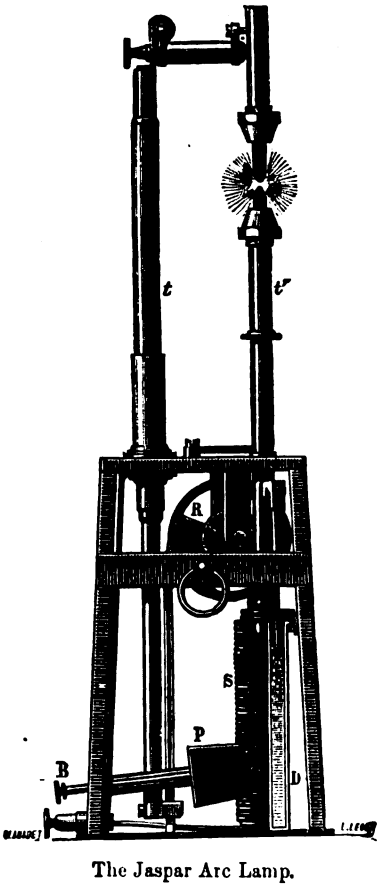
The accompanying figure shows the arc lamp designed by M. Jaspar, of Liége ; it is a lamp of the Achereau pattern, though more complete in its details and of greater sensitiveness than its prototype. The rod *t* is in connection with the positive terminal, and is completely insulated from the frame of the lamp. To the top of this rod the positive carbon-holder is fixed, and at the bottom a stud, sliding in a vertical groove, prevents the rod and holder from turning round. As in the case of the Serrin lamp, two regulating screws allow the upper carbon to be accurately adjusted with respect to the lower arc. A small cord attached to the projecting stud and to the pulley R serves to connect the movements of the two carbon-holders. The negative carbon is fixed to the rod *t'*, which is in electrical connection with the frame of the lamp and the negative terminal. This rod *t'*, which is of iron, penetrates into the solenoid S, and is connected by a cord to the rim of a pulley, which is upon the same axle as R, but which has a smaller diameter, so that the rod *t'* rises just half as much as *t* falls. Close to the solenoid S there is a cylinder, D, which is in the lamp's circuit, and contains a plunger, having a slight lateral play, and moving in a column of mercury. The plunger is connected to *t'* by a rod. The counter-weight P slides upon a horizontal lever, and from it a cord runs to a third pulley, fixed to the same axle as the other two. The screw B regulates the position of P, and thus increases or diminishes the effect ; another counterweight, *r*, is fixed between the spokes of the first pulley R, with a view to counterbalance the increasing pull of the solenoid upon the rod *t'*, as it rises further and further.

The working of the Jaspar lamp is easily understood. As soon as the current passes through the coils of the solenoid the rod *t'* is pulled down, and the arc is struck ; the rods are clutched in this position so long as the solenoid acts on its armature. The lengthening of the arc causes the attractive force of the solenoid to weaken, and the carbons, acted on by the weight of the rod *t*, come slightly closer together ; this naturally increases the strength of the current, and the solenoid again attracts its core. The counterweight P acts in opposition to the movement of the rod *t*, and by sliding the weight further along the lever the effect of P is increased, thus allowing us to use the same lamp on very different circuits. The piston moving in the mercury produces two equally useful effects ; *t* prevents sudden jerks and ensures a good electrical contact for the negative carbon. Contact is made with the rod *t*

* Translated from M. Hippolyte Fontaine's "Éclairage à l'Électricité" by kind permission of the author.

Digitized by Google

either by the friction of the rod against its case or by a little brush. M. Jaspar has overcome the difficulty presented by the additional magnetic effects of the solenoid the further the core rises, in a highly ingenious manner. Where the arc is struck, the weight r opposes the motion of the moving rod, but as the pulley turns, its effect slowly diminishes to nothing, and then gradually increases to a maximum in the opposite direction. By the figure we see that at the moment when the carbons are nearly consumed the weight of the rod t is increased by the full effect of the counter-weight r, and that if the pull of the solenoid is a maximum so is the counter-pull of t and r. The three chief features of the Jaspar lamp are—first, the mercury cylinder; second, the sliding counter-weight, allowing the lamp to



The Jaspar Arc Lamp.

be used with different currents; third, the variable counter-weight, keeping the length of arc constant so long as the lamp is burning.

ELECTRIC LIGHTING: ITS PRESENT POSITION AND PROSPECTS.

LECTURE BY Mr. W. LANT CARPENTER, B.A.

A lecture upon this subject was delivered at St. George's Hall, Langham-place, on Sunday last, 21st inst., by Mr. Wm. Lant Carpenter, B.A., B.Sc., before a large and aristocratic assemblage. In his opening remarks the lecturer said that the subject of electric lighting had an important bearing upon the social welfare of mankind. In New York it was considered that every arc lamp was worth a policeman, and the lamentable state of affairs in Whitechapel could not have existed so long if the district had been better lighted. As regarded the sanitary aspect of the question they all knew that buildings, shops, rooms, &c., lighted by electricity, were in a much freer condition from carbonic acid and other products of combustion in the air, than they would be if gas were used. There was also very little risk of fire. One of the reasons why electric lighting had not at present made greater progress had been the wild promises which had been made by inventors of primary batteries. People had been told that batteries could be supplied which would require no attention whatever. They merely had to purchase the article and put it in their cellars, and the whole thing was done. The sooner this fiction was exploded the better it would be for the prospects of electric lighting. Within the last few years enormous improvements had been made in the construction of dynamos, particularly with regard to their electrical commercial efficiency, which between 1882 and 1887 had been increased from 67 to 93 per cent., while their weight, bulk and cost had been correspondingly reduced. The dynamo of the present day was almost a perfect machine. People who were at present reluctant to take up the matter would endeavour to justify their position by saying that they would wait until the whole thing had been brought to perfection. To this he would reply, that as far as commercial efficiency was concerned, perfection had almost been reached, and that no further improvements were likely to be made in that direction, though possibly the weight, bulk and cost might be further reduced. There were, as they knew, two systems—the arc and the incandescent. With regard to the comparative cost of the two systems as against gas, he might say as to the arc lighting, that if they took into account the number of candle power which was produced, the arc light, under almost any conceivable set of conditions, was much cheaper than gas light. The reverse, however, was the case with the incandescent. He might incidentally mention the enormous saving of time and consequent expense effected by the use of electric light on ships passing through the Suez Canal at night, the result of which had been an annual saving to maritime commerce of £100,000. In consequence of the improvements in ventilation which had been made in coal mines the velocity of the air had been considerably increased, the effect of which was to make the Davy lamp decidedly dangerous. Here the electric light stepped in, and a syndicate was now bringing out a portable lamp (a specimen of which was shown in action) which it was thought would remove all liability of danger from contact between the flame and anything which might cause explosion. The lamp in question weighed 4½lb., would burn for twelve hours, and immediately the glass front was broken by accident or opened by design the light would go out. Several illustrations were given of private installations, notably those of Messrs. Pears, where accumulators were used, and of Baron Rothschild's mansion at Tring, where there were no accumulators but a duplicate set of machinery, dynamos, &c. The installation of the arc light at the Waverley Station, Edinburgh, was also instanced; here the cost per hour of each lamp had been reduced to a little over 1½d. Since the passing of the recent Electric Lighting Act the question of central station lighting had assumed considerable importance. When the question of central station lighting first arose electrical engineers were met by the wide and difficult question of distribution. There were two great systems of distribution, the first of which was known as the battery or storage system, and the second as the converter or transformer system. High potential currents would travel over very small wires, and the higher the pressure the smaller the wire. But these high pressure currents were dangerous for domestic lighting, and the Board of Trade would not allow a higher pressure than they considered safe, and engineers were then face to face with the problem of finding some means whereby a high-pressure current could be converted into a low-pressure current before it was safe for the supply to enter a house. There were then two systems introduced, one much older in point of time than the other—the battery or storage system which required continuous currents, and the transformer or converter system which required alternating currents. In the latter connection, several lantern photographs were exhibited on the screen, illustrative of Messrs. Gaulard and Gibbs' system. There was, of course, one objection to an alternating-current machine, and that was that it could be only used for lighting, while a continuous-current machine could be used for either lighting or motive power. The recent Electric Lighting Act of course materially improved the prospects of the industry, and, indeed, might prove to be the turning point in its history, inasmuch as it offered inducements to capitalists to put their money into new ventures; but still it was felt that new electric light companies were not given the same advantages as new gas companies. Since the passing of the Act in question at least 30 stations had been not only projected, but actively pushed forward, notably in Kensington Court (where the plant had recently been tripled), at Chelsea, and at various other places in London, the whole of the business part of Liverpool, at Bradford, at Leamington and elsewhere; all these were on the battery system. Transformer stations had been projected for Chatham and elsewhere. There were several towns which had not quite made up their minds, notably Tunbridge Wells, Southampton, Reading, &c., while Brighton, Hastings and other towns already had their installations. As they knew, the wires in connection with the electric lighting industry were at present overhead, but all electrical engineers were agreed that for permanent work there was no question but that wires must be laid underground. One of the obstacles in the way of overhead wires was the extreme difficulty of getting wayleaves. From this cause the Grosvenor Gallery installation could proceed no further east than the Gaiety Theatre. There had been considerable progress made in the direction of electric lighting abroad and even Honolulu, in the Sandwich Islands, had its installation. One of the reasons of the rapid progress it had made in the United States was the high price the Americans had to pay for gas, for which the usual charge was two to two and a-half dollars per 1,000 feet. He would give them some instructive figures as to the extent of electric lighting in the States. There were no fewer than 5,350 electric plants and stations, about 1,925,000 arc lamps, and about 2,250,000 glow lamps, absorbing together about 460,000 horse-power. Four or five factories can turn out 10,000 incandescent lamps in a day. The lecturer referred incidentally to the two great patent cases which had been recently heard, and suggested that instead of these very technical disputes being tried in the usual way in a court of law by the orthodox judge the matter should be left to the decision of experts, in the same way as naval questions were. It had been truly said that the first two or three days of the hearing of the cases in question were occupied in "educating the judge," which was rather a costly proceeding for those who had to pay the piper. A gentleman of his acquaintance, of high repute in the electrical world, had said that at the present time there was one great obstacle standing in the way of the greater extension of the electric lighting industry, namely, the natural conservatism of the English nation, which showed itself most strongly in the opposition of local and municipal authorities to all attempts in the direction of co-operative supply. The lecturer concluded by saying that if this country were to take the lead in the future application of electricity to lighting its common sense would have to be reawakened.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *October 13th*, 1888.

The report presented at the annual meeting of the Western Union Telegraph Company this week fully confirms the favourable anticipations which I have expressed in my letter. It appears that the gross revenue for the year ended June 30 was $19,711,164, and that the expenditure was $14,640,592, leaving a net income of just over five million dollars. Out of this sum close upon four millions were spent in dividends, and the balance of about $500,000 was carried to surplus, which now figures out $7,500,000. This is a good showing for a company with a capital stock of $86,000,000. During the last 22 years of its existence the company has earned and collected the magnificent sum of $91,383,000, and has paid in dividends $51,185,000. These figures are an indication that even if the Western Union stock has been somewhat liberally watered, the proportion between its capital and its earning capacity is not an unreasonable one by any means. It will be remembered, too, that the stock includes the amount of $5,000,000 issued during the year for the purchase of the Baltimore and Ohio system. At the close of its fiscal year the company owned and operated 171,375 miles of poles and cables, carrying 616,248 miles of wire, from which were sent during the year 51,463,955 messages. The company also carried on its business through 17,241 offices. The average amount received per message during the year was 31⅕ cents, as compared with 30⅘ cents the year before. Altogether, it must be admitted that the report is creditable to the management of such large interests in private hands, and it is evident that the transfer of such a system to Government control would not only require a very large sum of money, but would also present questions of the first national and political importance. It is somewhat significant of the smoothness with which the vast machinery of the company is kept in operation that at the meeting at which the report was presented only four gentlemen were present, two of whom are engaged in the building in the service of the company, Dr. Green and Mr. Van Horne. As regards the earnings of the company it is, of course, clear that the current year should show a much better record than that whose figures I have just recited above. The past year affords traces of the old fight with the Baltimore and Ohio Company, and the cable war was also carried on until a very few weeks ago. Thus the anticipations of those who expect to see the Western Union Company's Stock going to 100, and the dividends going up to 7 or 8 per cent., bid fair to be realised.

A very interesting article which appeared in this week's *Electrical World* gives an idea of the manner in which, even in such an old and well-established business as that of telegraphy, important improvements and economies can be introduced, bringing out better results and yielding better returns on the capital invested.

It appears that the old Siemens machines which supplied current for the circuits in the Western Union office in this city, till they were replaced by a new Edison plant, have been put up in the new office of the company at Pittsburg, and that they are used for similar circuits under somewhat novel conditions. These machines are now employed not only to supply current for the long-distance circuits, but are also drawn upon very largely for the "local" circuits, and this is the first time, we believe, that dynamos have been employed for that class of circuits. Another remarkable feature is that instead of the Siemens machines being driven from an engine they are operated by means of motors put in by the local Alleghany County Electric Light Company, and driven by current from that company's station, the motors being directly connected to the regular power circuit. It will thus be seen that the Western Union Company dispense altogether with the worries incidental to a large steam plant such as it would have had to put in, and that it is saved from the expense of engineers, firemen, &c., as well as from the annoyance of coal, ashes, &c. Moreover, the arrangement displaces about 12,000 cells of battery on the main lines, and about 1,100 on the locals, and those who are familiar with gravity batteries will know what it means to be relieved from the care, renewals, &c., of over 13,000 cells. The motors not only keep the telegraph generators going, but they furnish power to run the blower for the pneumatic tubes between the operating room and the receiving and delivery departments on the ground-floor. This is said to be the only telegraph office in the world where not a single cell of battery is in use, and the results obtained appear to have been highly satisfactory. It is also worth mentioning that fifteen calling generators are also driven for the telephone company in Pittsburg on the motor circuit of the Alleghany County Company. Such a utilisation of the motor both in telegraph and telephone service may strike some of your readers in England as a novelty, but we have already more than one instance of this kind in the United States, and the general impression is that there will be a very rapid extension of this class of work, and that the consequence will be a diminution in the field of usefulness of the primary battery.

The telephone litigation has once more been brought to public attention by an argument which took place this week before the United States Supreme Court at Washington. Some time ago a suit was brought by Acting-Attorney-General Jenks in the United States Circuit Court at Boston to have cancelled the two Bell patents, on the ground that they were obtained by fraud. The case, it will be seen, is a variation on the big suit recently decided, and was the outcome of the action of the Government in taking up the matter. In this suit the Bell Company entered a demurrer, in which they maintained, among other things, that in the absence of any specific statute the United States had no power to obtain a Bill in equity to cancel a patent for an invention. In this contention it was supported by the Court, which held the point to be well taken, and ruled also that even if the Court were not to go to such an extreme length the demurrer must be sustained on the ground that the main question raised against the validity of Bell's patents could be advanced in an infringement suit, and that the Attorney-General could not bring a suit to cancel a patent on grounds which constitute a defence in an infringement case. It is against this decision that the Government have brought the matter to the Supreme Court. Special interest was given to the argument from the fact that it was opened by Mr. Allen G. Thurman, who appeared on behalf of the Attorney-General, and who, in addition to being well known, now occupies a very conspicuous position before the country as the Democratic candidate for the Vice-Presidency.

In my last letter I made some reference to the utilisation of water-power in this country for electrical purposes, and gave a few statistics of the work that has been done or is proposed. In this connection it is interesting to note the report that has been made to the *Railroad Gazette* by Mr. E. H. M'Henry, engineer-in-chief, on the work done at the Stampede Tunnel in Washington Territory. This tunnel is the second in length in the United States, being 9,844ft. long, and it pierces the main range of the Cascade Mountains at an altitude of 2,800ft. above tide water. During the period of its construction arc lights were used with very good results, but it was deemed advisable to adopt the incandescent system for permanent use, the engineers on the Northern Pacific Railroad being of the opinion that with the incandescent system a better distribution of light would be had, with an economy in attendance and the cost of renewals. The plant was furnished by the North Western Supply and Construction Company, of Seattle, Wash. Terr., and consists of an Edison municipal machine, running at an E.M.F. of 1,200 volts, and maintaining 300 lamps of 30 candle-power each. These lamps are supported on iron brackets at intervals of about 66ft. on each side, thus giving a lamp to every 33ft. The lamps are arranged in six circuits, so that any or all of them can be lighted at will for the convenience of workmen or of trains, and it is noticeable that the lamps are placed rather low down, it being necessary to avoid the smoke which accumulates in the crown of the arch. Ordinarily this interesting plant is operated by water-power from the falls of Mosquito Creek, which furnishes a head of about 160ft., with but 400ft. of piping at the eastern entrance of the tunnel,

Digitized by Google

Provision is made against drought by a plant of a 50 horse-power high-speed Ball engine and a 60 horse-power steam boiler, and the dynamo is arranged to connect with either the steam engine or the Leffel water-wheel. This is not only an interesting plant in itself, illustrating the utilisation of water power and the use of electric lights in railway tunnels, but it shows very clearly how little distance is allowed in this country to interfere with this kind of work and the employment of the latest and most advanced facilities. Even to Americans the name of the Stampede Tunnel is still somewhat unfamiliar, and the region seems remote, as it undoubtedly is; and yet it will be seen that the work is carried out in good shape and under contract by an electrical supply company at a place where a few years ago not a single house was standing.

The American Institute of Electrical Engineers held a meeting this week at which Mr. Frank J. Sprague's Paper, delivered at the close of last season, on "The Electrical Solution of the Principal Rapid-Transit Problems," came up for discussion. The subject elicited quite a lively debate, which was opened by the presentation of two formal Papers, one of which was read by Mr. M B. Leonard, who is a resident of Richmond, and as a telegraph official familiar with electrical questions was enabled to take a disinterested view of the operation of the big Sprague road in that city. Mr. Leonard's Paper contained a number of valuable criticisms, some of which were well-directed and important, but none of which presented insuperable obstacles to the continued successful operation of the road. Mr. Sprague availed himself of the opportunity to reply to most of the points raised, and to add to his statements made last June. Perhaps the most striking fact he mentioned as showing the difficulties with which the road had had to contend was that for a period of some nine or ten months since the road started none of the cars had been under roof, but had simply been "housed" in the street or in the open car yard, subjected to all sorts of bad weather and other detrimental influences. In many cases the cars had to run through big pools of water and long stretches of mud. The result was that not only did the machines become beplastered with dirt till they were well-nigh unrecognisable, but they were constantly subjected to the danger of short-circuiting and burning out from the accumulation of moisture. Apparently it is along this line of improvement that Mr. Sprague's ingenuity has been working, for he reiterated his remarkable statement, that he proposed to have on his cars a motor that could practically be washed down with a hose, and an armature that could be plunged into a barrel of water and taken out and used. As to the use of the storage batteries upon which Mr. Leonard had touched, and for which he had expressed a preference, Mr. Sprague said that he considered the present storage battery altogether too heavy and certainly out of consideration for such work as was involved at Richmond, with its grades of 10 per cent. and sharp curves. At the same time he expressed his conviction, from what he knew of experiments being made, that the storage battery would very shortly be materially improved, not only being made up of plates that are practically indestructible, but having its weight cut down for the same output to a figure altogether within economy and practicability. As usual Mr. Sprague was positively brilliant in his discussion of the various criticisms offered, and won not only admiration for his ability as a practical electrician, but for his frankness in acknowledging shortcomings and defects. In his case, as in that of other of our workers in this field, however, the difficulties are acknowledged simply to be overcome.

As you are aware, there has been during the past year a marked movement in this country in the formation of local electrical clubs and societies, in which, according to the tastes of the organiser, the social or the scientific element has predominated, and in all of which the platform has been the promotion of intercourse among those engaged in the same lines of work. Cincinnati, Ohio, has now fallen into line, and has organised an electrical society. The step was timely from the fact that the Cincinnati Centennial Exposition just being held in the city has been notable chiefly for its electrical display, and for the reason that there has consequently been great activity in electrical circles. The first meeting was held this week, when Dr. Otto A. Moses, who is acting for the Commissioners of the Exposition as their juror for all groups containing electrical apparatus, was to deliver an address on "Electrical Education."

I alluded at the beginning of this letter to the condition and prospects of the Western Union Company, but it is, perhaps, not out of place to note that some of the New England papers have been talking about new opposition springing up in their section of the country on the completion of the Delany synchronous multiplex lines there. It is understood that the system, which, as you know, was acquired some time since by the English Government, and has been beset here by financial difficulties in its early stages, is about to go into operation between Boston and New York, and it has also been reported that gentlemen representing the Standard Oil Company and Pennsylvania Railroad were interested in pushing things. The statement is made that the new company will pay particular attention to the commercial transactions between the principal business centres, and will lease wires to the daily newspapers at $2,500 a-year; whereas the Western Union rate has been $4,000. As regards the Standard Oil Company, however, it may be well to point out, as offsetting some of the rumours, that one of the new Western Union directors is Mr. H. M. Flagler, a leading representative of that corporation. For a long time past the enmity between the Western Union and Standard Oil management has been a pretty well-known fact; but the adoption of Mr. Flagler into the Western Union directorate looks like an *entente cordiale* between the two parties, if, indeed, it may not mean something more. Probably those only know what it means who are in the swim.

CORRESPONDENCE.

PRACTICE *V.* THEORY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The correspondent whom you quote on the first page of your last issue, though he says some true things, is guilty of a serious exaggeration in his last sentence when he says that the practical men are usually one generation behindhand. In theoretical matters, and on points which do not appear to them likely to have an immediate practical bearing, they usually are, but it is a matter for admiration how rapidly their leaders manage to place themselves abreast with the latest scientific developments as soon as they appear likely to have a commercial bearing.

And this keen interest and rapid assimilation of new ideas on the part of men of application, who have such an immense mass of detail to attend to from which men of pure science are comparatively free, often put to shame the lethargy of pure physicists of the old school.

The healthy and vigorous activity of the science of electricity at the present time, the enterprise, one may almost say the existence, of journals such as your own, are all consequences of the applicability of electricity to daily life, and they are consequences which react upon pure science with the most beneficial and stimulating effects.—Yours, &c.,

19th October, 1888. OLIVER J. LODGE.

LIGHTNING CONDUCTORS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The enclosed fragment of a letter from Dr. Hertz to myself may perhaps be of interest to your readers, as showing, at any rate, what he thinks of some points which are in this country almost matters of dispute.—Yours, &c.,

OLIVER J. LODGE.

"Karlsruhe, 14th October, 1888.

"I read the Papers with the greatest interest, especially your Address before the Society of Arts 'On Lightning Conductors.' I often thought that these things would apply to lightning conductors, but did not know that the best part of such an application had already been given by you. In the

Digitized by Google

future I hope that such ignorance will not last, for I shall be glad if you will send me your Papers, and I will act accordingly. A colleague of mine is very interested in lightning conductors, and came to me a week ago to ask information about your heretic opinions. I tried to give it him, but it is very difficult to tell an electrician of the elder school that lightning does not go through copper nor iron, but goes only by means of air or gutta percha or insulators. I myself have made a great many experiments during the summer, which clearly illustrate the truth, and some of which are very similar to some of yours. I am proceeding now, and am very glad I did not publish anything before knowing your Paper.—Yours, &c, "H. HERTZ."

LIGHTNING.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The phenomenon to which Mr. W. P. Adams refers in his letter to *The Electrician*, p. 775, is one that I have observed on one occasion only, and though I have described it to several people, I have not hitherto found that it has been noticed by others.

It is now so long ago that I cannot remember all the circumstances, but the impression produced at the time was so vivid that I am certain of the following particulars:—

A thunderstorm travelling from S. to N. passed immediately over the village of Wing, in Rutland, at about 9 or 10 p.m. When it had travelled so far away that the thundercloud was low on the horizon, and the altitude of the top of the cloud was about half or a third, or possibly less, that of the lower bright stars in the Great Bear, at that time in their lowest position (and this fixes roughly the time of year), I noticed that while the true flashes of lightning between the cloud and the earth were often visible themselves, they were mostly accompanied by long thin flashes which extended up well into the space between the bright stars of the Great Bear, which were shining brightly in a perfectly clear sky. Sometimes but one of these lines of light would be formed, generally two or three, and I remember distinctly that one flash of real lightning, in or below the cloud, was accompanied by seven of these mysterious lines which simply went up from the cloud into the clear sky and left off.

These flashes had all the usual character of ordinary lightning, except that they seemed much thinner or less luminous. Their light, though seen direct, was much less than that in or below the cloud. I was sure that they were not the only flashes, but that they accompanied what I have called above the real lightning.

Though I have often recalled the circumstances I can offer no explanation. Perhaps they will be of interest to Dr. Lodge.—Yours, &c., C. V. BOYS.

Physical Laboratory, South Kensington.

THE "DARK" FLASH.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The dark lines in some photographs of lightning flashes are owing, in the opinion of the writer, to the exceeding transparency of the air occupying the space corresponding to the dark line. This would probably be proved by a close examination of the photograph; but to account for the transparency itself is another matter.

There can be no doubt that absolute uniformity in the density of any matter would render it transparent. Therefore, if we presume that the dark lines or flashes are the effect of comparatively perfect transparency of the corresponding portions of the air, we may take it for granted that they (the dark flashes) represent air, whether common or of any other kind, having an extreme uniformity of density in its constituent atoms; or, perhaps, it would be better to say groups of atoms. This throws a strong light on the nature of electricity.

Although it may not affect the *average* specific gravity of matter, electricity evidently affects the distribution, or what may be called the arrangement of its density amongst the atoms composing it.

There are probably few substances in nature, perhaps none, in which the specific gravity is absolutely uniform throughout, and the writer is of opinion that each substance is also liable to temporary variations of the manner, or pattern as it were, in which its different densities are arranged—sometimes abnormally approaching uniformity (which might be called an absence of pattern), at other times the reverse, namely, with an increased difference between the several densities; the direction in which the alteration may tend depending on the kind of electricity, positive or negative, with which it is charged. When that electricity is discharged the normal arrangement obtains, but not always, if ever, at one bound, but by oscillating from one of the two kinds of derangement, described above, to the other; for instance, supposing the charge of electricity to be of such kind as to produce an abnormal uniformity in the density of the substance, then a discharge of that electricity would produce (by what may be called oscillation) a system of densities having greater differences amongst them than there would be in the usual or uncharged state of the substance. It would now be charged with residuum electricity, to use the language of early electricians.

According to this, it would depend upon the number of oscillations that had taken place which kind of electricity, positive or negative, would be obtained from a residuum discharge.

To follow out this idea, it is evident that if we admit that the transparency of matter depends upon a uniformity of its density, nothing that is perfectly transparent can be charged with electricity, except at the expense of its transparency; and though that of the atmosphere is not perfect, experienced persons can often tell by its appearance that it is charged with electricity. The weather is then said to be "thundery," and after a thunderstorm the air is said to have been "cleared" by the storm.

To theorise a little more: an electrical discharge occurs when two substances (whether of similar or different natures), having their respective densities in two different states, come into contact. That is to say, for instance, when the arrangement of the several densities of one substance is normal, and that of the other abnormal, or when both are in abnormal states, one approaching uniformity more than usual, and the other the reverse.

When this occurs between two volumes of air, an oscillation follows the discharge, one extreme of which consists of a comparatively perfect uniformity in the density of the portion of the atmosphere affected; this produces transparency, and transparency with no luminous or illuminated body beyond it means darkness. Hence the dark flashes in some photographs of lightning.—Yours, &c., JOHN P. MOSS.

[We fear that our correspondent's views as to the relation between the homogenity and the transparency of matter are not borne out by facts, as commonly understood.—ED. *E.*]

"REMARKS ON TELEPHONIC SYSTEMS."

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In his article in *The Electrician* of October 19th Mr. Munro says that the telephonic exchange wires in Edinburgh and Dundee are supported on wooden standards. The matter is not perhaps of much moment, but, in the interests of accuracy, it may be well to correct an error into which Mr. Munro has no doubt inadvertently fallen. The wooden standards in Edinburgh, which Mr. Munro probably mistook for the Telephone Company's, belong chiefly to the Post Office, the North British Railway Company, and to various private proprietors. The Telephone Company own but very few, and these date from 1880 and 1881. In Dundee there are but two wooden standards belonging to the company, that at the central exchange and one other. The Edinburgh and Dundee wires are supported, like those in Glasgow and the other Scotch towns, by iron standards fitted with channel iron four-wire and six-wire cross arms and upright shackle insulators, on the system introduced by Mr. Bennett in Glasgow in 1881.

Mr. Munro likewise says that it was in London that the first public call offices were opened, but I venture to assert that the statement is not susceptible of proof. Would he mind giving the date and locality of the first London call office?—Yours, &c., A. S. T. E. AND E.

Edinburgh, October 22nd, 1888.

NOTES AND QUERIES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: May I ask when we are likely to get a description of the floating charging station of Messrs. Immisch? You stated, "We hope shortly to give a description of this station." That was some months back, since which we have seen nothing of the sort. I think the description would be of interest in view of the comparatively small space at Messrs. Immisch's disposal.

I was much interested in the description of the electrical tramway given this week in *The Electrician*, more particularly the way in which the motor stood the severe strain described by Mr. Dolan. Taking friction at 10lb. per ton (2,000lb. per ton), total horse-power = 35·5, and this will surely be under the mark, as 10lb. is a low estimate even for a Yankee street railway. Without allowing anything for curves, but taking it as it stands, this motor stood 137 per cent. above its nominal output, taking average weight of each passenger at 150lb. It would be interesting to know something of the construction of this motor and its weight.

In your account of the Leamington Central Station you state that the 3-wire system has been given up on account of the difficulty of regulation between the two circuits, and state that this difficulty may be stated to vary inversely as the number of lamps in circuit.

I am curious to know how this is, as we do not hear of any difficulty of the sort being met with on the other side of the water, and surely if they can manage it in Yankee-land we can manage it here. It has also been frequently stated that the 3-wire system saves upwards of 60 per cent. of the copper required for simple parallel. Now I can quite see that this is possible as a *tour de force*, but I do not quite see how much more than 30 per cent. can be saved in *practice* unless we neglect *heating effects;* for example—Let C = 2 (parallel system), diameter = 2, and R = 2; then energy wasted = $2^2 \times 2 = 8$. Now halve C = 1. If we make cross-section proportionate to C, and use a round conductor, as usual, then circumference radiating heat $\frac{2}{\sqrt{2}}$ and resistance = 2; therefore energy wasted $= 1^2 \times 2 = 2$, just a quarter of what it was before, and it has a larger proportional surface to radiate from, so all is safe; but if we are to keep the proportion $\frac{\text{total work}}{\text{lost work}}$ equal, then R = 8, and cross section $\frac{1}{8}$ and diameter $= \frac{2}{\sqrt{8}} = \frac{2}{2{\cdot}828} = 0{\cdot}71$; therefore, we have the same energy to be dissipated through less than half former area. Under these circumstances I should be afraid for my insulation, the weight being proportional to cross section, weight in each cable = $12\frac{1}{2}$ per cent. Now, we must make the centre wire equal in section to other two, else what would happen if one side had *no* lamps on? Therefore, total weight = $3 \times 12\frac{1}{2} = 37\frac{1}{2}$ per cent. of simple parallel, total saving = $62\frac{1}{2}$ per cent.

If we make cross-section proportionate to C, then weight of each cable = 25 per cent, and total weight = $3 \times 25 = 75$ per cent., and we save 25 per cent.; of course this saving may be increased by not having the centre wire the same section as the others. This seems to me the correct view of the matter, but I believe you hold the contrary.

I suppose your readers have often noticed the curious fact that tools (metal worker's) subjected to continuous vibration become somewhat strongly magnetic. In the course of the last eighteen months I have tested some hundreds of chisels, with the result of discovering the curious fact that they had N polarity at the cutting end. I have only found three exceptions, and those on inquiry had only been used for about half an hour, having just been to the toolsmith, and they had S poles at the cutting edge. It appears, therefore, that the polarity is reversed after some hours' use, as I found on testing them again after two or three hours' hard work. Scrapers are the same, but the polarity is less strongly marked. I do not know if this is new to you, as it is to me, but it is a very curious fact. I may mention that the works are lighted with gas, so that there are no means of accounting for it, except by vibration. Apologising for wasting your time to such an extent.—Yours, &c.,

MECHANIC.

COMPANIES' MEETINGS & REPORTS.

Western and Brazilian Telegraph Company. (Limited).

The sixteenth ordinary general meeting of this Company was held at Winchester House, 50, Old Broad-street, on Thursday, under the presidency of Mr. W. S. Andrews.

The SECRETARY (Mr. R. M. Cunningham) read the notice calling the meeting, and the minutes of the last ordinary and extraordinary general meetings.

The report of the Directors was taken as read.

The CHAIRMAN: This is the first half-yearly meeting of the Company held in pursuance of the resolution which was come to at the last annual general meeting, that the meetings in future should be held half-yearly. The matter for consideration to-day is confined to the report and accounts, and, therefore, I take it that we shall not have to detain you long, but that the business will soon be over. It is my pleasing duty on this occasion, as it was at our last meeting, to congratulate the shareholders upon the continued increase in the revenue. On that occasion I drew attention to the fact that the increase was continuous, and on this occasion, of course, that fact remains unaltered. We have had a continuous increase upon former satisfactory increases. We are considering at this meeting the working of the lean half year, not the fat one. The result of the half-year's working to the 30th June is a gross receipt of £86,874, compared with £81,419, showing an increase in the revenue for the half year of £5,454, which is very satisfactory. Now that deals with the revenue of the half year ended June, but I think the shareholders are entitled to information as to whether that satisfactory state of things is continuous, and I am glad to say that it is, and it is continuing in an augmented ratio, which is also satisfactory. Down to the present time in the current half year there is an increase, compared with the corresponding period of the previous year, of something like £25,000. That is a very large increase. Of course, in giving you the figures, you must understand that I am taking them from our estimates of revenue, but substantially you may rely upon the amount. It may be £100 or £200 more or less, but practically it is correct. Of course there are two and a-half months still to pass, and we do not know what the outcome of those two and a-half months may be, for we cannot predict the unknown. But judging from what has taken place, and what is taking place, we have no reason to think, in the absence of any misfortune—and we can see no misfortune on the cards—that the outcome of the year will be other than satisfactory to the proprietors. Having dealt with the revenue I will now go on to the expenditure of the same six months ended on 30th June last. The main fact in reference to that is that that an increase of revenue has been earned with a decrease of expenditure, but you must quite understand that that is owing to a particular circumstance with respect to renewals of cables, because everyone here must know as well as we do ourselves that you cannot conduct a larger business with smaller expenses. If you conduct your larger business with a small increase on the expenditure you are, generally speaking, extremely well satisfied. Well, now, with respect to the items of expenditure, the shareholders generally like to have all the information that can be given to them, and if you turn to abstract "A" you will find that the gross expenditure was £13,853, being a total increase on that account, which includes salaries, wages, and items in the working of the cable of £847. Then there are savings, which reduce that increase to £705. The largest item going to make up that £705 is £385, which is partly made up by increased payments in exchange account of some £60—and I explained that on the last occasion—and further by probationers who come on to the regular staff before they become telegraphists, and also on account of the increases of pay under our agreements. The next item of increase is that for travelling expenses £170, and that is owing to more time-expired men coming home and to more clerks having had to go out to take their places than was the case in the corresponding period. For new furniture we have spent £91, and £94 has been spent for addional stationery and printing required on account of our increased business. The sum of £54 was paid for quarters where we had to send our clerks, owing to the unhealthiness of the place they were stationed at. You will find those items make up £700. There are other small items not worth mentioning, and on the other hand there is a saving which brings the net increase in the expenses under Abstract "A" to £705, as I said before. Under Abstract "B," maintenance of ships, there is a gross increase of £791, and a net increase of £312. The "Norseman" was employed more actively during the half-year, consequently she used more coal, and there were more general expenses. Then the "Viking" was less actively employed, and there was a saving in her expenses of £479. The net increase under Abstract "B" is thus £312. The "Norseman" is the largest ship, and she was more actively employed. The increase in the expenses was rather larger than the saving which was effected by the less employment of the "Viking," that vessel being smaller. Under "C" expenses in London, there are increases of £162 and decreases of £232, and therefore under that heading there is a reduction of some £70. Then there is an item in the profit and loss account which really causes a considerable reduction in the expenses of the year for new cable, namely, in the half year ended June, 1887. We spent £2,430 upon new cable, whereas in the past half year to June last we spent £735, so that there is a saving of £1,695. The final result of all this is a net revenue of £54,061, to which we must add £3,464, brought forward, making together £57,525. Then we have paid during the half year £13,500 for debenture interest, £7,500 has been put to the renewal fund, and £6,000 has been placed to the redemption of debentures. Deducting these items we have a balance to deal with of £30,525. The shareholders have so fully endorsed that policy of redemption of debentures that I do not propose to go into it now. The outcome

Digitized by Google

is that the Directors are able to recommend a dividend at the rate of 4 per cent. per annum for the half year, as against one at the rate of 2½ per cent. per annum in the corresponding period of last year, and that is an increase at the rate of 1½ per cent. We then carry forward £3,293. There is a fact mentioned here with respect to the Platino Company. You will observe that we say in the report that the accounts do not include the contribution which we shall have to receive from the Platino Company. The accounts of the Platino Company have been generally somewhat later than ours. They have a number of stations a long way up the country. Communication is not so perfect. There are references to and fro, and the consequence is the arrival in London of their accounts at a later period than ours. It appears to have been usual in the Platino Company to declare interim dividends at the rate of 2½ per cent. Now, the revenues are pretty much the same, and I take it that in all probability the Directors of the Platino Company will declare an interim dividend at that rate. If so there will be a receipt by the Western Company from the Platino Company of between £300 and £400, which will go to the benefit of the current half year. With respect to the future the Board have it very much in their minds to accelerate these Platino accounts, because it would be manifestly far more convenient, and it would present a much more complete and more accurate picture of our affairs if we could bring the accounts of the Platino Company in simultaneously with our own, so that all our contributions and our figures, the whole thing, in fact, could be seen together, and you would know the exact outcome of the proceedings of the entire concern. We hope to do it. At all events Major Wood is doing his utmost locally to endeavour to bring about that desirable state of things. Well, gentlemen, there is really very little else that I have to tell you. At our last meeting we discussed the questions of debenture redemption, &c., and we discussed these questions, perhaps, at rather an early period; but we did it then because it was necessary to obtain your authority to put by certain sums in view of provision being made to deal with these questions when they were ripe to be dealt with. They are not ripe just now; but with the very sensible steps taken by the shareholders in giving their approval to the collection of certain funds, and with their assistance towards the very important objects that we all had in our minds, I think we shall rather hasten the reopening of these questions. We shall be able, I hope, to deal with them earlier than we otherwise might, and the outcome of this year, which we all think will be satisfactory, will probably enable us to somewhat accelerate the settlement of these questions. Of course we cannot say how far we may be successful, as there are many legal points involved, but we are giving our best attention to them, and we shall do our utmost at the first, so to say, prudent moment that occurs, to pull these things through. The exchange of shares with the Platino Company is going on very successfully, and it might perhaps be interesting to the shareholders to know the great change that has taken place in the Company's constituency. In 1882 we had 688 shareholders, and in October, 1888, we have 1,865, so that for every shareholder we had in 1882 we have three shareholders at the present time. The average holding in 1882 was 98 shares, while in 1888 the average holding is 60 shares, showing that the basis of the constituency of the Company is becoming much wider and the shares much more spread about in small numbers. That I think is a satisfactory feature as a rule, because the wider the basis, generally speaking, the greater the stability. There is nothing more for me to say except to move the resolution, which is

"*That the report and the accounts for the half-year ended June 30th, 1888, be and are hereby approved and adopted, and that a dividend at the rate of 4 per cent. per annum, or 6s. per share, free of income-tax, be and is hereby declared payable on the 1st of November next.*"

One of my colleagues will doubtless second that, and when it is seconded I shall be happy to reply to questions that may be put, if it is thought necessary to put any, and to give any further information that may be desired.

Mr. H. WEAVER: I beg to second that.

Mr. YOUNG asked whether he understood rightly that the Directors had provided a dividend at the rate of 4 per cent. on the £312,930 shares of the Western and Brazilian Company given in exchange for shares of the Platino Company; and that, on the other hand, the Western Company had not taken anything in the accounts presented as the proceeds of revenue from the Platino Company?

The CHAIRMAN replied that that was so, and that the revenue which the Company would receive from the Platino Company would come into the current half year's accounts.

Mr. YOUNG asked if there would be any objection in publishing the estimated weekly traffics to state those in the corresponding period of the previous year?

The CHAIRMAN pointed out that the shareholders could work out the information for themselves.

Mr. YOUNG said he wanted only to know if there was any objection to publishing the information.

The CHAIRMAN replied that there was. When a concern was very prosperous it was not wise to give every information; but they would be very happy to give any information to the shareholders at the offices.

Mr. GUESDON said there was one point he would like to express his satisfaction with, namely, that the Company were building up a reserve fund. The primary object to his mind for the consideration of all Directors was not the speculative but the *bonâ fide* investor, and it should be a first consideration to afford such information and to pursue such a course as would give to the Company that stability which would enable them to meet unforeseen contingencies. It was not the expected but the unexpected which was to be considered, and he assumed from the remarks which the Chairman had made that there was something lurking in his mind which had induced the conservative policy which the Directors had thought best for the Company. He did not wish to cavil, but he really thought that the office expenses, and so forth, were unnaturally large. The Company had passed through very serious vicissitudes, and it was now beginning to be understood that South America was a country which, at all events, had to be developed. Their shares had reached a price which he thought very few of the more sanguine among them expected to see reached at this period. It was clear that advantage had accrued from the reduction in the tariff which had been made to meet the competition. He held very strong views respecting the £8,000 cash which had been paid to the Directors of the Platino Company and others. He thought that a Director should not lose sight of the fact that he was a partner in an enterprise, and to handicap the concern with £6,000 for Directors was something that he regretted to see as a citizen. He felt very sorry that the Directors of the Platino Company should have exacted £6,000 for themselves and £2,000 for their *employés* as the basis of the bargain which had been made with the Western Company.

The CHAIRMAN pointed out that Mr. Guesdon was speaking about the affairs of another company, and that the Directors of the Western Company were going to give the shareholders their labour for nothing, so that the amount which had been paid to which Mr. Guesdon had referred would be recovered by the shareholders.

Mr. GUESDON said that that did not exonerate those who had exacted the claim in question. The fact was that the Directors of the Western Company were "cornered" in the matter, standing, as they did, in a position with respect to the Platino Company which rendered them powerless in the contingency of being forced into law.

The CHAIRMAN: That is not so. We were advised with respect to their claim, and I stated at one of the meetings that we did not think much of their claim, but it certainly did appear to us that these arrangements were in themselves beneficial for both companies. I think the Directors of the Platino Company made a very good bargain for their shareholders, and with respect to ourselves we determined, in order to smooth matters, and make them as agreeable as we could, that we would perform the labour of the Platino Company without any charge. Therefore, the Platino Company will be still charged year by year without any charge to this Company with Directors' fees, which will come back into the pockets of the Western and Brazilian Company, and you will be recouped every farthing of that money.

Mr. GUESDON: I see all that.

The CHAIRMAN: The arrangement being on the whole very beneficial for the shareholders of both companies, would it not be as well—it has been twice passed—to let the matter drop? There is nothing to be gained.

Mr. FRY said he had understood that a feeler had been thrown out to the Directors that the Globe Trust, having largely increased its interest in the Company, should be represented on their Board, but he thought, after their experience of the claim which had been made on them by the Directors of the Platino Company, that they ought to be chary before taking as a representative on their Board any member of the Globe Company. The Directors had the shareholders' confidence, and he trusted that the Directors had the same confidence in the shareholders. If it were necessary for the Directors to increase their strength he trusted they would consult the shareholders and ask for that strength from them.

The CHAIRMAN: I may say at once that there is no intention of increasing the Board or of appointing an additional Director.

Mr. W. GRIFFITH suggested whether the time had not arrived for appointing a second auditor.

The CHAIRMAN replied that it was not competent for the present meeting to consider that matter.

Mr. GRIFFITH merely desired to throw it out for the consideration of the meeting. At present everything in the accounts depended on the signature of one gentleman.

A SHAREHOLDER rose to order, and said that they could not go into the question at that meeting.

The CHAIRMAN put the motion, which was carried.

Mr. GRIFFITH protested, and said that he was quite in the dark as to the state of the Company's affairs.

A SHAREHOLDER: You should have come to the meeting earlier, and then you would have heard.

Mr. GUESDON said that the point referred to by Mr. Griffith could be met by Messrs. Turquand, Youngs and Co. being asked to select a fresh gentleman each time to audit the accounts.

Mr. RICHARD JAMES asked whether it would be convenient for the Directors to print in the accounts in red ink the amount earned and expended in the corresponding half of the previous year, so that the shareholders could easily compare one statement of accounts with the statement corresponding to it.

The CHAIRMAN said that it had been done at one time and was discontinued, and gave rise to a great deal of explanation.

Mr. GUESDON said it was competent for any shareholder to take his own accounts and put in the figures in red ink himself (laughter).

The CHAIRMAN: That is a very simple solution, and I congratulate you, Mr. Guesdon, in suggesting it.

On the motion of Mr. GUESDON, a vote of thanks to the Chairman and Directors was passed.

The CHAIRMAN having briefly acknowledged the compliment, the proceedings terminated.

The Brazilian Submarine Telegraph Company (Limited).

Report and accounts of the Directors for the half-year ended 30th June, 1888, to be submitted to the thirtieth ordinary general meeting, to be held at Winchester House, Old Broad-street, on Wednesday, the 31st October, at 12 o'clock:—

2. The revenue for this period amounted to £109,548. 11s. 9d., and the working expenses to £21,385. 9s. After providing £12,880 for debenture interest and sinking funds, and £1,660. 3s. 8d. for income-tax, there

Digitized by Google

remains a balance of £73,622. 19s. 1d.; to this is added £12,916. 4s. 6d. brought forward from 31st December last, making a total of £86,539. 3s. 7d. A quarterly interim dividend amounting to £19,500 has been paid, and £30,000 transferred to the reserve fund, leaving a balance of £37,039. 3s. 7d.

3. The Directors now recommend the declaration of a final dividend of 3s. per share, making, with the interim dividends, a total dividend of 6 per cent. for the year, and also the payment of a bonus of 2s. per share, both free of income-tax, which together will amount to £32,500, being a distribution in the aggregate of 7 per cent. for the year ended 30th June, 1888, leaving a balance of £4,539. 3s. 7d. to be carried forward.

4. On the 31st July last the sum of £13,900 was transferred to pay off the 139 bonds of the 1884 issue, drawn for redemption in April last. This repayment reduces the debenture debt to £174,000.

5. On the 4th August last the cable between Lisbon and Madeira, laid in 1874, was interrupted near Madeira. The Telegraph Construction and Maintenance Company's steamship "Britannia" was without delay despatched to make the necessary repair, which was accomplished after laying four knots of new cable, when the electrical condition of the cable was found to be perfect. During this interruption the entire traffic was satisfactorily carried by the duplicate cable.

6. All the Company's cables are in good working order except the one first laid between Pernambuco and St. Vincent, in which a slight fault has developed near the coast of Brazil; this, however, does not in any way interfere with the due transit of traffic. The Directors have made arrangements for the removal of the fault at an early date.

7. Sir Thomas Fairbairn and Mr. Henry Daniel Gooch retire by rotation at this meeting, and, being eligible for re-election as Directors, offer hemselves accordingly.

8. The two auditors, Mr. Henry Dever and Mr. John Gane, also offer themselves for re-election.

Maxim-Weston Electric Company (Limited).

At an extraordinary general meeting of this Company, held on the 19th October, 1888, at the Cannon-street Hotel, Mr. John Marks (Chairman) presiding,

Mr. SAMUEL JAMES BOYCE, the Secretary, read the notice convening the meeting.

The following special resolution, passed on the 3rd inst. :—

"*That the capital of the Company be reduced from £125,000, divided into 500,000 shares of 5s. each, to £62,500, divided into 500,000 shares of 2s. 6d. each, and that such reduction be effected by cancelling capital which has been lost or is unrepresented by available assets to the extent of 2s. 6d. per share upon each of the 312,000 shares which have been issued and are now outstanding, and by reducing the nominal amount of all the shares in the Company's capital from 5s. to 2s. 6d. per share,*"

was unanimously confirmed; and Mr. NEWTON moved, Mr. H. R. JONES seconded, and Mr. W. H. WHITE supported, the following resolution, which was also passed unanimously :—

"*That this meeting hereby requests and authorises the Directors to issue a circular to the shareholders, embodying the remarks of the Chairman, and accompanied by a form of application for shares, and that the shareholders be urged to apply for shares within a week of the issue of the circular, and that the Directors are hereby authorised to go to allotment upon applications being received for not less than 80,000 shares.*"

A vote of thanks to the Chairman terminated the proceedings.

The Edison and Swan United Electric Light Company (Limited).

The following is the report to be submitted to the shareholders at the fifth annual general meeting of this Company, to be held at the Cannon-street Hotel, on Tuesday, October 30, at 12 o'clock :—

2. The sale of lamps has progressed in a satisfactory manner during the year. The volume of the Company's business has increased, and has resulted in a credit balance of £25,123. 9s. 7d.

3. The directors have already informed the shareholders that in the recent suit against Mr. Holland, one of the users of the Anglo-American Brush incandescent lamps, Mr. Justice Kay decided that the defendant infringed the Company's Cheesbrough Patent, but that the Edison Patent, under which he was sued, was invalid.

4. The Directors, after consultation with their legal advisers, lodged an Appeal against Mr. Justice Kay's decision on the Edison Patent. The Appeal will probably be heard before Christmas.

5. The possession of the Cheesbrough Patent gives the Company a decided advantage over other makers of incandescent lamps; and as this patent has been pronounced valid by two Courts of First Instance, as well as, in one case, by the Court of Appeal, the Directors hope that the Company may not be put to any further necessity to defend their rights as to this valuable patent.

6. The Anglo-American Brush Company have brought two actions against the Company; the one in connection with electrical distribution, and the other alleging that we infringe one of their patents, in a matter of detail, in the manufacture of our lamps. The former is a matter of small concern to the Company, and in the latter we are advised that we have a complete answer to the alleged infringement. Much as the Directors regret these legal proceedings, they feel that they have no choice but to defend the Company's rights.

7. Lord Thurlow's Amendment of the Electric Lighting Act of 1882 is leading to a considerable development of electric lighting, and to a corresponding increase in the Company's business.

8. Mr. J. S. Forbes and Mr. F. R. Leyland retire from the Board, and offer themselves for re-election as Directors.

9. Messrs. Quilter, Welton and Co., the auditors, also retire, and offer themselves for re-election.

THE LIGHTS AT PADDINGTON.

A well-known electrical engineer sends us a reply to "Lines to the Electric Light at the Great Western Terminus," by a "Misanthropic Gasholder," from which we extract the following :—

You say I jump and jerk, sometimes in turn.
You always flicker, never steady burn;
Each puff of wind will make you flaunt and flout,
If such a trifle does not put you out.

'Tis clear to me, within your mind there lurks
Imagination as to jumps and jerks;
These don't occur with me, my friend so bold,
Since you yourself have said, "both are controlled."

Such contradictory statements stand for nought,
And show "the wish was father to the thought,"
Proving that your conclusions are all fudge,
And showing you a biassed, envious judge.

For by my brilliant light the streets around
Security to traffic now have found;
And tho' by an old gas holder I'm twitted,
The splendour of my light by all's admitted.

By a later post we receive another effusion of the same character, from which we make an extract :—

Though through my inconstancy
Many a bitter foe have I,
Votaries I still possess
Who my frequent flickerings bless.

Mark the lovers' grateful glance
After my eccentric dance!
Could a soft farewell take place
Were I ne'er to dim my face?

Why should we be so correct?
Who perfection can expect?
Were you ne'er accused of greed?
Did you never overfeed?

Does your mental series coil,
Inclination, never spoil
Bankers' balances by sore
Tempting you to overdraw?*

Should such inclination show
When your E.M.F. is low?
Does your shunt coil, conscience, mark
And contract your lengthening arc?

C. A. B.

* This is really intolerable.—ED. *E.*

LONDON CHAMBER OF COMMERCE.

MEETING OF THE ELECTRICAL AND ALLIED TRADES' SECTION.

A meeting was held on Monday at the offices of the London Chamber of Commerce, Botolph House, Eastcheap, for the purpose of completing the organisation of an Electrical Trade Section of the Chamber.

On the motion of Mr. H. S. Price, seconded by Mr. Emil Garcke, Mr. R. E. Crompton was voted to the chair.

The SECRETARY (Mr. Kenric B. Murray) read the minutes of the meeting held on the 13th July last, and scrutineers were afterwards appointed to go through the ballot-papers for the election of the proposed working committee.

In their report, the organising committee recommended that a working or executive committee (elected annually by the general body of the trade in accordance with the bye-laws of the Chamber) be charged with the ordinary business of the section, and that in the first instance it consist of 33 members, this number to be increased to 48 at the first annual meeting of the section, if the membership then obtained should warrant a larger representation. It was proposed that the working committee should meet whenever occasion required, and that meetings of the whole or part of the section, in addition to the usual annual meeting, should also be called from time to time. With a view to an equitable representation on the working committee of the various branches of the electrical trade, the organising committee, after preparing a classified list of members, recommended that the committee be divided into the following sub-sections, viz. : Telegraph companies, 5 members; telephone companies, 3; electrical supply companies, 6; electrical manufacturers and contractors, 13; consulting electrical engineers, 4; general, 2. The committee recommended that members of the working committee be elected by ballot. Having regard to the bye-laws and regulations of the Chamber, the committee did not advise the adoption of special rules to govern the section and its committee, as they were of opinion that for the present it would suffice to follow the procedure of other trade sections. As regarded applications for admission into the section it was suggested that the working committee should be allowed an opportunity of scrutinising them before presentation to the Council of the Chamber for election.

The CHAIRMAN invited remarks or questions on the report, and stated that the organising committee would be prepared to answer them. He

Digitized by Google

would also then be very glad to afford any information, and explain the reasons and line of thought which had governed them when they prepared the report. He might state that the way in which the sub-section had been drawn up had not been fixed on without considerable heartburnings. The number of 33 members was that which was allowed by the rules of the London Chamber of Commerce until such time that they could increase it up to 48, which would be the full number. The organising committee thought that 33 was sufficiently large to represent the section at its present strength; but there was every reason to believe that their numerical strength would soon be increased by 50 per cent., if not doubled, when they could increase the number of their sectional committee up to 48.

Major-General WEBBER said that the organising committee had felt very strongly that the working committee should be of as representative a character as possible, that its members should be elected as far as possible by the actual suffrages of the members of the section, and that there should be no recommending, as it were, from themselves. They started with about 200 members, and it had, therefore, been a comparatively easy matter to send out voting papers to the members, with the list of the whole number of their body, from whom they might select the 33 members they desired to form the working committee. In that respect he thought that the organising committee were to be congratulated on having made a fair start. Having answered certain criticisms in the electrical press on their mode of procedure in this matter, and defended the course taken by the committee, he expressed his belief that when the committee of 33 met together, the real work of the section would begin, and that their increase in number to 48 would very soon take place.

Mr. ROBERT HAMMOND stated that he had been to San Francisco since he had last met his electrical friends, and the measures adopted for the formation of the section had been taken during his absence. He could only say that he was very glad to see that the City had at last been recognised as the centre where subjects interesting to their trade or profession could be discussed. He would like to hear something as to what this particular section of the London Chamber of Commerce was going to do, as there were one or two other societies connected with electricity.

The CHAIRMAN replied that for some time past most of them who had been working at their new branch of engineering—electrical engineering—had felt that united action was most desirable on many points, as isolated action with other bodies—local authorities, for instance—had had a bad effect, and certainly had not advanced their interests. At that moment he held in his hands a series of regulations which had been addressed to them from the Board of Trade, and other papers had been forwarded for approval by the Board of Trade. At the present moment, to speak of the metropolis only, the London local authorities were face to face with many applications either for provisional orders or licenses under the new Act. It would appear far better that they should discuss dispassionately the mode in which they should deal with the local authorities. It had been asked whether the latter would make them pay "ransom" in connection with the public lighting, or whether they were to be rated on the mains under the streets, or whether they would have to put their wires underground or run them overhead. All such questions could best be discussed among themselves, and when they had arrived at a general opinion as to what was best for their interests they could agree as to the conditions on which they would or would not accept the terms that might be offered by the local authorities. To take a personal question, about six months ago—owing to an order given by the Amalgamated Engineers regarding piecework—there was a strike at the works of his firm; and this was a question which affected every one connected with the manufacturing branch of their industry. His firm held out, and dismissed the men who were connected with the Amalgamated Engineers; but it would have been a good thing for his firm—or any other firm where the strike might have occurred—if concerted action could have been taken in the matter. There were various other questions which had to be dealt with—the hours of electric light men, and the subject of overtime paid in regard to hours in other trades, which were the regular hours in the electrical trade. There was one matter which he rather fought shy of at the present moment, but which he was convinced would come up—the question of prices. Many of those present might think that the trade would never be able to come to an agreement on that point, but they found it was customary in other trades for an agreement to prevail as to the question, and why should not that be the case in their own business generally. They were all now "standing on their feet." They knew that they were in strong competition, and most of them knew when an estimate was given in whether they could make a profit on it or not. Although the subject of prices would not enter into their discussion at that meeting, yet he considered it quite reasonable to suppose that electrical manufacturers and contractors would eventually fix on some standard lists and would keep to them as closely as was done by makers of gas and steam engines. That would be a great point gained. Beyond that there were many questions which concerned the public. A great many names were entered under the heading of "general," many of them being consumers of electricity. It had not been very usual, he believed, in these cases to include consumers among the working body of the committee, but he believed that that course would prove advantageous to their interests. They desired to increase their trade, and they wanted to take those who purchased their goods into their confidence. He thought in their future deliberations they would have the benefit of getting the views of consumers. Among consumers of electricity he saw the name of Mr. Alexander Gordon, a gentleman who used more electricity than almost anyone else in London, and his views as to how it paid and on other points it would be advantageous to know, and they were matters which could be discussed among themselves, though not at places devoted to the more scientific aspect of the subject. He thought he had mentioned the points which had struck him most forcibly; but there were many other matters which if he had had notes he might have mentioned to them. His deficiencies, however, in that respect might be supplied by other speakers. He might mention that the organising committee had had considerable difficulty in getting at the members to form the different proposed sub-sections, 33 being too small a number, and many names had been omitted from certain sub-sections which they would have liked to include. They could not help themselves, however, being bound down to the number of 33 at present. The telegraph companies had had an organisation among themselves for a long time, but the committee could not have allowed those companies a less number than proposed, though it was doubtful whether they would take any great part in the future proceedings of the section.

Colonel RAYNSFORD JACKSON observed that the Chairman had no doubt represented generally the views of the London Chamber of Commerce; but having himself been a director of the Manchester Chamber and also connected with employers' associations, he confessed that he had thought the Chairman was somewhat intermixing the functions of the two. He had never known a Chamber of Commerce to deal with the question of wages or of disputes between employer and employed, or to take part in fixing the prices which were to regulate the dealings of any trade. He had always considered such questions as outside of the function of a Chamber of Commerce. With reference to the work of the organising association, he thought the members of the section must feel thankful to the committee for the way the work had been done. He had no doubt it had been a difficult matter to fix the representation of the different portions of the electrical trades, and he had no doubt that what had been done by the organising committee would be perfectly satisfactory to them all. He thought it would be a pity if any one of the classes into which the section was divided was entirely unrepresented at the working committee, and he thought that provision might be made that each class should have one representative on the committee. Let them take, for example, the case of the telephone companies; there were matters with which the Chamber might be asked to deal very similar to those alluded to by the Chairman—the running of wires overhead or underground, the powers to be obtained from Parliament, and many other points; and if any one of the proposed sub-sections was entirely unrepresented on the working committee the effect might be that the interests of that class might be lost sight of, although possibly there might be means of communication between the working committee and outsiders which would enable the interests of the latter to be dealt with.

Mr. F. L. RAWSON observed that it was proposed in the report of the organising committee that there should be two members of the "general" sub-section; but supposing all the members present voted for only one name, in that case the working committee would choose some one themselves. He understood from Mr. Murray that that was the course taken in similar cases where the sections were not completed. He assumed that the committee would not take into consideration any matter in respect, say, to electrical engines, unless a quorum of electrical engineers were present. With reference to the question of the subjects to be dealt with by the sectional committees, the London Chamber of Commerce left it to each committee to take up what questions it liked. They must remember that their section of the Chamber was the offspring of an idea which had endeavoured to fructify a good many times in the shape of having a representative body to deal with various subjects, and there were many questions outside those ordinarily taken up by the Chambers of Commerce which were vital to to those interested in electrical matters. There was the all-important question of electric lighting fire rates; another question was the price to be charged where companies overlapped. No doubt different companies among the electrical supply companies would overlap certain districts, and if any differences arose from that cause it would be much better if they could be arranged through the working committee. That led up to the question of arbitration, and he was sure that most of them would willingly go to an arbitrator or arbitrators appointed by the committee. Then it might be found that certain bodies would proceed against certain members of the trade, and they themselves might like, as a general body, to take up the question at issue. Again, there was the large question of parliamentary matters. There was no doubt that a requisition or statement coming from a body of electrical engineers, backed by the London Chamber of Commerce, would come with far more weight than it would coming from any individual. There were, also, the questions of patents and of rates of rental. He suggested that the working committee should have the power to elect their chairman and vice-chairman from outside their own body, if they wished to do so.

Mr. ROGER WALLACE proposed a resolution in accordance with this suggestion. He agreed with Col. Jackson that a Chamber of Commerce was not the body to deal with the question of wages, as a chamber should look to the interests, not of one class of a trade, but of all classes. His (the speaker's) interests, as those of a consumer, were that electricity should be supplied to him as cheaply as possible, but Mr. Crompton's view on that point might be different. There would thus be an issue between two sections of the committee, and therefore he thought that that kind of dispute should not come within the limit of the matters to be discussed by the Chamber of Commerce. As to other questions referred to by the chairman—questions as between rival companies and the way in which they should act with regard to the Board of Trade and local authorities—they were most important points which the committee would have to consider.

The motion of Mr. Wallace having been seconded by Mr. BROWN MARTIN,

Mr. GARCKE said they knew from experience that all past attempts to form the association had failed almost entirely from the difficulty of formulating their functions. He thought it very fortunate that they had found in the London Chamber of Commerce a constitution and set of rules under which they could come together and settle what questions they should discuss and what questions they should leave alone. He agreed that most of the topics mentioned by the chairman would form suitable subjects for the section to consider, but one or two of them he hoped the section would not attempt to deal with. He did not consider

Digitized by Google

it unfortunate that he should differ from Mr. Crompton on this particular point; on the contrary, he thought they should have the opportunity of coming together and finding out where they agreed and where they differed. What they wanted was a centre of intercommunication where they could gather at any critical time and ascertain the views of the trade. He really felt that the most important functions of the committee would be of a deliberative rather than of an administrative character. An important direction in which the section would be of immense use would be in the selection of one to speak for the general interest—say, in regard to legislative matters or to the fire offices. He was, however, sure that any attempt to regulate prices or stifle competition would end in failure. All electrical contractors were aware that from time to time specifications of an imperfect character were issued for carrying out electrical work—specifications which no electrical contractor would work to. Contractors in acting in their individual capacity felt a difficulty in dealing with such contracts, but if they could be brought together at a few hours' notice the question could be discussed as to the desirability of that sort of work being contracted for. Every interest was represented in the section, and he believed they would thus have the opportunity of ascertaining the views of every section interested.

The CHAIRMAN put the motion, and it was carried *nem. con.*

Mr. RAWSON said he presumed that when the working committee was appointed they would have the power to subdivide as much as they liked, and that the committee need only communicate with those sections whose interests were affected.

The CHAIRMAN said he believed that that was so. In reply to Mr. Garcke, the Chairman added that he had, in his former remarks, suggested that the price question would be likely to crop up because he was sure that it would. It was, however, unfair, when one spoke of regulating prices in a manner which everyone could understand, to talk of stifling competition—a matter which had nothing whatever to do with his suggestion. The idea was to fix on a price from which such discount as could be afforded could be allowed. It was possible that it might be outside the objects of the Chamber to deal with the labour question, but it should be remembered that the electrical trade was not, like other trades, long-established, and which had their associations of employers. That would be the first association of a commercial nature connected with the electrical industry, and it would no doubt give them the opportunity of forming an employers' association. The chamber had also means within itself of providing references.

On the motion of Mr. WALLACE, seconded by Mr. BROWN MARTIN, a vote of thanks was passed to the organising committee.

Mr. REEVES then proposed, and Mr. BROWN MARTIN seconded, a resolution for the adoption of the report of the organising committee. This motion was carried unanimously.

The meeting then terminated, it being arranged that the secretary should inform the members by post of the 33 names elected for forming the working committee.

ELECTION OF THE WORKING COMMITTEE—RESULT OF THE VOTING.

The names are placed in order of number of votes given, and those bracketed together indicate a tie.

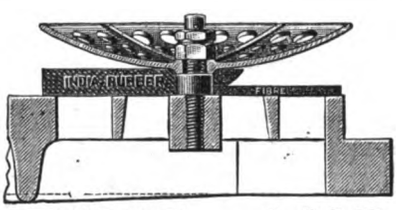
NEW VALVE

No Rubber, Percha, or Leather.



One-half the price of Rubber or Metal.

FOR CIRCULATING AND AIR PUMPS.

Unaffected by any Lubricating Oils. Does not Expand in diameter. Feed Water may be worked at any temperature. Suitable for any shaped guards. Only one quality manufactured.

"12, John-street, Sunderland, 26th Sept., 1885.

"Dear Sirs,—In reply to your letter of the 25th inst., the Valves I got from you have done their work well, and ARE AN UNQUALIFIED SUCCESS. I will continue to get them from you as required.—Yours faithfully, JAMES WESTOLL."

For further Testimony and Prices, apply to **MOSSES & MITCHELL, 68-71, Chiswell Street, London.**

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended October 19th, 1888, amounted to £5,123.

CONSOLIDATED TELEPHONE CONSTRUCTION AND MAINTENANCE COMPANY.—The directors of this company have declared an interim dividend at the rate of 5 per cent. per annum, payable on the 14th prox.

EASTERN TELEGRAPH COMPANY.—This company announce the payment on November 1st of interest for the half year ending October 31st on their Four per Cent. Mortgage Debenture Stock. Transfer books will be closed from October 27th to November 1st, both days inclusive.

GREENWOOD AND BATLEY (LIMITED).—Application has been made to the Stock Exchange for a special settling day and quotation for the Ordinary shares, Seven per Cent. Cumulative Preference shares, and Five per Cent. Debentures in this company.

INDO-EUROPEAN TELEGRAPH COMPANY.—The Board of Directors of this company, on Monday, declared an interim dividend for the half year ended the 30th June last, at the rate of 5 per cent. per annum, the same as a year ago, free of income-tax, payable on and after the 1st November next.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended October 19th, 1888, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company, were £4,282.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—At the approaching half-yearly meeting of this company the Directors will recommend a dividend of 12s. per share on account of arrears on the first preference capital, placing £2,000 to the reserve fund, and carrying over £1,255. The estimated traffic receipts for the half month ended October 15th, 1888, were £2,482, as compared with £2.742 in the corresponding period of 1887. The June receipts, estimated at £5,484, realised £5,550.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL SCIENCE, INDUSTRY AND ENGINEERING.

No. 546.—Vol. XXI. FRIDAY, NOVEMBER 2, 1888. Price 4d.

NOTES.

At the meeting of the Society of Telegraph-Engineers and Electricians on Thursday next the Members will be called upon to vote upon the momentous question of changing the title of the Society to that of "The Institution of Electrical Engineers." It is already known that the result is a foregone conclusion; out of the 846 replies which have been received to the circular sent out in February last 837 expressed approval.

If, according to a famous dictum, "chemicals" are the barometer of British trade, it is at least equally certain that the condition of the trade in incandescent lamps forms the readiest clue to the progress of electrical engineering. It must, therefore, be a cause for general and unqualified satisfaction that as a result of the year's trading the Edison-Swan Company can show a balance of over £25,000 to the good on the profit and loss account, and moreover that it has now wiped out the losses on account of actual working expenses incurred during the earlier years of its existence. In fact, the Chairman was clearly justified in asserting that the company has at length arrived at the status of a money-earning concern. On the other hand, the unfortunate shareholders will derive no immediate benefit. In the present state of uncertainty as to costs in the recent action and the pending appeal, any distribution of profits has been rightly judged to be out of the question. It must, however, be a source of unqualified gratification to the lawyers that both the Edison-Swan and their opponents, the Brush, are showing such unmistakable signs of vitality.

With regard to the future of the incandescent lamp trade, no less than that of electric lighting in general, we entertain no doubt whatever that a substantial reduction in the price of lamps would be rapidly followed by a more than commensurate increase in the demand. The experience of those who are engaged in central station lighting work seems to be unanimous on this point. The cost of lamp renewals is an item which appeals very closely to the economical instincts of the would-be consumer, and is regarded with even greater disfavour than the rental of the meter. We think that the Edison-Swan Company would be doing a wise and politic thing in announcing a reduced rate *before* the result of the pending appeal case is made known, since it is quite certain that if the judgment is not in their favour their hand will very soon be forced.

The situation in Chelsea is rapidly becoming exciting, there being signs that this district will form the battle ground on which some of the outstanding questions relating to electric lighting will be fought out. Legal as well as Technical matters are involved. The Chelsea Electricity Supply Company have had their Provisional Order confirmed in the last session of Parliament and are already at work upon their underground mains. Meanwhile the Cadogan Company have invaded their territory with overhead wires, and the London Electric Supply Corporation have given notice of their intention to follow suit. Here then, is the crux:—How far does the possession of a Provisional Order (confirmed by Act of Parliament) operate to exclude an opponent who seeks to escape altogether from the scope of the Electric Lighting Act by keeping to the housetops? This is a question which the position of affairs in other parts of London as well as in Chelsea will shortly press for decision.

Meanwhile, in self-defence the Chelsea Electricity Supply Company have issued to their "future customers" a very ably-written pamphlet, in which the superiority of underground to overhead wires, of batteries over transformers, and of this particular company over all others are expounded in forcible and well-chosen terms. The company "trusts that the residents of Chelsea will not encourage desultory and indiscriminate competition, which can only result in unsatisfactory service." It is, however, noteworthy that, as a result of the threatened competition (however "desultory or indiscriminate"), the Company have decided to charge only 8d. per Board of Trade unit, instead of 10d., to which they are entitled by the Act. This charge does not seem at all too high for a battery system, although we have sufficient confidence in the promoters of this undertaking to believe that they will not fix a tariff which would prove finally unremunerative. In this particular the Supply Company are also entitled to sympathy, owing to the somewhat sharp practice of the Cadogan Company (whose central station was described in *The Electrician* of July 20, 1888). The latter company profess to charge 6d. per unit, but since this is based upon the current put into the consumer's battery, there is not in reality much difference between the two tariffs.

The company-mongering scandals which have been the disgrace, as they have also proved well-nigh the ruin, of the electric lighting interests in this country, have nowhere found more vigorous or unsparing denunciation than in these columns. We venture, however, to add that our criticism has also been of

Digitized by Google

a discriminating character, and has again and again been justified by events. This is just the element which is conspicuously lacking in a leading article which appeared in the *Financial Times* of Monday last. In this remarkable effusion almost every prominent name which has been connected with electric lighting is held up to contempt and ignominy. But in this wholesale abuse the writer betrays either an exemplary ignorance or a most reprehensible disregard for facts. His remarks on the "Duplex," the "Phœnix," the "Fyfe-Main," and the "Maxim-Weston" Companies are, no doubt, of a defensible character. But such statements as that the Whitehall Electric Supply Company "is a trumpery concern," that Edison-Swan "exists in a sort of a way," that Gülcher "has retired into obscurity," that the works of the Brockie arc lamp know it no more, and that Jablochkoff (like Edison-Swan) has "a sort of existence," are of a kind which makes it necessary to remark that a little accurate information should not be considered altogether superfluous in leader writing for a financial journal.

At the end of the article referred to in the previous Note we are warned against confounding any other concern with that of the "London Supply Company" (*sic*), "which has an organised system and possesses works and patents." It may therefore be as well to state that the London Electric Supply Corporation—which we presume is referred to—are not the owners of any patent rights. With regard to the Ferranti patents, they simply occupy the position of customers.

The laying of the foundation-stone of the first municipal electric lighting station in this country is an event which deserves a passing notice. The Corporation of Bradford, by their liberal and enlightened policy in this matter, have earned for themselves a position of some historical importance in the annals of electrical engineering. Several unforeseen obstacles have retarded the progress of the work during its earlier stages, but we are not sure that this is entirely a matter for regret, and although the event of Friday last was described as the laying of the "foundation-stone," yet the actual building operations are in a forward state, and the laying of the cables will commence almost immediately. Under the able superintendence of Mr. Shoolbred, and with Messrs. Siemens Bros. as contractors, we may look for success in the fullest sense of the word.

Dr. Oliver Lodge, in his letter on "Lightning," which will be found elsewhere, proposes that experimental—or rather observational—lightning conductors should be set up at every meteorological observatory. This should certainly be done, especially as the cost need not be great. Definite results would, however, be sooner arrived at if such experiments were carried out in latitudes where thunderstorms are somewhat more frequent and more violent than with us. Possibly some of the Submarine Telegraph Companies, which have already done so much for the cause of science, and which possess especial facilities for the task, may be inclined to undertake it. It would certainly be difficult to over-estimate either the scientific or the practical value of a well-conducted series of observations of the character suggested.

Mr. Raine calls attention, in our correspondence columns, to the fact that as long ago as 1842 Prof. Henry had obtained experimental evidence of the existence of the oscillatory discharge. Although this was new to us, we were already conscious that the work of Prof. Henry has been too much neglected, and readers will have noted that in our last issue Dr. Fleming commenced some Papers on Electro-Magnetic Induction with a brief history of Prof. Henry's researches. It will shortly be found that by the application of modern theory to these early experiments Dr. Fleming has been able to arrive at some conclusions which are both novel and important.

In the columns of a contemporary, Prof. Elihu Thomson and Mr. Wightman have recently described an interesting experiment which seems to indicate a novel method of obtaining rotation by means of an alternating current. The experiment is described in several forms, but the principle is briefly this: A bar of iron, preferably unlaminated, is wound with a coil of wire, of which the turns near the end of the bar form a closed circuit. This is brought near to a thin disc of iron, balanced at its centre on a vertical pivot. When an alternating current is sent through the coil the disc rotates. The best effect is obtained when the centre of the disc is brought in a line with the junction of the two parts of the winding. We are told that the effect is sufficiently powerful to produce rotation at a distance of three or four feet, with a coil of nine or ten inches in length, but the current employed is not mentioned.

The inaugural *conversazione* given on Tuesday evening by the directors of the Institute of Medical Electricity, at the rooms of the Medical Society in Chandos-street, was a decided success. The graphophone was, of course, to the fore, and attracted the usual amount of attention. In another room the Woodhouse and Rawson Company made a fine display of electro-medical appliances. A miniature incandescent lamp for lighting up the cavities of the throat was the first object of considerable curiosity; indeed, one venturesome spirit undertook to illuminate his vocal chords *pro bono publico*, but in spite of recent publications, no one present knew where to look for them, so that the public-spirited experiment was wasted. Microbes and bacilli were also on view, so that there was a highly judicious blend of electricity and medicine. After a brief address from the chairman, Mr. Wm. Lant Carpenter, explaining the objects of the Institute, Prof. Silvanus Thompson began his lecture "On Old and New Views of Magnetism." The lecture was naturally of an elementary character, and was greatly appreciated by the audience. Prof. Thompson did not let slip this opportunity of rescuing the name of Dr. Gilbert from the partial oblivion it so little merits. Dr. Gilbert, and not Charles II., we were assured, was the real founder of the Royal Society; Dr. Gilbert, and not Bacon, was the genuine inductive philosopher; and,

Digitized by Google

if we remember rightly, Dr. GILBERT and not the overrated SHAKESPEARE was *the* glory of the Elizabethan era. We are afraid nothing short of an entire re-arrangement of historic reputations will satisfy the professor. The Institute of Medical Electricity has made an excellent start, and we look to it to clear medical electricity from the stigma of quackery under which it has too long laboured.

SOME progress has been made with the erection of the telephone wire between London and Birmingham. Between 30 and 40 miles have been completed, and the way-leaves have been obtained for the greater part of the remaining distance. It is also intended to run a line to Reading, and the way-leaves for this are being obtained. Lastly, the Croydon line is being extended to Sutton and Mitcham. And yet people say that the United Telephone Company shows no enterprise.

OH! electricity,
With what delight
Do we saunter where
Thy effulgence bright
Knocks nightness into dayness
And darkness into light!

Progressive Age (New York).

Blenheim Palace.—Blenheim Palace has lately been fitted with a fine installation of the electric light, no less than 1,200 incandescent lamps being employed.

The Electric Light at the Royal College of Surgeons.—The magnificent library of the Royal College of Surgeons has just been provided with the electric light, and the installation has given great satisfaction.

Dublin.—On Monday last the Dublin Corporation, by 20 votes to 2, adopted the report recommending that steps be taken to supply electricity for private as well as public purposes, and that a special committee be appointed to give effect to the provisional order.

The Ironmongers' Exhibition.—The International Ironmongers' Iron and Metal Trades Exhibition opens at the Agricultural Hall, Islington, on Monday, November 12th, at 1 p.m., and remains open till Saturday, November 24th. This, the first exhibition of the kind, bids fair to be one of general interest.

Belfast.—The National Telephone Company has just completed the reorganisation of the Central Exchange Office in Belfast. The system in use up to the present having become insufficient for the increasing business of the exchange, the company has introduced the multiple switch-board of the most recent type.

The Electric Light at Suakin.—The Eastern Telegraph Company's ship "Electra" left Suakin on Thursday last for Suez direct, taking the wounded and sick. Great credit is due to the electricians, engineers, and officers of the "Electra" for repairing the electric light on the Shata Gate and for the general assistance rendered by them to the Government.

Mr. Magnus Volk.—We are pleased to hear that the Sultan of Turkey has decorated Mr. Magnus Volk. This well-known electrician has recently joined Messrs. Immisch as manager of their launch department. He is now at Constantinople with the electric dog cart recently supplied to the order of His Majesty the Sultan. The dog cart seems to give great satisfaction.

Personal.—We are requested by Mr. A. A. Campbell Swinton to state that his appointment as consulting electrical engineer to Messrs. Sir W. G. Armstrong, Mitchell and Co., of Elswick, which we mentioned last week, in no way affects his position as manager of the Equitable Telephone Association, which position he will still retain, and that his address will continue to be 75, Queen Victoria-street, E.C.

The Cox-Walker-Swinton Magneto Bells on Board Ship.—A number of these bells are being fitted by the Equitable Telephone Association on board the cruiser "Piedmonte," now being armed on the Tyne for the Royal Italian navy. The fact that these bells do not require any battery is expected to prove a great advantage, particularly for use at sea and in hot climates, where batteries are apt to get out of order.

Queensland.—From the Queensland Postmaster-General's Report for 1887 we learn that at the end of that year the mileage of telegraph lines in Queensland was 9,037, the mile age of wire being 16,447¼. There were 293 telegraph stations in daily operation, of which 23 had been newly opened during the past year. The net revenue from telegraph and telephone services amounted to £83,908. 18s., and the expenditure to £107,113. 13s. 1d.

Restoration of Communication with Australia.—Telegraphic communication with Australia was restored on the 29th of October by the ss. "Sherard Osborn," which is now engaged on a renewal of the duplicate cable, and in order to complete the work as carefully and expeditiously as possible the Eastern Extension, Australasia and China Company's ss. "Recorder" is assisting in the work. It is, therefore, hoped that no further inconvenience will be caused to the telegraphing public.

Otley.—The Otley Local Board are making inquires with a view of seeing whether their surplus water-power at Ellar Gill can be applied economically to the lighting of the public streets. The members recently inspected the Victoria Printing Works of William Walker and Sons, of Otley, which are now lighted by electricity in all the departments. The installation consists of a 300-light dynamo, serving a large number of glow-lamps, and three arc lamps of 3,000 candle-power each. The plant has been fixed by Messrs. John Roper and Co., of Bradford.

The Lighting of the Brighton Pavilion.—At the meeting of the Finance Committee of the Brighton Town Council, on October 22nd, a letter was read from Messrs. Boxall and Boxall, stating that the solicitors to the Maxim-Weston Electric Company had referred their dispute with the Corporation to arbitration, and requesting the committee to name an arbitrator to act on behalf of the Corporation. It was resolved to refer the matter to the town clerk and the solicitor to the Corporation, with power to take such course as they might think most advisable under the circumstances.

Electric Light and Telephone Contracts.—The following circular has been issued to members of the Electrical and Allied Trades Section of the London Chamber of Commerce:—"The following is a translation of a paragraph which appears in a report of the Belgian Consul-General on openings for the investment of foreign capital in the Canary Islands:—'Electric lighting is also wanted at St. Croix (Teneriffe) and Las Palmas (Grand Canary), and a contract would be made with a company willing to undertake it. It is the same for the telephone for the various towns of these islands.' The full report may be consulted at the offices of the Chamber."

Digitized by Google

The Electrical Purification of Quartz and Kaolin.—Electricity is gradually being introduced in ceramic operations to purify quartz and kaolin from oxide of iron. The powder to be operated on is placed in a hopper, whence it falls into a receiver rotating rapidly on a vertical axis. This receiver is surrounded by powerful magnets of triangular section. The purified powder then falls into a second receiver, and after undergoing a similar purification in this, it is, as a rule, ready for use. The cost of this process is small, and it is stated that owing to its employment substances can now be used which were formerly rejected on account of the amount of iron contained in them.

Bath.—A meeting of the Town Council, sitting as the Urban Sanitary Authority, was held on Tuesday, October 23rd. The report from the Electric Lighting Committee was read. Alderman Gibbs formally moved the adoption of the report. Mr. Sturges, who seconded, thought the electric light would be a great advertisement for Bath. Mr. Cox was prepared to accept the report with the addition of this admendment:—"That the Corporation shall have the power to buy the whole of the plant at the end of seven years, at a fair valuation." Captain Franklin seconded Mr. Cox's amendment. When the amendment was put, 25 members voted for it. No one holding up his hand agaist it, the ex-Mayor declared it carried uuanimously.

The Buckingham Electric Light and Power Supply Company.—A meeting of the directors and shareholders of the Buckingham Electric Light and Power Supply Company (Limited) was held on Wednesday, the 17th inst., at Buckingham, Mr. A. C. Rogers presiding.—The Chairman said they had much upon which to congratulate themselves. They had forty shareholders, holding 858 shares, and the sum of 10s. had been paid on each share. They had ample capital for lighting the town by electricity. Several shops were already illuminated in this way, and the light was giving every satisfaction. Altogether the scheme promised to be a most successful undertaking. The directors for the coming year were then elected unanimously—Messrs. A. C. Rogers, J. W. Thorpe, A. Vyle, Geo. W. French, and H. Thorpe.

Society of Telegraph-Engineers and Electricians. — A special general meeting of members of the Society of Telegraph-Engineers and Electricians will be held at the Institution of Civil Engineers, 25, Great George street, Westminster, on Thursday, 8th of November, 1888, at 7:45 p.m., when the following resolutions will be proposed:—1. That the name of the society be changed to "The Institution of Electrical Engineers." 2. That the office of honorary secretary be abolished, and that the Articles of Association be altered by omitting all reference to the honorary secretary in Articles 36, 38, 40, and 43. Should the resolutions be passed by the required majority, they will be submitted for confirmation as special resolutions to a second special general meeting of members, which, in the absence of further notice, will be held on Thursday, November 22nd, at the same place and time.

Milan.—A correspondent, who has recently returned from Italy, writes enthusiastically as to the electric lighting of the city of Milan. The principal streets are lit by Thomson-Houston arc lamps, which are suspended high up above the centre of the roadway, an arrangement which effects a very satisfactory distribution of the light. He continues as follows:—"But the most perfect and startling effect is in the Piazza del Duomo, which is the large open space in front of the Cathedral. Here the Thomson-Houston lamps are on exceedingly handsome and artistic iron standards. The exquisite carvings on the old cathedral can be seen in bold relief, and the effect of the soft light of the electric lamps, which burn without a flicker, show up the white marble of this magnificent piece of architecture in a marvellous manner, and it may now truly be said that Milan Cathedral by night is probably one of the most impressive ecclesiastical edifices in the world."

Mill Lighting.—The installation at the mills of Messrs. Merrall and Son, spinners, Haworth, near Keighley, which has been put in under the supervision of Mr. W. Ricketts, has just been completed. The plant consists of two Luther shunt-wound dynamos, which are run in parallel, and have an output of 166 amperes at 90 volts. The dynamos are fixed in a separate room, upon a solid bed of stone; they are driven by the mill engine through 9in. single belts. In the dynamo room there is a fine slate switch-board, 4ft. by 2ft. 9in., supplied by Luther Hanson and Co., of Halifax, and provided with the necessary switches, voltmeters, ammeters, and Woodhouse and Rawson automatic magnetic cut-outs. There is also a smaller switch-board similar to the above. All the cables and branches are run in casing. In addition to the two main machines there is a small pilot 3½-unit dynamo, run off a water-wheel, and intended to supply three 32 candle-power lamps in each room of the mill when the machinery is stopped.

The Direct Spanish Telegraph Company and the Barcelona Exhibition.—The landing place at Barcelona of the Direct Spanish Telegraph Company's cable from Marseilles being within the grounds of the International Exhibition, it was arranged between the Municipality of Barcelona and the Company that as the iron hut which had done duty as a cable house for several years required replacing, a new and suitable cable house would be erected by the company before the opening of the Exhibition. In this cable house specimens of the different testing and other apparatus used in the company's service were shown, but for adequate reasons it was not considered desirable for the company to be included among the exhibitors. The jury of the Electrical section of the Exhibition, in their signed report to the council, have now recorded "That if the Direct Spanish Telegraph Company (Limited) had been included amongst exhibitors, the gold medal would have been awarded for the model cable house and fittings of the Barcelona-Marseilles cable, erected in the Maritime portion of the Exhibition."

Barnsley.—At the last meeting of the Barnsley Town Council Mr. Tinker moved "That the Lighting Committee be recommended to take into consideration some scheme for providing a better and more economical system of lighting the public lamps in the borough." He pointed out that in Barnsley the lamps were lit 2,500 hours per annum for £2 each; five-light Bray's lamps were charged £10. 10s., and three light lamps £6. 6s. per annum for that time. In Dewsbury the lamps were £1. 16s. 8d. per annum, and the Bray's lamps averaged £4. 9s. each, burning from dusk to dawn all the year round. Halifax paid £1. 4s. 11d., less 12½ per cent., each lamp burning 3,250 hours; Wakefield £1. 6s. per lamp, each burning 3,477 hours per year. The Barnsley price was too high, the number of hours too small, and the result was that on many dark mornings there was no light for people going to work. He thought the gas company might give them 500 hours per year more for the same money, and if it would not meet them the committee could inquire as to the cost of the electric light, which had been introduced in many towns.—Mr. Haigh seconded the motion, and it was ultimately carried.

The Barnet Central Station.—At the meeting of the Barnet Local Board on the 9th inst. a committee presented a report to the effect that as the electric lighting contractor had failed in his contract, and the light was indifferent, he be given fourteen days' notice to terminate the contract. At the urgent

Digitized by Google

request of certain members of the Board, it was decided to suspend the notice for a fortnight to see if the contractor made satisfactory progress. The matter accordingly came before the Board at their meeting on the 23rd October, on the question of serving the notice, and Mr. Pooley observed that the report and recommendation of the committee having been agreed to at the previous meeting, their duty was clear. They must have some report as to the progress made, and if it was unsatisfactory, all they had to do was to proceed with the resolution. The surveyor (Mr. W. H. Mansbridge) submitted a report as to the general condition of the lighting from the 3rd to the 22nd inst.; and, in answer to the chairman (Mr. C. Stephens), said he could not regard it as satisfactory. It was therefore proposed that the notice suggested by the committee should be served on the contractor. An amendment was, however, brought forward to grant him another week's grace, and if by that time satisfactory progress had not been made, to give him notice to terminate his contract. Eventually this was agreed to.

Electric Lighting in Birmingham.—The most complete and extensive installation of the electric light which has yet been attempted in Birmingham has just been finished. The Corporation-street Estate Company (Limited) have erected one of the most important blocks of business premises in the town at the corner of Martineau-street and Corporation-street, from the designs of Mr. J. P. Sharp. The building consists of 19 large shops and basements, with spacious and well-ventilated offices on the floors immediately above. The two upper stories of the building are arranged for warehouses, work rooms, or dwelling-apartments as may be required, and access will be given to these rooms by lifts worked by electric motors. The electrical plant and appliances have been designed by Mr. T. C. Sharp, C.E., and consist of two 50 I.H.P. semi-portable compound steam engines, which have been made by John Fowler and Co., of Leeds. Current is generated by two 600 light shunt-wound dynamos, by Elwell-Parker, of Wolverhampton, who have also supplied large storage batteries, switch-boards, and all the necessary wiring. Fowler and Lancaster, of Albert Works, Birmingham, have provided the lamps and fittings. When the works are quite complete the total number of lights supplied will be about 1,000 16-candle-power incandescent lamps inside the buildings, and two 3,000 candle-power arc lamps on the exterior. The arc lamps supplied are of the Brockie-Pell pattern. One of the engines and a dynamo was run for five hours as a trial on Saturday with a satisfactory result.

Abandonment of the Electric Lighting Scheme at Exeter. At a meeting of the Exeter Town Council last week a report was considered from a special committee on electric lighting. The committee opened tenders for lighting the selected district by electricity as follows:—Exeter Electric Light Company, 65 arc lamps, 1,200 candle-power, £19. 17s. 6d.; wires, £3; total per lamp per annum, £22. 17s. 6d. Messrs. Allen and Son, Taunton, 65 arc lamps, 1,200 candle-power (Thomson-Houston)—overhead, per lamp per annum, £24; underground, £28. 10s.; Brockie-Pell or Pilsen-Joel, 1,000 candle-power, £21 and £25. 10s. respectively. Messrs. Newall and Co.—Thomson-Houston, 1,200 candle-power, overhead, £23. 10s. underground, £27. 10s.; Brush, 2,000 candle-power, £25. 10s. and £29. 10s. respectively. Messrs. Sharp and Kent, 2,000 candle-power lamps, £35 and £40. Anglo-American Brush Electric Light Corporation (Limited), 2,000 candle-power lamp, overhead, £43 per annum. The whole of the above figures were on a seven years' basis. The committee pointed out that the lowest tender represented a cost of £1,486. 17s. 6d. per annum, while the present cost of lighting the same district by gas was, according to the surveyor's report, £666. 11s. 8d. The total illuminating power of the existing gas lamps at the posts would be 2,000 candle-power, while that of the electric light would be 32,000 candle-power. Having regard to the large increase in the cost, as compared with that of gas, the committee did not recommend that any of the tenders be accepted, and the Council concurred.

Swansea.—At the meeting of the Swansea Town Council last week, the minutes presented by the Special Gas Committee stated that at a meeting held on the 2nd inst. reports from the town clerk as to the powers of the Corporation with regard to the erection of new gasworks and the lighting of the borough by electricity were received. The surveyor was directed to obtain such information as would enable him to fully report on the extent of works for public lighting which could be erected by the Corporation for an annual expenditure of £4,060, and also as to the cost of such further works as would admit of a supply to private consumers. He was likewise instructed to report as to the desirability of adopting oil lamps. It was resolved that, in the opinion of the committee, it was desirable to light the borough by electricity, and that the town clerk be instructed to apply to the Board of Trade for a Provisional Order accordingly. At the meeting of the committee on the 12th inst. they decided which streets in the borough should be lighted by electricity; and it was resolved that the Council be asked to invest the committee with full powers to conclude a contract with some substantial company for the lighting by electricity of the area in question. A letter was read from the Swansea Gas Company, asking the corporation to enter into a contract with them for the supply of gas to the public lamps for one, two, or three years at 2s. 10d. per 1,000 cubic feet; and the Town Clerk was directed to reply that the corporation were not at present prepared to enter into any contract. The minutes were adopted.

The Proposed Electrical Railway in the New Forest.—A meeting of the New Forest Union Highway Board was held on Monday, October 22nd, when a letter was read from Mr. St. Aubyn Angrove on behalf of the promoters of the Lyndhurst Road Tramway, in which he said they intended "to avail themselves of a further opportunity for more effectually gauging the general feeling of the parishioners of Lyndhurst by means provided by law." A memorial, signed by 160 persons, was read, expressing their approval of the scheme of Messrs. Haynes and Poole. Later on a telegram was received from Mr. St. Aubyn Angrove, stating that he withdrew his letter, and that Mr. Haynes would attend. It was unanimously decided to hear what Mr. Haynes had to say. Mr. Haynes was then called in, and said they had amended their plans since he was last at the Board. He found that there was an average width of 8ft. of waste on the south side of the road, and they would be able to keep their rail 4ft. to 5ft. from the side of the metalled road. The narrowest part would be 3ft.—Mr. Roy proposed that the matter be adjourned until the next meeting, the 5th of November, and that a deputation be appointed to see the proposed line as staked out.—This was seconded by Mr. Humby, and carried by 11 to 6.—Mr. Roy suggested that the Crown should be asked whether they would give their consent to the tramway being run partially or wholly over their property, which was agreed to.—It was also decided that the clerk should write to the London and South Western Railway Company, asking them if they would give the tramway promoters power to run over their property.

NOTES ON ELECTRO-MAGNETIC INDUCTION.*

BY DR. J. A. FLEMING, M.A.

(Continued from page 786.)

Inductive Effects Produced by Transient Electric Currents.—Since secondary currents, which have, as we shall see, very brief duration, can in turn generate induction currents of higher orders, it was an obvious inference that Leyden jar discharges or the transient currents formed by discharging charged conductors, should in like manner be able to give rise to a family of induced currents in suitably placed circuits. Prof. Henry opened up this field of research, and it has been also diligently cultivated by Marianini, Abria, Matteucci, Reiss, Verdet, and many other physicists. Henry's first experiment was as follows: A hollow glass cylinder (*see* Fig. 4) of about six inches in diameter was prepared with a narrow riband of tinfoil about thirty feet long pasted spirally around the outside, and a riband of the same length pasted on the inside, so that the corresponding spires of the two were directly opposite each other. The ends of the inner spiral passed out of the cylinder through a glass tube to prevent direct communication between the two circuits. When the ends of the inner riband were joined by the magnetising spiral containing a sewing needle and a discharge from a half-gallon jar sent through the outer riband, the needle was strongly magnetised in such a manner as to indicate an induced current through the inner riband in the *same direction* as that of the current of the jar. If instead of using the magnetising spiral the ends of the inner riband were brought near together, a small spark was detected at the instant of sending a jar discharge through the outer conductor. Experiments were next made in reference to the production of induced current of different orders by electric discharges. For this purpose a series of glass cylinders with tinfoil spirals pasted on them was prepared and joined up so that the inner spiral of one cylinder was in connection with the outer spiral of another. When a

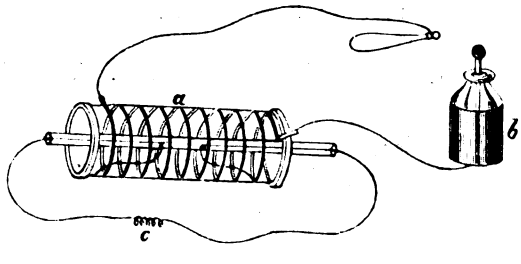

FIG. 4.

discharge was passed through the outer riband of the first cylinder it produced an induced secondary discharge circulating in the inner spiral of the first and the outer spiral of the second cylinder. This in turn generated a tertiary current, and so forth. Each of these discharges was a brief wave of current, and by the use of the magnetising spiral in each circuit an attempt was made to determine the direction of the discharge. Here, however, an anomaly presented itself. By the use of this magnetising spiral it appeared that the induced discharges were all in the *same direction*. Leyden jar discharges were then passed through the first member of the series of coils and helices used in the experiments on galvanic currents, and here the directions of the induced discharges in the several conductors were found to *alternate*. After various experiments Prof. Henry considered that he had found the solution of this anomaly in the different distances of the inducing and inductive circuits. As an experiment illustrating this he gives the following:—Two narrow strips of tinfoil about twelve feet long were stretched parallel to each other, and separated by thin plates of mica to the distance of about $\frac{1}{50}$th of an inch. When a discharge from a half gallon jar was passed through one of these an induced current in the *same* direction was obtained from the other. When the ribands were separated to a distance of about $\frac{1}{8}$th of an inch, no induced current, as evidenced by the absence of effect in the magnetising spiral, could be obtained. When the circuits were still further separated the induced current reappeared, but in the *opposite* direction to the primary discharge. The distance at which the induced discharge changes direction appears, according to Prof. Henry, to be dependent on a number of circumstances, such as the capacity and charge of the jar, and on the length and thickness of the wires.

With a battery of eight half-gallon jars and parallel wires of about ten feet long, the change in direction did not take place until the wires were separated by twelve or fifteen inches.

The currents of all the higher orders were found to change sign with a change in the distance between the inducing and inductive circuit.

One interesting experiment was made by Henry to illustrate the induction effect of jar discharges across considerable distances. In this case a primary circuit was formed consisting of an insulated wire eighty feet long. Around this and separated from it by a distance of about twelve feet was another wire one hundred and twenty feet long. When the discharge from thirty large Leyden jars was sent through the primary wire an induced discharge was obtained in the other sufficiently strong to magnetise to saturation a small needle placed in a magnetising spiral interpolated in the secondary circuit. We may, however, remark here, once for all, that all these experiments directed to determine the direction of induced discharges in which the magnetising power of the discharge is made use of for this purpose are difficult to interpret, and too much reliance must not be placed on the conclusions thus drawn. Leaving out of account for the moment all consideration of what are called electric oscillations, to which we shall allude subsequently, we can say that if two discharges are passed through a magnetising spiral, the discharges being oppositely directed and of equal *quantity* but different *durations*, the resulting direction of magnetisation will be dependent upon several conflicting elements. Speaking generally, the intensity of magnetisation is determined by the relative magnitude of the maximum current strength during the discharge, and of two discharges having equal quantity, the one lasting the shortest time would rise to the highest current strength during the period of the discharge, and exercise the greatest magnetising force. Even then it would not be safe to draw too pronounced a conclusion from the direction of magnetisation as to the relative magnitudes of the maxima of two alternate discharge currents rapidly succeeding each other, for, as Abria has pointed out* long ago, the demagnetisation of a steel needle requires a less magnetising force than that necessary to magnetise it in the first instance, and hence the final results are complicated by the relative order of imposition as well as the relative maximum magnitude of the magnetising discharge currents. One fact which has to be borne in mind in attempting to interpret these results of Prof. Henry is that the magnetising current whose direction we are seeking to determine acts by induction on the mass of the needle or iron in the testing magnetising coil, and generates in its mass induction currents circulating round its surface. Under the head of *Magnetic Screening* in a later section we shall examine the circumstances under which such currents induced in a metallic mass shield to a greater or less extent conducting circuits lying beyond them from inductive effects. Meanwhile we can say that the effect of a very *sudden* discharge in one direction in the magnetising coil is to induce eddy currents in the surface of the needle which shield the inner and deeper portions of the steel from the magnetising action, and the resulting magnetisation is chiefly superficial. If, however, the discharge is prolonged or dragged out whilst retaining the same electric quantity, the shielding action will not be so pronounced, and the magnetisation will penetrate deeper down into the mass of the steel. Accordingly two equal discharges, *i.e.*, discharges of equal quantity, may produce a greater or less magnetic moment in the steel, according as the duration of the same is greater or less, a *very* sudden discharge having much less relative magnetic-moment-producing power than the same quantity more dragged out. We may in general also say that the magnetising power of a discharge current is determined by the value of the maximum current strength during the discharge,

* Abria, *Ann. de Chim. et de Phys.* [3] Vol. I., p. 429, 1844.

Digitized by Google

and hence, of two equal quantity discharges, the one which lasts the shorter time, and which has, therefore, the greatest maximum value, will, if the discharges are approximately equal in duration, produce the greatest magnetising effect.

The tertiary currents, produced by ordinary galvanic currents, and the secondary currents, produced by Leyden jar discharges, consist, as we have seen, in their simplest form of a double discharge or flow, one part *inverse*, or oppositely directed to its inducing parent current, and the succeeding part *direct*, or similarly directed, the two component currents of the total discharge having equal quantity but different durations. In general the first portion, or the inverse current, is that which has the greatest maximum value and the shortest duration, the second half, or the direct current, being more dragged out in time; and, for a reason to be stated further on, the approximation of the induced and inducing circuits exaggerates this difference, or increases the maximum value of the inverse current at the expense of its duration. The explanation which may be offered, then, of the phenomena of the magnetisation of steel by tertiary currents, or by the secondary currents due to Leyden jar discharges, is as follows:—When the induced and inducing circuits are not very near to each other, and when the inducing current reaches its maximum not very suddenly, the two halves of the induction current are not very different in duration, but the first or inverse current has, of the two, a rather greater maximum and less duration. There results then a magnetisation in the needle, which, on the whole, is in the direction produced by the inverse current, and the inference from the direction of magnetisation is that the induced and inducing currents are in the opposite direction. If, however, the inducing current reaches its maximum value very suddenly, as it does if the circuits are very close, then the first half, or the inverse induced current, is so brief in its duration that the magnetisation of the needle due to it is very superficial. On the other hand, the magnetisation due to the rather more prolonged direct current is more diffused through the needle, and the resultant magnetisation found on testing the needle is that apparently due to the *direct* current, and the inference from the resulting magnetism of the needle would be that the induced and inducing currents are in the *same* direction. By some such explanation as the above we may reconcile these anomalous results of Prof. Henry with known facts, but it is evident, since the resulting magnetisation of the needle is an effect determined by the relative maximum values of the two portions of the total induced current, and by their duration, as well as by their order of superposition, that considerable caution is necessary in attempting to interpret the results of experiments made with a magnetising helix.

(To be continued.)

LIGHTNING CONDUCTORS.—I.

BY DR. OLIVER LODGE.

Theory of the Experiment of the Alternate Path.

In the *Philosophical Magazine* for August I gave a general statement of the considerations which had to be attended to in a discussion of experiments on the division of a Leyden jar discharge between the two branches of a divided circuit, and pointed out that by making one of the branches an air-gap a considerable simplification of the theory would result.

It has recently been objected to this experiment that it does not imitate at all closely the conditions of lightning. For the moment I do not care whether it does or not; it is in any case an instructive experiment, and worth understanding; and inasmuch as it sometimes seems to give anomalous, or at least unexpected, results, it is worth analysing to the bottom. It is easy to make more imitative experiments, and to discuss them afterwards. In my lectures to the Society of Arts, the experiments of the alternative path constituted only one series of many described, some of them more directly and apparently imitative of lightning conditions, but none, perhaps, more necessary to thoroughly understand, or throwing more light upon the others when once properly understood. For the present, therefore, I propose to confine myself to a discussion of this series of experiments.

1. The diagram of connections may be drawn in various forms, which, though apparently different, are essentially the same. Figs. 1, 3, 5 are identical, and are the most convenient arrangement in practice. Figs. 2, 4, 6 are really the same thing, but they have the disadvantage of being liable to make the alternative path part of the charged system, so that it is

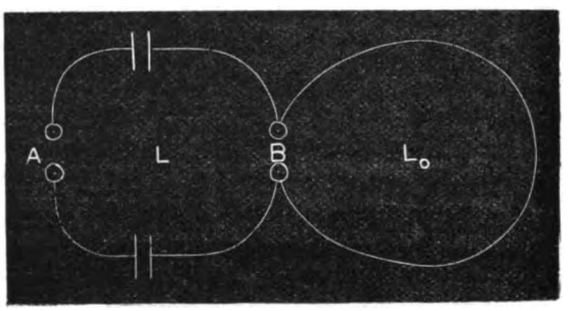

Fig. 1.

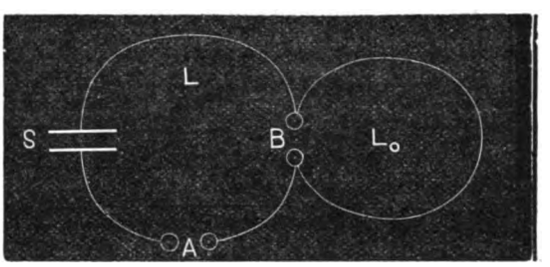

Fig. 2.

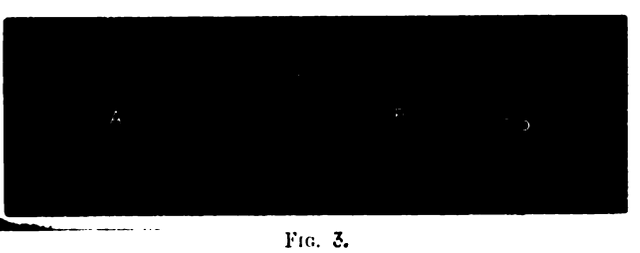

Fig. 3.

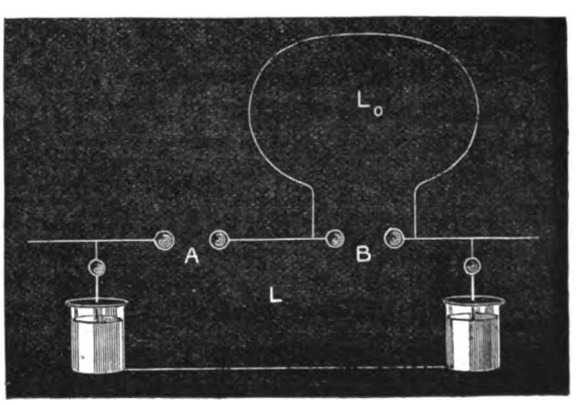

Fig. 4.

unpleasant to touch; moreover, the effective capacity is more troublesome to reckon. If these arrangements had any advantage these slight objections could be easily overcome, but I see no advantage in them. I have employed them all, however, at one time or another. Fig. 6 has the additional disadvantage of leaving the length of the A spark vague, so that there is no guarantee that the jar shall be charged to the same potential every time.

The electric machine is not shown in these figures. It can be connected up in any convenient way to the A knobs. To

Digitized by Google

prevent the machine itself from becoming an important part of the circuit and having to be taken into account, I often connect it up to the A knobs by imperfect conductors, such as a couple of penholders or lead pencils. They supply the charge fast enough, but they take no appreciable portion of the discharge. Very often, however, the A knobs are those of the machine itself, fixed a measured distance apart.

The capacity charged is the A knobs and wires and the coats of the jars attached to them. The other two coats of the jars are obviously connected together, and may, for convenience of handling, be connected by some imperfect conductor with the earth. The difference of potential to which the jars are charged is given by the length of the A spark and the size of the A knobs. The circuit conveying the discharge current varies according to circumstances. It consists of two loops, the portion labelled L and the portion labelled L_0. One might call them the A loop and the B loop; but perhaps it is less ambiguous to call them the L loop and the L_0 loop, respectively; the latter being the alternative path.

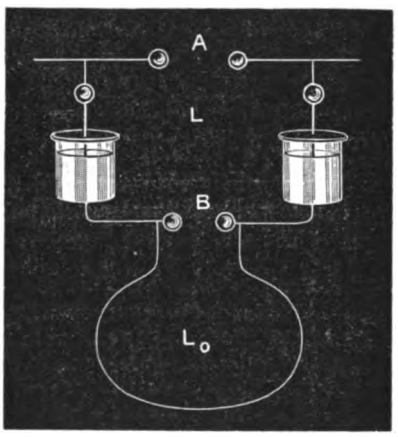

Fig. 5.

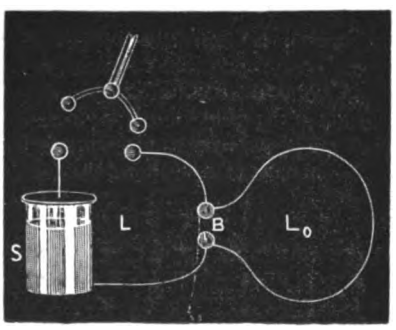

Fig. 6.

Now the circuit conveying the discharge current consists of the whole of L and a variable portion of L_0. On arriving at the B knobs the current divides, part going on round L_0, part jumping across the air gap. It is not possible without bringing the B knobs into contact, nor would it be of any service, to make the discharge circuit consist of L alone; some portion is sure to patronise the L_0 route. Only when the alternative path is removed altogether does the circuit consist of L alone.

The simplest case is when nothing jumps across the air gap; and in that case the discharge circuit consists solely of both loops in series, $L+L_0$. But ordinarily there is a spark at B, and even if there is no real spark a little brush is visible in the dark between them at every discharge. Perhaps the quantity passing in this brush is negligible; if so, the simplest case is attained by separating the B knobs until their spark just fails. Experimentally it is easier and feels more satisfactory, to separate the B knobs till about half the sparks fail and half pass; but perhaps the best combination of advantages, convenience of experiment and simplicity of theory, is secured by adjusting the B knobs so that some 90 per cent. of the sparks there fail, the occurrence of the remaining tenth showing that they are not separated altogether beyond a possible range. The distance of the B knobs is read with great ease, and more than sufficient accuracy, by supporting them on a micrometer screw arrangement with its head graduated to the 400th of a millimetre.

2. Calling the self-inductions of the two loops L and L_0, and their resistances R and R_0 respectively, we have in the simplest case when the B sparks are just failing, the inductance of the discharge circuit equal to $L+L_0$, and its resistance equal to $R+R_0+$ resistance of the A spark.

The capacity of the jars (in cascade, if there are two) and charged portion of the leads being called S, the total quantity discharged each time is SV_0; and the strength of the discharge-current at any instant after commencement of discharge is given by the equation

$$C=\frac{V_0}{n(L+L_0)}e^{-mt}\sin nt \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where $$m=\frac{R+R_0+A}{2(L+L_0)};\quad n^2=\frac{1}{S(L+L_0)}-m^2;$$

and $$(R+R_0)^2=\tfrac{1}{2}n(\mu l r+\mu_0 l_0 r_0) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

$$\simeq\frac{\mu l r+\mu_0 l_0 r_0}{2\sqrt{S(L+L_0)}}-\left\{\frac{\mu l r+\mu_0 l_0 r_0}{8(L+L_0)}\right\}^2,$$

where l is the length, and r the ordinary resistance, of the L loop; and l_0, r_0, the same things for the L_0 loop of the circuit.

The impedance of the alternative path is

$$P_0=\sqrt{\{n^2L_0^2+R_0^2\}},$$

and the difference of potential between the B knobs at any instant is

$$V=P_0C \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

This is the quantity whose maximum value is measured by the length of the B spark. This, therefore, is the quantity which we experimentally observe, and have to analyse the theory for, in its applicability to different conditions.

First Approximation.

3. Now, the complete expression for V being rather long and unwieldy, it is better to begin by making approximations; and as a first approximation we can suppose resistance negligible as compared with inertia, at any rate for the first few oscillations. Making this simplification, $m=0$, and the current amplitude is—

$$C_1=V_0\sqrt{\left(\frac{S}{L+L_0}\right)}$$

$$P_0=nL_0=\frac{L_0}{\sqrt{S(L+L_0)}},$$

and $$V=\frac{V_0L_0}{L+L_0}, \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

a very simple expression, independent of the capacity of the jar, and showing that the B spark with the alternative path L_0 is shorter than it would be without any alternative path at all in the ratio

$$\frac{V}{V_0}=\frac{L_0}{L+L_0}.$$

It should be easy to verify this under circumstances when the first approximation is applicable; and if it turn out reasonably accurate, it would give an easy means of comparing the self-induction of two short and well-conducting simple circuits; for

$$\frac{L}{L_0}=\frac{V_0}{V}-1$$

and V_0/V may be taken as the ratio of the B spark lengths, first without, and then with, the alternative path L_0.

One sees from these equations, that when the fixed portion of the circuit, L, is much bigger than the alternative path, L_0, the B spark is very short, and roughly proportional to L_0; but that when L is much smaller than L_0, the length of the

Digitized by Google

B spark hardly depends upon the alternative at all, and is much the same whatever the nature of that path, or even if it is absent altogether. For sensitiveness, therefore, it is better to have L rather the bigger of the two. But then remember that all this only applies as to the case when the resistances concerned are sufficiently small to be neglected. It is not likely to apply, therefore, to long or badly-conducting circuits. For these we must proceed to a further approximation.

Second Approximation.

4. As a second approximation we had better take into account that effect of resistance which is likely to become important first.

Now, resistance has three main effects. First, it diminishes the value of n, thereby lessening the inertia part of the impedance; but since it increases C just as much, this does not affect the value of V_0. Secondly, it increases the damping coefficient and more rapidly brings down the current amplitude, so that if the B spark does not jump until after the accumulated momentum of several oscillations, it is likely, by reason of damping, to be shortened. Its third effect is an increase in the total impedance by reason of the R_0 term.

Of these three effects, the first scarcely affects V, the last tends to increase it; only the second acts so as to make V smaller with increasing resistance. Hence any diminution of V which may be actually observed to accompany an increase of R_0 must be due (so it would appear) to an effect of the damping term, involving the coefficient m.

Let us see what this term becomes in any very short time, say at the end of a complete oscillation period T—

$$m\,T = \frac{2\pi m}{n} = \frac{\pi (R + R_0 + A)\sqrt{S}}{\sqrt{\{(L + L_0) - \tfrac{1}{4} S (R + R_0 + A)^2\}}} \quad . \quad . \quad . \quad . \quad (5)$$

$$\simeq \pi (R + R_0 + A)\sqrt{\left(\frac{S}{L + L_0}\right)}.$$

For this to be of any effective magnitude, S and one of the R's must be great, but the L's have most effect when they are small; in fact, their smallness may easily imperil the oscillatory character of the discharge, and may end by making $m\,T$ infinite or worse.

Third Approximation.

5. If there is the least tendency for m to become comparable in size with n—that is, for the oscillation-period to be appreciably lengthened by the resistance, or damping, co-efficient—there is a fourth effect which may possibly have to be taken into account, viz., this :—

The equation (2) is by no means a complete expression for the resistance of a conductor to currents of all frequencies of vibration; it is only accurately true for infinitely rapid vibrations. So soon as n falls below a certain magnitude, a much more complicated expression has to be employed, viz., as Lord Rayleigh has shown,

$$\frac{R}{r} = \text{real part of } \frac{J_0\sqrt{\left(-\frac{4 n l \mu}{r}\right)}}{J_0'\sqrt{\left(-\frac{4 n l \mu}{r}\right)}} \quad . \quad . \quad (6)$$

where R is the resistance of a conductor to currents alternating $\frac{n}{2\pi}$ times a second, and r is its ordinary resistance to steady currents; l is the length of the conductor, and μ its magnetic permeability; J_0 stands for Bessel's function of order zero, and J_0' for its first derived function.

For $n = 0$ the value of the right-hand side is 1. For $n = \infty$ it becomes infinite, being equal to

$$\sqrt{\left(\frac{n l \mu}{2 r}\right)}.$$

Now, although this last expression may be used as a good approximation to the right value of the resistance ratio for very great values of n (and it is what we have used so far), yet if there be any decrease in the frequency of oscillation below a certain ill-defined value, the more complicated expression must be used to calculate the effective resistance, and it will have a smaller value.

The effect of high resistance may thus, in a curious way, diminish total impedance, and so tend to make the B spark actually shorter for a resisting material than it is for a better conducting one, especially in the case of a long circuit of not very high conductivity—a circuit, that is, in which resistance is an important portion of total impedance; while its damping effect, by bringing down the violence of the current oscillation, tends still further in the same direction.

Notice further, that the expression for R, besides the length of the conductor and its ordinary resistance, contains the magnetic permeability of its substance; and thus the effective resistance or throttling part of total impedance for an iron wire is considerably greater than for a non-magnetic substance of the same dimensions and specific resistance, while the inertia portion is much the same. Hence it would appear possible that iron wire used as alternative path is liable in certain cases to give a shorter B spark than such substances as copper on the one hand or lead on the other.

The whole thing could be easily calculated out and exhibited in curves or numbers if only a table of Bessel's functions were available.

I hope the recently appointed British Association Committee on Mathematical Tables will speedily see their way to calculating and issuing these much-needed tables. Meanwhile, I do not lay any stress on this, what I have called, "fourth effect" of resistance; I merely note it as *possibly* acting in the direction suggested, and anyhow not to be lost sight of when the second approximation is used.

6. Lastly, there is a fifth effect, which I may as well also note, though it is probably too small to have much practical bearing. It depends on the value of the inductance of a conductor being affected by the mode of distribution of a current throughout its substance. With steady or slowly changing currents the current is distributed uniformly all over the cross-sectional area of the conductor, and accordingly the self-induction of a single circular loop of length l, made of non-magnetic wire whose circumference is c, is

$$L = 2 l \left(\log \frac{8 l}{\cdot 7788\, c} - 2\right). \quad . \quad . \quad . \quad (7)$$

But very rapidly-varying currents are concentrated near the outer surface of their conductor, and hence the constant under the logarithm has to be modified for them, until in the limit it is unity; so, when n is very great,

$$L' = 2 l \left(\log \frac{8 l}{c} - 2\right), \quad . \quad . \quad . \quad . \quad . \quad (8)$$

and this is slightly smaller than the preceding value; but I doubt if the difference is great enough to be noticeable.

I now propose to record and examine in detail some experimental results, with a view to ultimately seeing how far the above attempted theory is really applicable to them.

The Sunbeam Lamp.—This lamp appears to be making rapid progress, and has displaced both the arc lamp and the small sixteen candle-power incandescent lamp in many places. Messrs. Sydney F. Walker and Olliver, of Cardiff, have had a 500 candle-power lamp running at Bodringailt Colliery, in the Rhondda Valley, since last November. The Powell Duffryn Company have also made use of them at several of their collieries, with uniform success. Several of the large collieries in the counties of Durham, Northumberland and Cumberland have adopted them in place of arc lights, and in particular they have been adopted all through by the Ebbw Vale Company, at their Victoria Ironworks, to replace the arc lamps previously used there.

The Protest against the Competitive Examination System.—Among the signatures appended to the protest which appears in this month's number of the *Nineteenth Century* against the system of competitive examinations we notice those of Lord Armstrong and Profs. Dewar, Dittmar and Hicks.

THE DEPTFORD CENTRAL LIGHTING STATION.

We now supplement the description of this undertaking which appeared in our last issue with a sketch plan of the ground floor, and with some views, engraved from photographs, showing the present state of progress. From the sketch plan it will be seen that there is room towards the river to erect a second battery of boilers of 40,000 horse-power, and, although this is not shown, an equal space is available on the opposite side for increasing the dynamo and engine plant to the same extent. We may add that the whole area of the ground floor is covered with a layer of concrete 4ft. in thickness, and the walls are in many places 6ft. thick. Some 8,000 cubic yards of concrete and about 33 million bricks have already been used, besides several thousand tons of iron.

LAYING THE FOUNDATION STONE OF THE BRADFORD CENTRAL STATION.

(FROM OUR OWN CORRESPONDENT.)

The foundation stone of the generating station* now in course of construction at Bolton-road, Bradford, for the supply of electric light to the central portion of Bradford was laid on Friday last by Alderman Frederick Priestman, chairman of the Electric Lighting and Gas Supply Committees. The object of the scheme is to supply the electric current to consumers occupying premises in Market-street, Kirkgate, and other streets in the centre of the town by means of a system of underground wires. The generating plant which is to be used for the present consists of three complete sets of boiler, engine, and dynamo machines, each equal to 150 horse-power indicated, and the contract for its supply and erection has been undertaken by Messrs. Siemens Brothers. The current will be carried from the dynamo-house by two main cables in brick or composition trenches, one along Market-street as far as the Town Hall, and the other through Kirkgate and Darley-street to the Markets and Free Library, the arrangement being such that a service can be attached at any particular point. The buildings are being arranged so that if necessary a rapid extension may be made so as to meet any sudden demand. There were present at the ceremony the Mayor (Alderman Morley), the Town Clerk (Mr. W. T. M'Gowen), Alderman F. Priestman, Mr. D. Barker (deputy-chairman of the Electric Lighting and Gas Supply Committees), Mr. C. Sowden, Mr. F. W. Hill, Mr. R. Shackleton, Mr. John Wright, Mr. R. W. Silson, Mr. John Vior, Mr. W. Priestman, Mr. Brewer, Mr. Empsall, Mr. J. Cooper, and Mr. J. Akam, members of the Town Council; the Rev. Canon Bardsley, D.D.; Mr. David Swallow, gasworks engineer; Mr. James N. Shoolbred, C.E., the engineer of the works, and others.

Mr. Barker (deputy chairman) deposited under the stone a box containing copies of local newspapers and a London newspaper, together with a short description of the works and current coins of the realm.

The MAYOR, in calling upon Alderman F. Priestman to lay the stone, said that that gentleman had been chairman and vice-chairman of the gas committee for about ten years, and any work which he undertook was always done most thoroughly. The electric lighting scheme was no ordinary undertaking, and he ventured to say there was only one man in the Council who could have approached it with the ability with which it had been inaugurated (hear, hear). It gave him immense pleasure to present, on behalf of the gas committee, to Alderman Priestman a trowel and mallet with which to perform the ceremony.

The Rev. CANON BARDSLEY having offered prayer,

ALDERMAN F. PRIESTMAN proceeded to lay the stone. Having discharged this task, he said the Mayor had told them the reason why the Corporation had determined to lay down electric plant. Briefly, the reason was that they had determined that there should be no king in Bradford but the Corporation. After thanking the gas committee for their handsome gift, he said he should have been pleased if that committee had seen its way to ask down some eminent electrician to perform the ceremony; but as he had been asked unanimously he could only say that he appreciated the honour in a very high degree, and was proud to have his name so prominently associated with this new enterprise—an enterprise which was destined to become a great commercial industry, and in which Bradford had the proud distinction of being a pioneer. He had been asked when the works would be ready. He was sorry not to be able to give a definite reply. Owing to circumstances over which the Corporation had no control the works were not begun as early as they ought to have been, the intention having been to finish them by the 1st of October. They had been unable to get powers from the Government authority sufficiently early to enable them to accomplish this; but no time had been lost since leave to construct was granted, and they were now in a forward state. The buildings would probably be ready for the roof in ten days or a fortnight, and the other departments of the work were approaching completion. The chimney would be the last, but that need not necessarily prevent them from commencing. Nearly all the cables were in Bradford, and he anticipated that they would begin to lay them in a week or ten days. He was told that the engines and dynamos were nearly finished. The works would be ready for a start early next year, and Mr. Shoolbred hoped to be able to deliver a supply in the middle of December. Another question which had been asked was whether the Corporation intended to light the streets by electricity, and in answer to that he had to say that such was not

their intention. It would not be to the interest of the ratepayers that they should do so until their gas works were found to be too small for the demand made upon them. It might, perhaps, be a proper thing to light such places as Forster-square by means of electricity. Some people had got the idea that it was intended to carry the light to Allerton. It must have been because his friend Mr. Sowden was taking such an active interest in the affairs of Allerton, where the gas was so dear and the rates so easy (laughter). There was no intention to do more at present than light the central portion of the town. As to the price to be charged he might say that the committee did not intend to supply either lamps or fittings, and it would be for the consumers to make their own contracts with electricians, of whom there were many in the town. The Corporation would not do more than supply and charge for the current, and it would be charged for by meter, or by the number of arc lamps to be supplied. If consumers would tell Mr. Shoolbred the number of lamps they wished run he would probably be able to give them an idea of the cost. Some discussion had taken place as to the desirability of having the cables overhead or underground. They had decided, and he thought very wisely, to place them underground. There was some danger in fixing heavy cables to chimneys, and, moreover, the Corporation had refused to allow other people to construct overhead wires. There was something like a war going on as to the respective merits of alternate and continuous currents. It was something like the old battle of the gauges, and, as in the case of that contest, he thought the present discussion would very soon be decided by experience. The system which they had adopted was that of the continuous current. He was sorry to say that up to the present time there had not been an application for current for electric motors. He believed the electric motor would be found to be a most convenient method of running light machinery which was only wanted to run for a few minutes at a time. Another question which had been asked referred to meters. It was said that great improvements had taken place with regard to the construction of electric meters, and that they had been brought to a considerable degree of perfection as measurers of the electric current. There was one which he believed was absolutely correct, and a gentleman in Bradford was engaged in making another, and there was every reason to believe it would be a success. There could be no doubt that he was on the right track. It might impart confidence to those who doubted whether Bradford had done right in pioneering the electric light if he were to say that during the last three or four months there had been a very great extension in this direction. The electric lighting acts had been much improved, and the public had gained great confidence in the electric light. In Bradford a large number of people had put down installations, not only in their mills, but in houses. He had got an installation in his own house, and had parted with all his gasfitings and chandeliers. The light was of immense superiority over gas. In London, Brighton, Eastbourne, Hastings and Leamington, and many other towns, private installations were being put down, and Mr. Shoolbred told him that many municipal authorities were adopting the new method of lighting, and companies were obtaining powers for supplying other places. Electricians were busy all over the country, and there was a great demand for electrical appliances of all descriptions. He congratulated Bradford on having let their contracts so early as they did, because he believed it would be much more costly to let the same contracts at the present time. He thought they might look forward to the time when their works would be very largely extended (applause).

Mr. BARKER proposed a vote of thanks to the Mayor and to Ald. F. Priestman, which was seconded by Mr. JOHN WRIGHT, and carried with acclamation.

A similar compliment was paid to Canon Bardsley for his presence, and the proceedings then concluded.

LETTERS FOR LEARNERS AND UN-PROFESSIONAL READERS.

BY H. D. WILKINSON.

SECTION II.—ELECTRO-MAGNETIC FIELDS.

(Continued from page 766.)

134. *Electro-Magnetisation of Short Iron Rod.*—The necessary apparatus having been explained, we shall detail the method of taking observations, to show the gradual magnetisation of a short iron core placed within a coil of wire through which definite currents are passed. Referring to the apparatus, as arranged in Fig. 112, the magnetometer and galvanometer must first be levelled and adjusted in position till their respective pointers coincide with the zero marks on the scales. If the controlling magnet is employed with the graded galvanometer described in para. 132, it must first be removed several feet away while the instrument is being levelled and adjusted to zero. The latter is effected by turning the instrument round until the pointer is at zero, and the levelling is effected by the two screws seen in the figures. The controlling magnet is then placed in position, and if not in the plane of the meridian will deflect the pointer a little away from zero. To rectify this the adjustable screw on the arm F of the needle box is turned until the pointer is restored thereto. By a measurement, taken immediately before the readings, the controlling magnet used was found to reduce the sensitiveness twenty-one times (n). Its field at the needle was therefore (para. 132)

$$H(n-1) = \cdot 18 \times 20 = 3 \cdot 6 \text{ C.-G.-S. units.}$$

The first thing to be done is to put two or three different strengths of current through the coil alone, and read the corresponding deflections on the two instruments. From these observations, when plotted on squared paper, it can be seen what must be deducted from the readings taken with coil and core together to give the true magnetic effect of the core. Having done this, the current is switched off and the core inserted into the coil.

The core used in this experiment was a cylindrical rod of unannealed iron, 10 centimetres long and 4·3 millimetres diameter. Its sectional area was therefore

$$\frac{\pi d^2}{4} = \cdot 7854 \times \cdot 43^2 = \cdot 1452 \text{ square centimetres,}$$

and its volume $= \cdot 1452 \times 10 = 1 \cdot 452$ cubic centimetres.

The length of the core being only some 23 times its diameter, there was considerable demagnetising effect. The core being shorter than the coil, care was taken by measurement to push it into an exactly central position in the coil. The latter being held down by a clamp this operation could not shift its position.

Now it is important to notice at this point whether the magnetometer is deflected; if it is, the core has some traces of magnetism which should be removed before commencing the test. This may be done by heating it and then allowing it to cool while lying horizontally in an east and west direction; or a few light taps at the end while held in the same position will generally suffice.

The resistance switch is now turned so as to put the greatest amount of resistance in circuit, and the current is then put on. Both magnetometer and galvanometer deflections must now be read as each successive reduction is made in the resistance, and the same jotted down in two vertical columns. Some of the readings are here appended, the galvanometer deflections being divided into columns corresponding to the position of the needle-box on the platform when the respective readings were taken.

Magnetometer Deflections.	Galvanometer Deflections.					Ampere-turns.
	4	8	16	32	Reduced to 32	
17	35¼	—	—	—	282	4512
2	—	—	—	5	5	80
14	—	—	—	20	20	320
38	—	—	23½	—	47	752
72	—	—	45	—	90	1440
102	—	35½	—	—	142	2272
113	26¼	—	—	—	210	3360
126	33	—	—	—	264	4224
131	41¾	—	—	—	334	5344

It is convenient afterwards to reduce them all to their value at position 32. At this position, with the controlling magnet in use, the current is equal to

$$(\cdot 18 + 3 \cdot 6)\frac{D}{32} = \frac{D}{8 \cdot 47} \text{ amperes,}$$

where D is the deflection reduced to position 32, and 3·6 (as given above) is the field of the controlling magnet, which was used throughout. The number of turns on the magnetising coil being 135, we get the number of ampere-turns by multiplying the current by this number—that is,

$$\text{ampere-turns} = \frac{D}{8 \cdot 47} \times 135 = 16 \text{ D.}$$

The deflections reduced to position 32 and multiplied by 16 give, therefore, the magnetising forces in ampere-turns, these values being worked out in the last column of the above table.

The curve in Fig. 115 is plotted on squared paper from the readings. The horizontal ordinate is divided off in divisions, each representing 1,000 ampere-turns, and the above values marked off accordingly. On the vertical ordinate it is more convenient to plot the magnetometer deflections first, which

Digitized by Google

are proportional to the field produced by coil and core together, as we have to subtract the effect of the coil before we can estimate the magnetisation of the core, and this is most readily done by plotting the deflections. This gives a straight line

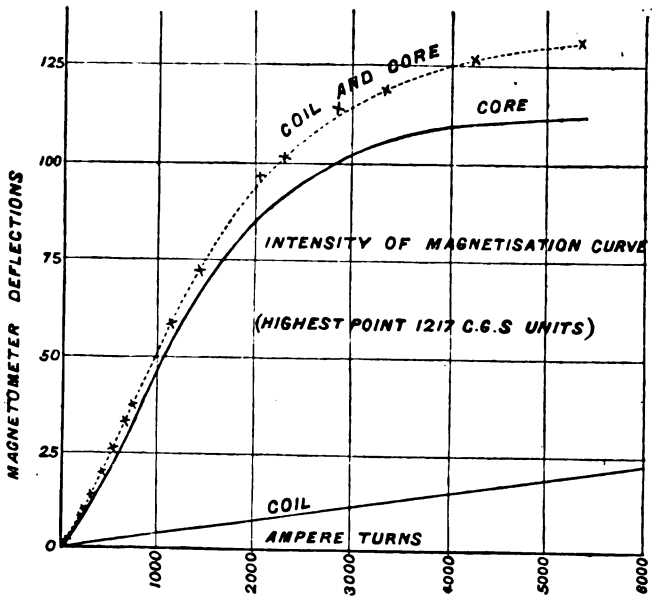

FIG. 115.

for the coil alone, and a regular curve (shown dotted) for the variation in external magnetic field of the coil and core together. Taking now a point on the horizontal ordinate for any given number of ampere-turns, the height of the vertical line from this point to the straight line of the coil must be subtracted from the height of the vertical line from the point to the dotted curve; this gives one point on a new curve which represents the effect of the core alone. This operation having been repeated for several points on the base line, we get a corresponding number of points on the new curve, which may then be connected by a line, giving the curve shown. By inspection of this curve we can see what deflection the magnetometer would have indicated had it been acted upon by the core alone. Calling this angle of deflection α, the tangent of which, as before explained, is equal to the deflection divided by 100, we may find the intensity of magnetisation of the core cerresponding to any given point in the curve by

$$I = \frac{\text{moment}}{\text{volume}} = \frac{r^3 H \tan \alpha}{1{\cdot}452} \text{ C.-G.-S. units.}$$

Now $$r^3 H = (20^2 + 5^2)^{\frac{3}{2}} \times {\cdot}18 = 1577,$$

and $$\frac{1577}{1{\cdot}452} = 1086.$$

Therefore, $$I = 1086 \tan \alpha.$$

Take the highest point in the curve; the deflection is 112, and therefore

$$I = 1086 \times 1{\cdot}12 = 1217 \text{ C.-G.-S. units.}$$

Values of I can be worked out in this way for any other point on the curve. It should be noticed, however, that the shape of the magnetisation curve is the same whether we plot strength of pole, moment, intensity of magnetisation, or deflections on magnetometer due to core, since all these quantities are proportional to one another. Similarly, the curve will be the same whether the magnetising force is plotted in ampere-turns or C.-G.-S. units.

The foregoing example is detailed with the view of furnishing the student with material sufficient to guide him in observations and calculations of his own. Experiments made on however small a scale, the results of which are reduced to known units of measurement, are the best means of acquiring cleaar conception of terms and their relative values. Near the higher part of the curve, although the readings were taken as rapidly as possible, the current perceptibly warmed the coil and core, and this may have prevented the iron acquiring a higher magnetisation. The fact of coils becoming heated when large currents are used is a bar to obtaining more than a few hundred C.-G.-S. units of magnetising force this way. We have previously shown (para. 130) that the magnetising field in C.-G.-S. units produced in the interior of a long narrow coil is equal to

$$\frac{\text{ampere-turns}}{\text{length of coil (centimetres)}} \times 1{\cdot}257;$$

and therefore, in the case before us, in which the coil is 1ft. (30·48 centimetres) long, the magnetising force per 1,000 ampere turns is

$$\frac{1257}{30{\cdot}48} = 41{\cdot}24 \text{ C.-G.-S. units;}$$

and, therefore, for, say, 6,000 ampere-turns, which is about 200 ampere-turns per centimeter length of coil, and not far from the maximum exciting power possible to use with one layer of wire, we obtain a magnetising force of only $41{\cdot}24 \times 6$, or about 250 lines of force per square centimetre in the coil. If the number of layers of wire is increased, the current put through cannot be as strong as through a single layer, since the radiation of heat is slower, and a limit of exciting power is soon reached probably not much above 300 ampere-turns per centimetre length of coil. This prevents the investigation by the magnetising coil method of the direction taken by the magnetisation curve under very high magnetising forces—that is to say, whether it ever reaches a maximum height beyond which no additional force will increase it, and if this condition of things (which means *absolute* saturation of magnetism) does take place, whether the curve continues horizontal or shows an inclination to descend. If these points, which are of the greatest interest, are to be determined, recourse must be had to some other method of magnetising, the iron, by which powerful fields can be brought to bear upon it.

Immediately on reaching the highest current considered safe for the insulation, the resistance was increased again, step by step, and readings taken on both instruments as before. This gave the descending curve of magnetisation which followed pretty closely the shape of the ascending curve, but at some distance higher from it. The residual magnetism in the core was calculated by the above formula from the magnetometer deflection after the current was switched off. This deflection being 10, the residual magnetisation was

$$I = 1086 \times {\cdot}1 = 108 \text{ C.-G.-S. units.}$$

This is only 9 per cent. of the total magnetisation acquired, and is due to the demagnetising effect of the core on itself, already spoken of.

In order to prove that the magnetometer has worked all right during the set of readings taken, as soon as the residual magnetism has been measured the core should be withdrawn from the coil and placed at a distance, upon which the needle of the magnometer should return accurately to zero. We shall next consider the magnetisation of a wire of annealed iron, of sufficient length to render the demagnetising effect inappreciable.

THE ELECTRICAL TRADES.

The project which was set on foot just before the summer holidays, in order to obtain for the electrical trades of this country a corporate representation in the LONDON CHAMBER OF COMMERCE, has met with such general support that last week we had the satisfaction to announce the actual formation of the new Section, and the election of its working committee. The task of the organising committee—that is to say, of the original promoters of the scheme—has been neither light nor easy. Some of the difficulties which presented themselves when the more ambitious idea of establishing a separate and independent society, advocated in these columns, re-appeared in connection with the later alternative, but have happily been over-

Digitized by Google

come. Patience and a little diplomacy have contributed to this end, no doubt; but probably the best friend to the general understanding has been the existing Rules of the CHAMBER on which the new Section had to be constituted, and which afford adequate guarantee that it will not exceed the functions which an organisation of that kind is intended to discharge. It was remarked by one of the speakers at the meeting that all past attempts to form an electrical association had failed chiefly because of the difficulty of formulating its functions. We should rather say that the difficulty was in reconciling various and sometimes conflicting views as to what those functions ought to be. Some diversity of opinion was manifested at the first meeting of the Section; but, as the same speaker observed, it was fortunate that they had in the London Chamber of Commerce a constitution and set of rules, based upon a wide experience, under which it was easy to see what questions were proper for discussion and what were not. The steadying element supplied by an influential body at its back will be of inestimable service to the Electrical Trades Section in the earlier stages of its career, and will undoubtedly contribute to its harmonious working hereafter.

We have on a former occasion expressed our opinion as to two or three delicate questions which some of the members desired should form part of the Section's programme. That they have been publicly mentioned and criticised is not at all to be regretted. Probably they will be followed by other suggestions which a little discussion may prove to be inexpedient or altogether impossible. Very soon the members will discover common grounds on which their united interests may take their stand; and it is no objection to a scheme of usefulness that it cannot be utilised in any and every imaginable direction. If wages, and prices, and contracts may not be fitting subjects for adjudication by a trade body, there are plenty of other subjects which are fitting; and if we are asked to name them, we need only point to the various Chambers of Commerce in London and the provinces as sufficient evidence of their utility. What has been good for other trades will be good for electrical and allied trades, which, after long feeling the need for it, have formed a combination to promote and defend their industrial welfare. No more categorical statement of its aims is at present necessary or desirable.

Nearly two hundred members of the trades represented have already sent in their names to the LONDON CHAMBER OF COMMERCE for enrolment on the new Section, a number which at this stage must be considered highly satisfactory, and which it is confidently predicted will soon be largely augmented. At the meeting which we reported last week the working committee, consisting of thirty-three members, was elected. We believe the names will command general confidence, and they certainly possess the merit of being the freely elected representatives of the whole body. It seems necessary to explain that the number was determined by the general Rules of the CHAMBER, a larger committee of forty-eight being permissible only when the strength of the Section reaches a higher figure than it does at present. This being the case, it was necessary to apportion the representatives as nearly as practicable to the number of members in the several sub-sections; but in some instances this object has been sacrificed to the desire to have on the working committee certain members whose presence would be valuable to it, although the sub-sections to which they strictly belonged were disproportionately weak. We published the full list in our last week's issue, and we think that a fair examination of the names will do away with the objection raised against their distribution by our correspondent Mr. J. B. VERITY, whose letter appears in another column. It is true that it does so happen that all the sub-sections save one are represented by one-third of their respective members, whilst the exception, representing electrical manufacturers and contractors, is assigned less than one-seventh. The anomaly, if it is felt to be one, can be remedied when the committee is brought to its full strength; but meanwhile the matter is in the sub-sections' own hands, and nobody can seriously suspect them of having purposely slighted the very strongest and most important of their number.

On some other points raised in Mr. VERITY's letter we would venture to make a few observations, not because of the intrinsic gravity of his complaints, but because they have evidently weighed with him in determining to hold aloof from the scheme, at all events for the present. Mr. VERITY is perhaps not alone in his misgivings as to the future conduct of this newly organised body, and we should like if possible to allay them. At the outset, however, one obvious retort may be made by the promoters: "If you apprehend mischief, why don't you come and prevent it?" If staying away would hinder what we dislike or misdoubt, the case might be different; but staying away will do no such thing; the association is an established fact, and those who study their own best interests will do wisely to frankly take part in it, and try to guide and direct it in the right way. As to the rest we have as little reverence for the ballot as Mr. VERITY himself; but it has its useful side in commercial and social affairs; and if the CHAMBERS OF COMMERCE are responsible for the Rule which he disapproves, his only chance of modifying it is by becoming an active member. Similarly, if there is the smallest danger of the Committee dwindling into a "family party," the best possible way of averting it is to step in and take a chair at the gathering. We entirely share Mr. VERITY'S candid view that no intention of establishing a trade clique is at present apparent; but if suspicion and hesitancy on the part of many members of electrical trades should prevail in keeping them aloof, there is no telling what the inside organisation might degenerate into. Several electrical interests—conspiciously those of the Telephone companies—are very inadequately represented at present in the general body of membership. To them and to all such we would say, Make haste to join this combination: with you it cannot fail to do you much good; without you it may do you some harm.

MEAN INTENSITY OF MAGNETISATION OF SOFT IRON BARS OF VARIOUS LENGTHS IN A UNIFORM MAGNETIC FIELD.*

BY A. TANAKADATÉ.

The series of experiments now to be described on the mean intensity of magnetisation in soft iron bars of various lengths has been carried out in the Physical Laboratory of Glasgow University, and in accordance with Sir William Thomson's instructions.

The experiment consisted in subjecting the piece of iron to different strengths of magnetising field, and in measuring the magnetic moments thereby acquired. The amount of residual magnetism was also observed by reducing the field to zero after each magnetisation.

The magnetising field was obtained, as usual, by means of an electro-magnetic solenoid, consisting of fine insulated copper wire wound upon a brass tube. The length of the wound part of the tube was 11·9 centimetres, and the total number of

* Paper read before the British Association meeting (Section A) at Bath, September, 1888.

Digitized by Google

turns was 13,158, so that the magnetic field due to one ampere was $4\pi 13158/11{\cdot}9 \times 10 = 1309$ in C.-G.-S. units, neglecting the effect due to the broken ends. The current through the solenoid was varied by inserting resistances by steps; its strength was measured by observing the difference of potentials at the terminals of the solenoid by means of one of Sir Wm. Thomson's graded potential galvanometers.*

The solenoid was laid at right angles to the magnetic meridian, and in the prolongation of the axis of this solenoid was placed a reflecting mirror magnetometer. Under this circumstance, the deflections of the magnetometer consist of two parts—one due to the solenoid and the other due to the magnetised iron in it. The first of these was taken account of by making a separate observation on the magnetometer deflections without the iron in it before each experiment.

The iron pieces were cut into required lengths and were heated to redness in a gas flame and slowly cooled; the oxide coating formed on the surface was removed by rubbing with emery paper, except in the experiment represented in the curve II.

The mean intensity of magnetisation was obtained by dividing the magnetic moment of the bar by its volume, the calculation being as follows:—

Let $2l$ = length of the bar.

d = diameter of the bar.

r = distance of the bar's centre from centre of the magnetometer needle.

H = the intensity of the horizontal component of the earth's magnetic field (assumed to be ·152 in C.-G.-S. units).

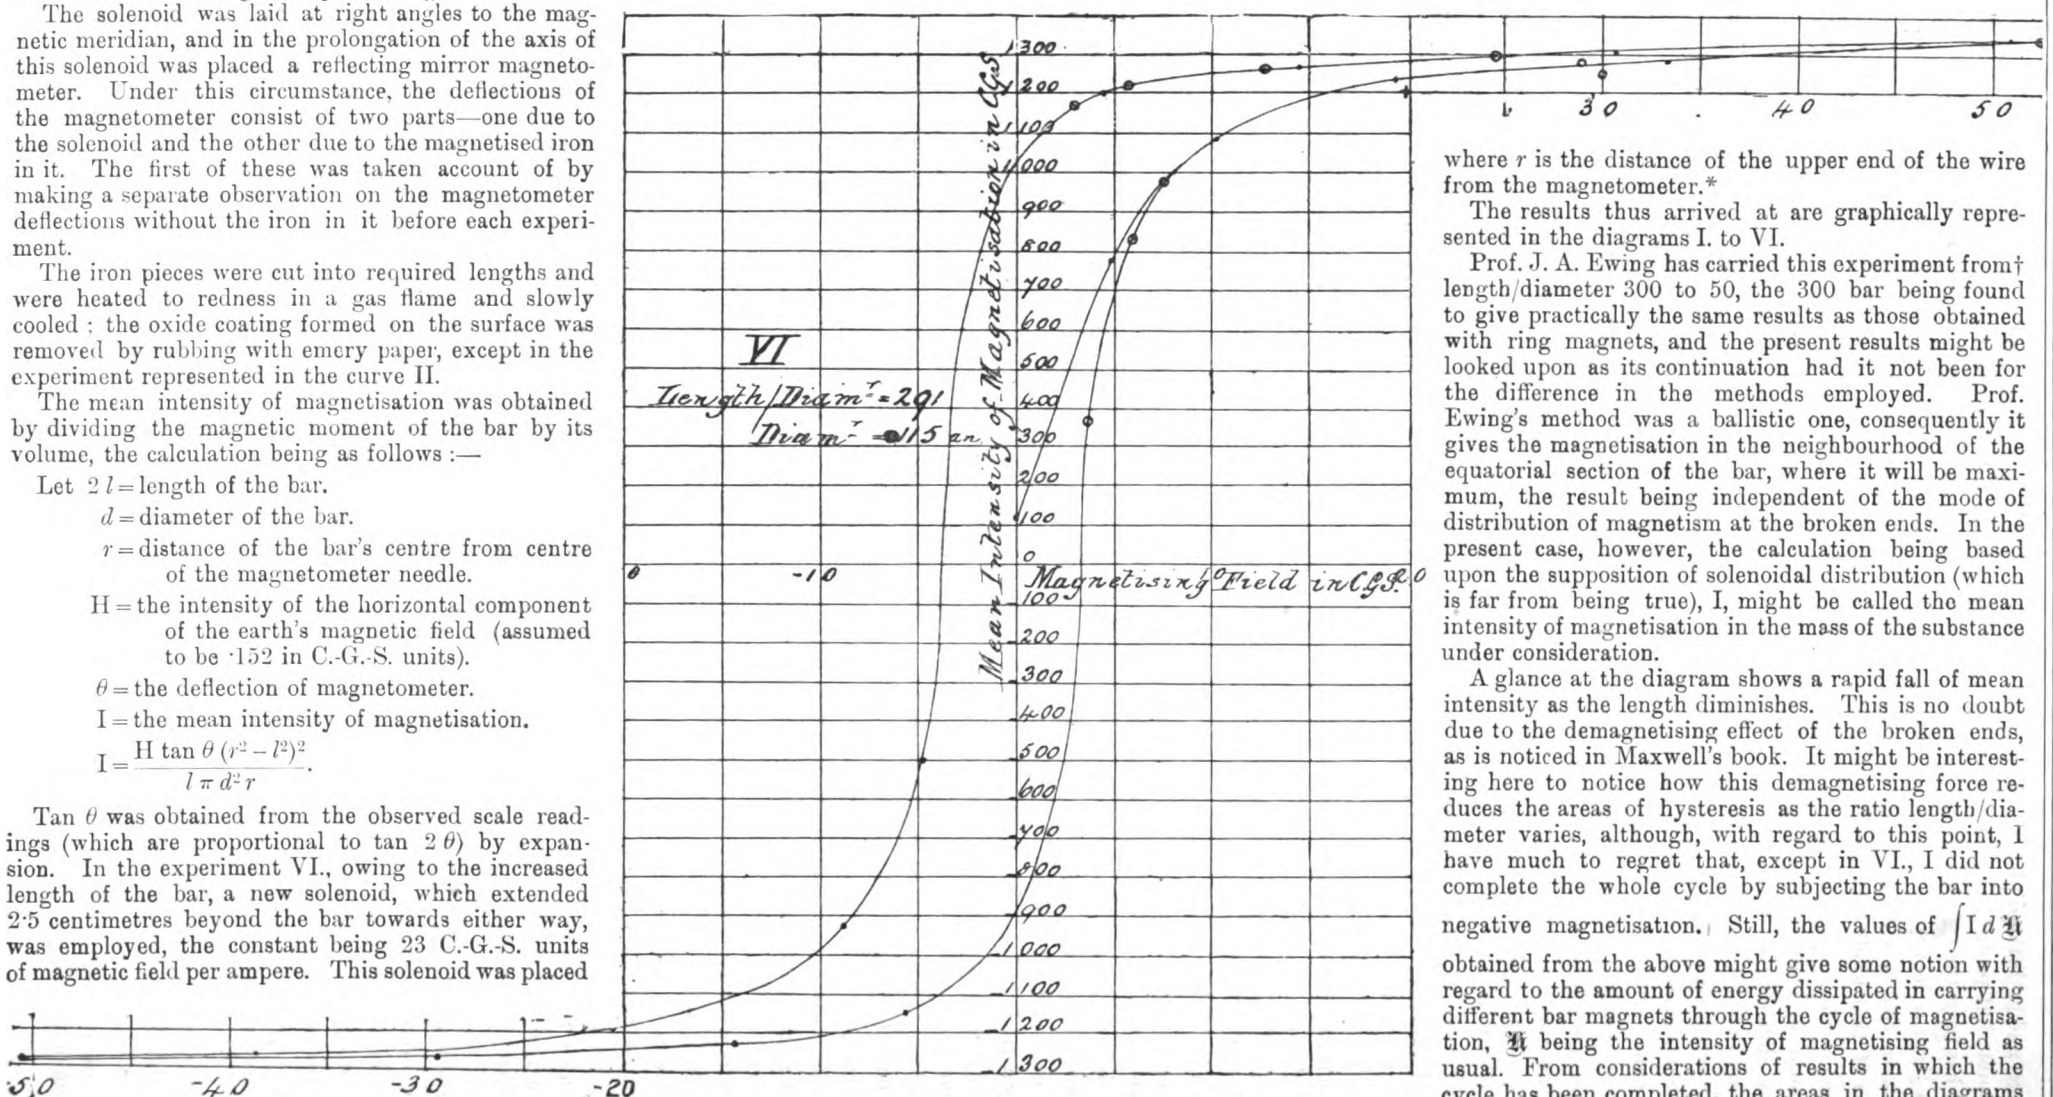
θ = the deflection of magnetometer.

I = the mean intensity of magnetisation.

$$I = \frac{H \tan \theta (r^2 - l^2)^2}{l \pi d^2 r}.$$

Tan θ was obtained from the observed scale readings (which are proportional to tan 2θ) by expansion. In the experiment VI., owing to the increased length of the bar, a new solenoid, which extended 2·5 centimetres beyond the bar towards either way, was employed, the constant being 23 C.-G.-S. units of magnetic field per ampere. This solenoid was placed vertically due west of the magnetometer, the upper end of the iron wire being slightly above the level of the magnetometer. The calculation for the mean intensity in this case was

$$I = \frac{H \tan \theta \, r^2}{\frac{\pi}{4} d^2 \left(1 - \frac{r^3}{(r^2 + l^2)^{\frac{3}{2}}}\right)},$$



where r is the distance of the upper end of the wire from the magnetometer.*

The results thus arrived at are graphically represented in the diagrams I. to VI.

Prof. J. A. Ewing has carried this experiment from† length/diameter 300 to 50, the 300 bar being found to give practically the same results as those obtained with ring magnets, and the present results might be looked upon as its continuation had it not been for the difference in the methods employed. Prof. Ewing's method was a ballistic one, consequently it gives the magnetisation in the neighbourhood of the equatorial section of the bar, where it will be maximum, the result being independent of the mode of distribution of magnetism at the broken ends. In the present case, however, the calculation being based upon the supposition of solenoidal distribution (which is far from being true), I, might be called the mean intensity of magnetisation in the mass of the substance under consideration.

A glance at the diagram shows a rapid fall of mean intensity as the length diminishes. This is no doubt due to the demagnetising effect of the broken ends, as is noticed in Maxwell's book. It might be interesting here to notice how this demagnetising force reduces the areas of hysteresis as the ratio length/diameter varies, although, with regard to this point, I have much to regret that, except in VI., I did not complete the whole cycle by subjecting the bar into negative magnetisation. Still, the values of $\int I \, d\mathfrak{H}$ obtained from the above might give some notion with regard to the amount of energy dissipated in carrying different bar magnets through the cycle of magnetisation, $\mathfrak{H}$ being the intensity of magnetising field as usual. From considerations of results in which the cycle has been completed, the areas in the diagrams I. to VI. will be seen to be something like one-third of the whole area. The areas computed from these diagrams are given in the table and in Fig. VII.

* The resistance of the solenoid was 406·5 ohms at 50° F., and was assumed to be constant throughout the experiments; as the temperature of the room was never far from that temperature, and the strength of current was never greater than $\frac{1}{10}$ ampere at the most, the error arising from the variation of resistance due to that of temperature could not have been anything serious.

* This experiment VI. is not strictly comparable with the other five, not only on account of the difference in the methods employed, but also on account of the difference in the specimen of iron used.

† *Phil. Trans.*, Part II. 1885.

The last column of the table gives the probable rise of temperature of the iron, due to one complete reversal of magnetisation, supposing the whole energy dissipated is used in heating the iron.

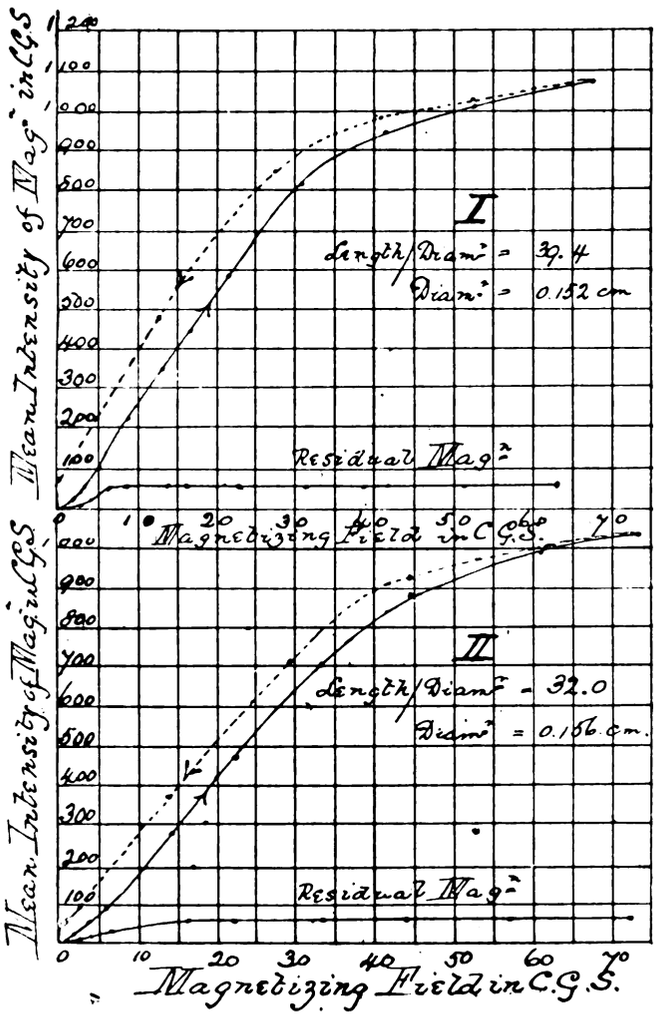
In connection with the present results I beg to mention some results of mine which were obtained in 1883 in Japan.

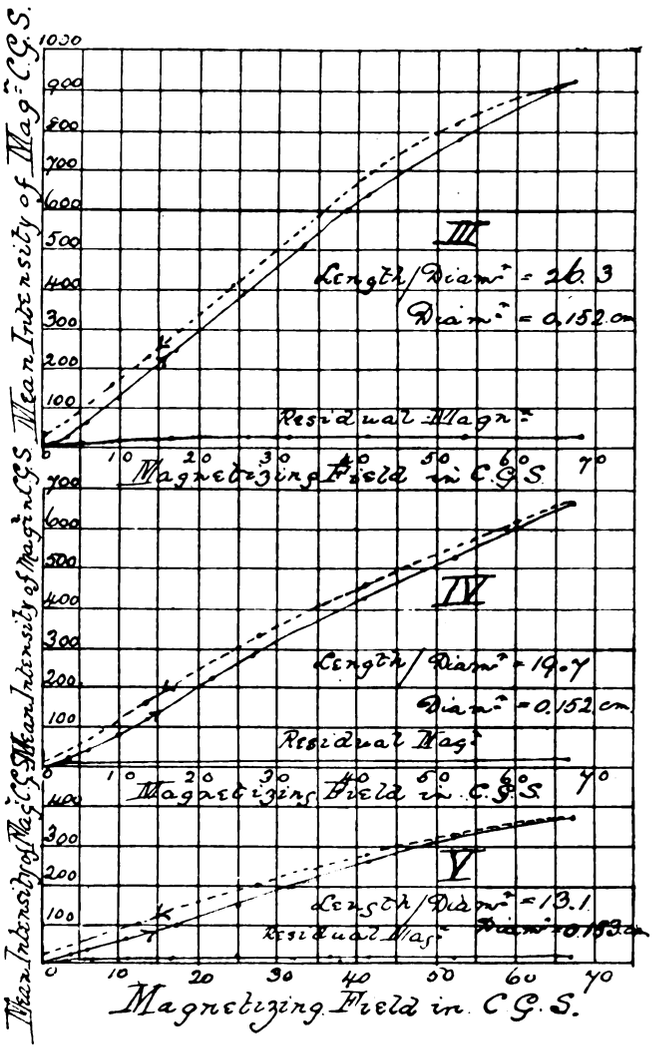


The experiment was carried out in the Physical Laboratory of the then Tokyo Daigaku. It was very similar to the present one in its nature; conducted, however, in a different way so far as the magnetising field was kept constant while the mass of iron magnetised was increased by steps.

The arrangement of the magnetising solenoid and the magnetometer was the same as in the present experiment. The dimensions of the solenoid were:—Length, 9·25 cm.; external diameter, 2 cm.; internal diameter, ·86 cm.; number of turns of wire per centimetre, 132·6. The length of soft iron wire was 9 cm., and its diameter 1 mm.

In the first experiment the magnetising field of 46 in C.-G.-S. units was kept constant, and the soft iron wires were put into the solenoid one by one. At first these wires were sucked into the solenoid very vigorously, and the magnetometer readings were very nearly proportional to the number of wires in the solenoid. But when the number of wires was about 10, some of the wires began to throw themselves out of the solenoid, and even when pushed in again with the finger would jump out upon its removal. They were, however, capable of being kept in their normal position by a careful adjustment. Obviously every one of the wires is under two forces—one, that due to the solenoid, tending to keep the wire in; and the other, that due to the magnetism of its fellow wires, tending to push it off; consequently, when the latter becomes greater than the former the wires will be in unstable state (such a state might be imagined to be taking place between parts of a solid bar). It is interesting to see that after this event the magnetometer readings fall rapidly short of being proportional to the number of wires in the solenoid; and after the number was increased to about 25 the magnetometer readings remained practically constant, even if the wires were increased to as much as 41.*

The diagrams represent the results of this experiment. Curve VIII. shows the increase of magnetic moment due to



the increase of iron wires, and curve IX. the mean intensity of magnetisation in the whole substance of the iron.

Similar experiments were made for the constant magnetising fields, 50, 11, 5·5, 2·75 C.-G.-S. units. These are drawn in arbitrary scales, for the want of the original notes at the present. By comparing these, however, with the curves for field = 46, one can form a fair estimate of what they would be in C.-G.-S. units. It thus appears that we may roughy obtain the moments in C.-G.-S. by multiplying the number in the y – ordinate of curve X. by 6·7; and the mean intensity of magnetisation by multiplying the numbers in y – ordinate of curve XI. by 10.

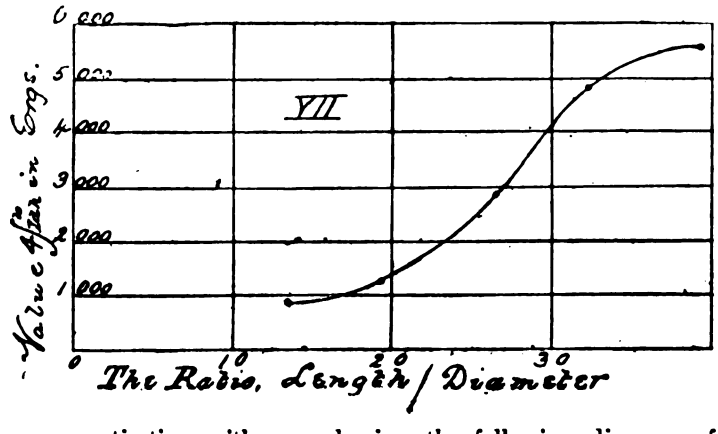
From the curves I., II., III., IV., and V., I construct the following curves of mean intensity of magnetisation as a func-

* After the number of wires was increased to 38 the wires did not jump out even if slightly disturbed from the normal position. But I could not tell whether this was a magnetic effect, or simply a mechanical one due to the increase of friction.

Digitized by Google

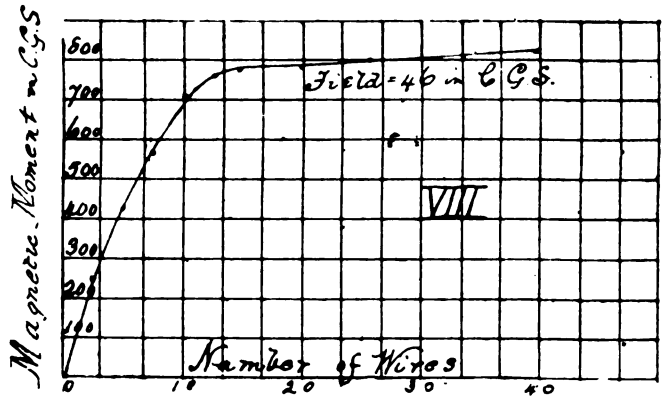
tion of the ratio length/diameter of the bar for different magnetising fields. From the curves we see that the mean intensity of magnetisation falls very rapidly as the ratio length/diameter diminishes. As this ratio increases the curves will bend towards the x-axis, and will ultimately be parallel to it as long as the magnetisation of ring magnets is finite.

As a means of comparison I construct from the curves of

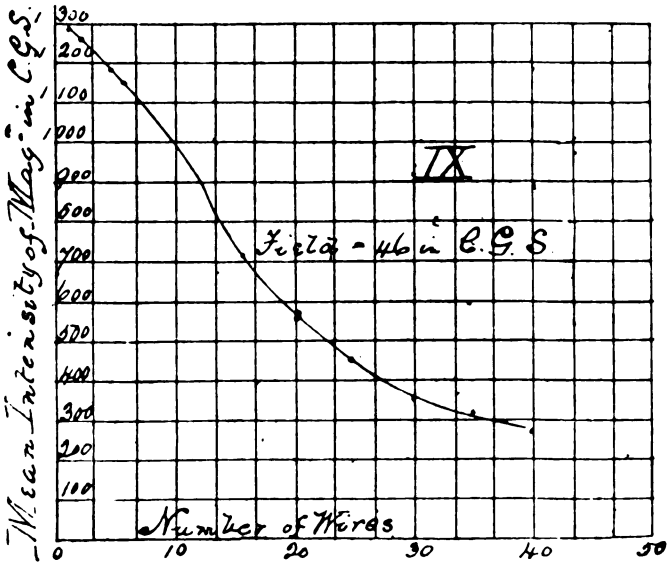


magnetisation with several wires the following diagram of mean intensity of magnetisation as function of

$$\text{length}\Big/\sqrt{\text{sectional area}}\ \frac{4}{\pi};$$

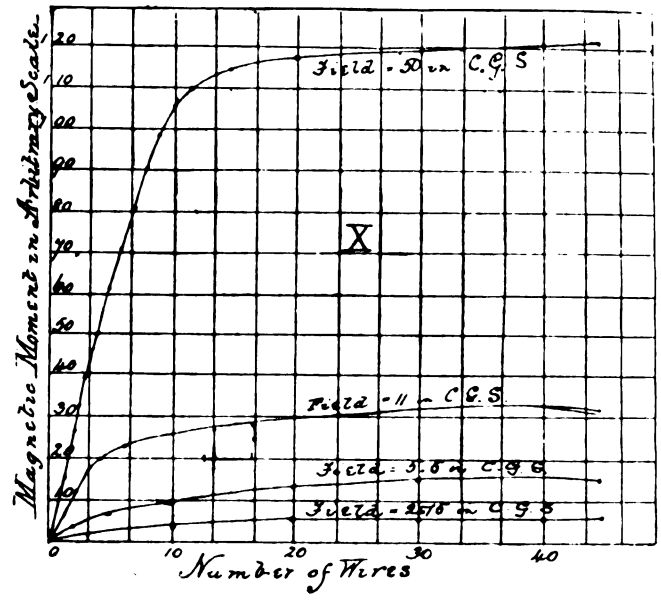


that is, what the ratio length/diameter would become had those wires been moulded into a single cylinder at each step

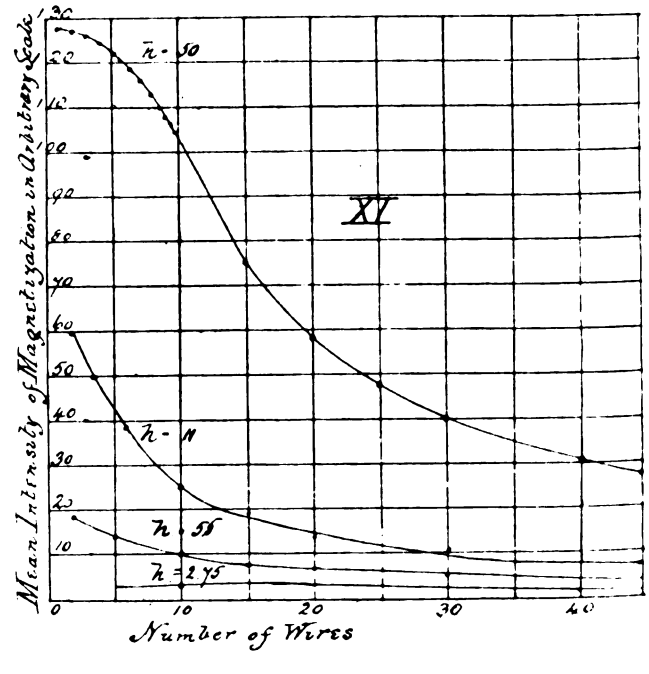


instead of being separate wires side by side, as in the actual case. By comparing this with the curve XII. we see that they both show that for a very flat plate the mean intensity will be extremely small; also for the case of separate wires the bend of the curve occurs earlier, *i.e.*, for less value of length/diameter

From the way in which the curves VIII. and X. tend to be asymptotic, it would seem that the induced magnetic moment in a soft iron bar is not increased by increasing its thickness beyond a certain proportion of its length. These curves, however, are in reality obtained from experiments made on bundles of wires of given length, with various thicknesses of the bundle. Thus there may be material difference between this case and



the case in which an actual solid bar of given length is made to vary in its thickness. We have no experiment of this latter case, but if we assume that when similar bars of the same magnetic substance are placed in uniform magnetic fields of the same intensity, both of them will give the same amount of the mean intensity of magnetisation; or, in other words, if we suppose the intensity of magnetisation in uniform magnetic field to be independent of the absolute sizes of the bars, and merely dependent upon the shape and nature of the magnetic substance, then we can trace the increase of magnetic moment

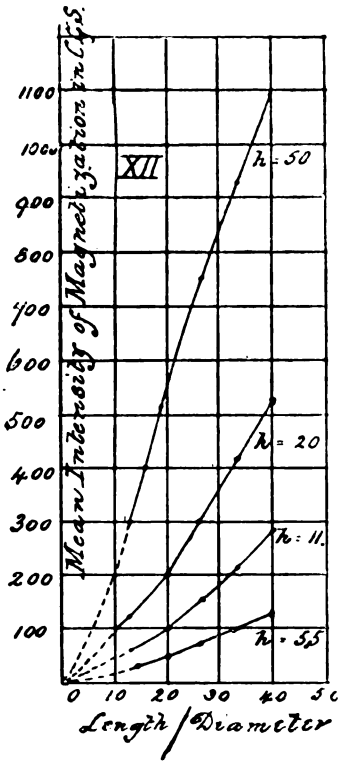


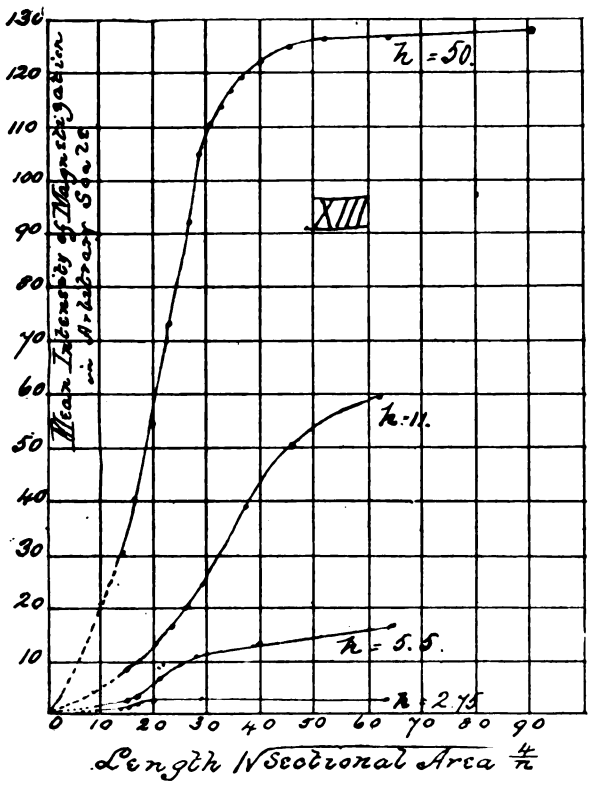
due to the increase of section in a bar of given length, from the data we have in the curves I. to V. To do this we have to reduce the bars to some common length, and find their several diameters, which will make their shapes similar to the original ones. Taking this common length to be be 1 cm., and finding the diameters and volumes which each of the bars

Digitized by Google

would come to have, we obtain, from the table given on page 825 :—

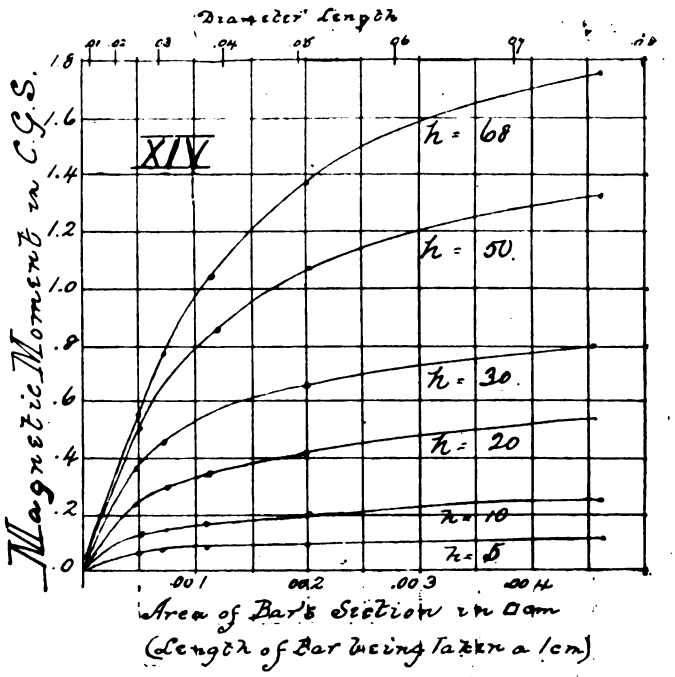
Reference number.	Reduced diameters.	Reduced volumes.
I.	·0253 cm.	·00051 cu. cm.
II.	·0312 ,,	·00077 ,,
III.	·0380 ,,	·00114 ,,
IV.	·0507 ,,	·00203 ,,
V.	·0765 ,,	·00457 ,,





To find, now, the induced magnetic moment due to any field in any of the reduced bars, we have to take the mean intensity of magnetisation corresponding to that field, from the particular curve which belongs to the original bar, and multiply that intensity by the reduced volume. The following diagram (XIV.) shows the increase of magnetic moment due to the increase of the section of soft iron bars deduced in this way. On the top of the diagram numbers indicating the ratio diameter/length is placed for convenience of reference. The moment here being given in C.-G.-S. units for bars of one centimetre long, we can find the moment of induced magnetism due to any field for a soft iron bar of any given dimensions, supposing magnetisation to be independent of the absolute size of the bar. For this purpose we have to take the moment corresponding to the particular ratio diameter/length of the given bar, and the particular field required, and multiply that moment by the cube of the length—that is to say, within the limits to which the experiments extend.

The curves are similar in character to those obtained with bundles of wires, only they are not so decidedly asymptotic as the latter. We cannot, however, draw a definite conclusion as



to the real difference between the two cases, on account of the difference of the specimens of the wires employed. From both sets of these experiments we see that, after the diameter is about $\frac{1}{15}$th of the length of the bar, there is not much increase of moment due to the increase of the thickness of the bar; that is, the induced magnetic moment will be practically independent of the mass of iron.

This statement, paradoxical as it sounds, is not much to be wondered at, if we consider that when the bar becomes very thick the substance of the bar itself will be forming a kind of internal armature to the free ends of the bar. Thus, it seems likely, where thick bar magnets are used in practice, that there may be found waste of material of iron, although in many cases different shapes and the presence of external armatures will modify the condition from the case of the experiments described.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *October 20th*, 1888.

Some interesting changes have been announced this week in the relationships between the Westinghouse and Sawyer-Man interests. The new agreement which has been entered into between the Westinghouse Company and the Consolidated Electric Light Compeny of this clty gives to the former, it appears, absolute control of the latter's patents and property. The Consolidated Company and the Sawyer-Man Company have been carrying on a big lamp factory at Twenty-third

Digitized by Google

Street in this city, and the Westinghouse people have had another factory at Pittsburg, manufacturing lamps of their own on Sawyer-Man patents. It is stated that under the new arrangement the Westinghouse Company is to enjoy control of everything, and in return the Consolidated Company is to receive $150,000 per annum every year during the continuance of the contract. This sum, it is reported, will amount to a guaranteed dividend of 4 per cent. per annum to start with, and as soon as certain matters and claims are adjusted it will represent 6 per cent, and in addition thereto the Westinghouse Company agrees to pay one cent. for every Sawyer-Man lamp sold. There are, it is understood, about 150 stockholders in the Consolidated Company to whom the enjoyment of regular dividends will be at once an unfamiliar and welcome sensation, as that company has been at considerable expense in carrying on its business and fighting for its patents. The Westinghouse Company further contracts to subscribe for unissued stock of the Consolidated Company amounting to a par value of $125,000, the Consolidated Company's nominal capital being $250,000.

It appears from this arrangement that the old company will have little to do, their business being taken over completely for incorporation into the Westinghouse system; but a further announcement is made that the Sawyer-Man Company will be the exclusive agent for apparatus of the Thomson-Houston Company under certain conditions, and for certain territory. The wording of the announcement is not so clear as it might be, but it is gathered that a very large portion of the incandescent work of the Thomson-Houston Company, whether for isolated or central plants, and whether with direct or alternating current, will be attended to by the Sawyer-Man Company. There is considerable discussion in electrical circles this week over the terms of the agreement, and as time goes on the situation will be clearer, and we shall know more definitely as to the relations to exist hereafter between the Westinghouse and Thomson-Houston Companies, which are thus, apparently, brought closer together by the absorption of the whole Sawyer-Man property by the former.

Some idea of the magnitude of the work carried on in central stations in this country may be formed from the description of a big electric light switch-board appearing in the electrical journals this week. The board in question has been built by Mr. Foree-Bain, of Chicago, for New Orleans, for the Fort Wayne Jenney Station there. The board is 12ft. high and 21ft. long, and has a capacity for 75 dynamos and 30 circuits. Every precaution seems to have been taken to ensure the safety of those handling the circuits, and to provide against fire. No metal of any kind is to be seen on the front of the board, and the terminals are attached at the back, being enclosed in a test proof case. The terminals are made in the shape of a spring jack, and are plugged into by harpoon plugs, through rubber bushed holes in the front of the board. Each spring jack is provided with openings for two plugs, the object being to allow the insertion of a temporary plug in the process of switching, so that a dynamo or circuit may be added to or taken from any other without opening the circuit. The dynamo wires enter the board at the top and the circuit wires from the bottom, being firmly attached to their jacks by means of half inch bolts with checknuts and washers. An ammeter is provided for each circuit, and a lightning arrester with fusible blow-outs is placed on each side of every circuit. The absolute condition of every line can be read at a glance by the superintendent or electrician. This board, although so large, is probably not the biggest in this country, as it is equalled by other electric light boards to be found in such cities as New York and Philadelphia, but it appears to be a good example of advances made in this line of work. The New Orleans Company, to whom the board has been sent, have a valuable franchise for the lighting of the whole city, which takes, I believe, in the neighbourhood of 2,000 arc lights.

From time to time I have made allusion to the work which has been done by the Lighthouse Board to light up Gedney's Channel, at the entrance of New York Harbour. Some time ago it occurred to Lieut Com. Mackenzie that a buoy lighted by electricity might be of great service, and one was placed near the lighthouse depot at Tompkinsville, S.I., experimentally. Good results were obtained, and it was determined to light up Gedney's Channel with electricity, the lamps being connected with the shore by cable. One of the notable advantages in such a system recommending it to the authorities was that if a gas buoy was used and were sent adrift by collision with vessels or with ice, it would still keep alight and prove more dangerous than useful. Mr. Mackenzie and Lieut. J. Millis proceeded, therefore, to equip the channel with six spar buoys, each connected with the station and the shore through special conductors and cables, the water serving as the return. These spar buoys are of juniper, 50ft. long and about 1½ft. in diameter. Each of them is attached by heavy iron rings to sinkers at the bottom of the channel, so that they may swing freely with the motion of the sea. The cables from the shore run out in two groups of three, and then each individual conductor is carried up each spar buoy in a slot, which is covered up after the insertion of the wire, and at the top of the buoy is the lamp. The light itself is a special Edison lamp, giving 100 candle-power, protected by very thick plate glass, which in turn is shielded by a skeleton jacket of metal, likely to afford protection against ice or anything of that kind. The lights are placed three on each side of the channel, and are red and white. The buoys float in 35ft. to 45ft. of water; they thus provide means for the navigation of the channel in the darkest night and stormiest weather. The light will, of course, be under control from the station on shore, where there is a very compact and neat plant in duplicate, so as to provide against every possible emergency of mishap or breakdown. The Bishop gutta-percha cables have been furnished to special specifications, to run out from the shore in two lengths of 15,000ft. or 16,000ft. of three-conductor cable, and in six unequal lengths of single-conductor cable. The total cost of the plant is put at about £4,000, and it is believed by electricians that the plan devised by the two officers named will prove very successful, being far more effective than any other system that has been mentioned. It is amusing to note, however, that this improvement, like all others such lately introduced in New York waters, has met with opposition. One complaint was made in the daily papers, that as each of the buoys will weigh 125lb., it would be dangerous for any vessel running in before a gale to dash against one of them. This letter, apparently from one who ought to be experienced, altogether ignores the fact that the buoys will yield to the slightest pressure, being constructed with that end in view, and takes it for granted that the captain of the vessel or officers and men on duty would be so blind as to be unable to see these six lights of 100 candle-power, until they had actually rubbed the nose of the ship against them. As has been pointed out by one of the electrical papers here, it was this sort of criticism that was levelled against the big electric light torch at Hellgate, as well as against the electric lights in the torch of the statue of Liberty, and those which have been used so long and with such good results in illuminating the big Brooklyn Bridge. The lights on the bridge are at the present time the object of special attack, though they certainly will not be removed, as it would be easy to screen them, so as to prevent their light shining upon the waters; but the joke of the matter is that the pilots of the city's fire boats of their own volition have just sent in a letter to the management of the bridge stating that they experience no inconvenience whatever from the electric lights on the bridge.

The station equipped by the Julien Electric Traction Company for the Fourth Avenue Tramway in this city presents many points of interest. The plant is intended to have a capacity for keeping ten new cars in regular operation, and many methods have been adopted for the convenient and expeditious handling of the batteries, which are the main consideration in a plant of this character. The generating plant comprises two steel boilers; two straight-line engines, each developing 70 horse-power; and two United States dynamos, each of 190 amperes, at 300 volts, or 57,000 watts each. The E.M.F. of the dynamos, however, is variable from 250 to 300 volts, in order to adjust itself to the varying condition of the batteries during the time of charging. The batteries are charged in series, so as to obtain perfect uniformity throughout the whole. For the purposes of charging, the cells, as they are taken from

Digitized by Google

the car which has been doing its duty, are placed upon low trucks, which are then wheeled alongside each other, and are connected in series to the charging circuit. There is a very ingenious economy of space in the station by arranging the dynamos on a solid platform immediately over the engine, each belted to separate counter-shafts, from which each dynamo is driven directly. A small repair shop is also neatly worked in, suspended on a platform at one side of the station, out of the way; and an overhead railway leading to it allows of any part of the equipment to be taken to the tools without any trouble. The generating plant is also made to drive a 6 horse-power Baxter motor, which performs a variety of duties in a very effective way. Distilled water for the batteries is obtained by drawing steam from the boilers and forcing it through lead coils placed in the feed water tank, where it is condensed and drawn off; thus waste of heat is prevented, as the heat drawn from the water in the course of condensation serves to warm up the feed water on its way to the boiler. Each car is provided with two sets of batteries, each having a capacity of 125 ampere-hours. With these the car makes three round trips, or a distance of 33 miles, though much longer runs could be made if it were desired on the same battery capacity. One of the troubles in charging storage batteries has been skilfully overcome. As is well known, it has always been more or less troublesome to connect up the cells, and in the present instance, instead of soldering to the plates the long leaden strips which are generally used, and are bent over to form the connection, a copper cartridge shell, filled with mercury, is placed at the centre of the strips, connecting the positive and negative plates of the contiguous cells. This copper shell is housed in a short length of rubber tubing, and embraces also a stout insulated copper connecting wire. The whole point is covered with insulating paint. By these arrangements all metallic surfaces are enclosed, and the connecting wire is so firmly gripped that it cannot slip out in any way, although whenever it is desired to make any change or combination in a group, a blow of the hand will remove the connecting wire by raising it out of the metallic cups. The device works freely, rendering it easy at any time to replace one cell or set of cells by another. The connection is a good one, avoiding the introduction of internal resistance into the battery circuits, and at the same time is such as to be unaffected by the acids, which too often are very troublesome in this respect. This station, which has just gone into operation, is of considerable interest from the fact that it is the first of the kind in this country, and that many of the problems presented have been worked out in an original manner.

It is amusing sometimes to see how much of politics creeps into the affairs of our electric light companies and enterprises. It is no fault of the companies, who simply have to take things as they find them, and make the best of it. Your readers will already have formed some idea of the manner in which the Board of Electrical Control in this city has been connected more or less from its very start with the political fortunes and ambitions of various men, and perhaps they will not be surprised to learn that over in Brooklyn a not dissimilar state of affairs exists. For a long time past the local Edison Company has been working hard to get a franchise enabling it to lay its wires and begin business. The aldermen have stood in the way, however, and have been openly accused of working in the interests of the Citizens' Company, which does all the electric lighting there, and has a good grip on the business generally. To offset this local opposition, the Edison Company carried its case to the State Legislature, and secured special legislation. This in turn was vetoed by the Governor, and thus the matter was referred back to the Board of Aldermen. The matter came up for consideration again this week, when the Mayor of the city urged the subject on the attention of the aldermen, and then one of the men who had been strongest in opposition came forward, at the Governor's instigation, it is alleged, with a resolution, which was unanimously adopted, to the effect that the Edison Company should be given permission to lay its conduits and wires if it began the work in ten days. The company will now go ahead. I judge from the things which we see in the English papers occasionally that the progress of the electric light is beset by like difficulties in England.

CORRESPONDENCE.

LIGHTNING.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The interesting phenomenon observed by Mr. Boys and by Mr. W. P. Adams, and recorded by them in your two last issues, suggests a case of discharge by overflow. I mean that the upper layers of the atmosphere—the region of virtual high conductivity (really weak dielectric strength)—may have discharged down to the cloud until that overflowed to the earth. Or it might be that the flash from cloud to earth so lowered the potential of the cloud as to permit a discharge or set of discharges from the high-potential regions above. I should thus regard it merely as a case of a couple of sparking intervals in series.

Many things seem to suggest that it is the upper layers of atmosphere that are primarily charged, and that clouds are either conducting protuberances or else stepping stones; probably sometimes one, sometimes the other.

Mr. Boys would, perhaps, say whether there was anything in his observation irreconcileable with this simple idea.

I may take this opportunity of remarking how much work can be done at meteorological stations and observatories in the matter of accurately observing and recording lightning; photographic records, obtained by proper appliances for distinguishing multiple from successive flashes, being, of course, superior to all others.

An experimental lightning conductor on a flagstaff near every meteorological observatory would also be a most desirable addition. It need not be associated with danger; a system of fuses or cut-outs, or an east and west steel bar, might be used to record the passage of a flash, and the rod need not be examined until after the cessation of violent disturbances. By having the conductor of different thickness at different parts one could learn what size is really likely to be melted. One could also arrange so as to gain information about side-flashes.
—Yours, &c., OLIVER J. LODGE.

ELECTRICAL THEORY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I have prevailed on Prof. Poynting to let me send you the enclosed two letters, wherein he continues the discussion of electrical theory begun in Section A at Bath. It must be understood that the letters are merely hasty epistles, not intended for publicity; but Prof. Poynting's ideas are so original and weighty that one is glad to extract from him, when possible, a casual contribution to a discussion, as well as one of his sledge-hammer communications to the Royal Society. I hope that this may be the means of extracting a reply or a criticism more competent than anything of mine would be.—Yours, &c., OLIVER J. LODGE.

"Dear Lodge: I thank you very much for the copy of your exceedingly interesting account of Electrical A. Perhaps my gratitude would be best shown by silence, but I am tempted to show my appreciation by asking you to help me with some difficulties.

"My first difficuly is as to the interpretation of Hertz. You say—though, I think, Fitzgerald is responsible for the statement—that ether is a demonstrated fact. I do not see how Hertz adds to our certainty. Is not our belief in ether due to the fact that light takes time to travel in interplanetary spaces, where we cannot put enough matter for it to travel by, so that we have to imagine something else for it to use. The fact that the velocity of light is nearly the same in vacuo and in gases, and not widely different in denser substances, of course supports the view that on the earth it also uses ether. Hertz shows that there is an 'interference' in electro-magnetic disturbance which we can only (at least, with our present knowledge) put down to wave motion travelling with a definite velocity which he finds equal to that of light. Hence these disturbances probably make use of the same ether. Does this prove its existence any more? I should expect a sceptic to ask why may not electro-magnetic disturbance make use of air, since

Digitized by Google

Hertz carried out his experiments in air. I could only reply to the sceptic that he was a very disagreeable person.

"Secondly, Thomson's 'Simple Hypothesis' Paper* appears to be a very serious attack on Maxwell's theory; in fact, on reading it over carefully, I can only come to the conclusion that it would lop off not only Maxwell's excrescences but his whole theory. According to the concluding sentence of § 4, ('each component of electric current at any point is equal to the electric conductivity multiplied into the sum of the corresponding component of electrostatic force and the rate of decrease per unit of time of the corresponding component of velocity of liquid in our primary') the current $u = C\left(-\frac{d\Psi}{dx} - \frac{du_1}{dt}\right)$; which = 0 if C the conductivity = 0, so that Maxwell's f (his 'displacement' current) goes altogether. The x component of Maxwell's E.M.F. will contain a term $-\frac{\mu}{4\pi}\frac{K}{}\iiint\frac{d^2P}{dt^2}dx\,dy\,dz$, since Maxwell's u = Thomson's $u + \frac{K}{4\pi}\frac{dP}{dt}$, where P = E.M.F. along x. This has no representative in Thomson. Thus with a homogeneous but leaky condenser with no connecting wire, we have, according to Maxwell, total current = 0, for leak is made up for by yield of displacement;

$$\therefore\ P = -\frac{dV}{dx},$$

where V is potential due to electrification in plates.

"According to Thomson, u is to be taken as rate of leak, and is positive,

$$\therefore\ P = -\iiint\frac{du}{dt}\frac{}{r}dx\,dy\,dz - \frac{dV}{dx}.$$

"According to Maxwell there is no magnetic effect, since total current = 0.

"According to Thomson—using his notation—x component of magnetic force $u_2 = \frac{dw_1}{dy} - \frac{dv_1}{dz} = -4\pi\nabla^{-2}\left(\frac{dw}{dy} - \frac{dv}{dz}\right)$ from Thomson's equation (7), *i.e.*, if ∇^{-2} and $\frac{d}{dy}$, &c., are transposable.

"But $u = KP$, $v = KQ$, $w = KR$,

$$\therefore\ u_2 = -4\pi\nabla^{-2}\left(\frac{dR}{dy} - \frac{dQ}{dz}\right)$$

$$= -4\pi\nabla^{-2}\left\{\frac{d}{dy}\iiint\frac{dw}{dt}\frac{}{r}dx\,dy\,dz - \frac{d}{dz}\iiint\frac{dv}{dt}\frac{}{r}dx\,dy\,dz\right\}$$

the term in V disappearing. This is awful; but I see no reason to suppose that it vanishes. If it does not vanish, then the existence of magnetic effect would decide against Maxwell.

"Thirdly, I note on p. 10 of your sketch that Rowland and Fitzgerald consider that electrostatic potential is not propagated by end thrust, and you remark that it is the magnetic potential which travels, generating the electrostatic potential as it goes along. I think I remember that you have expressed the view that potential energy must undergo a kind of conversion, and that unless it be born again as kinetic energy it can in no wise go forward on its journey.† With strained solid waves it looks as if it were so, though it is, I think, possible to regard both energies as going forward linked together, yet retaining their individuality. And if potential energy is, after all, kinetic, but of another kind, it is conceivable that they should keep their separate identities. But with electrostatic and electromagnetic strains, which is potential and which kinetic? I know it is usual to call the magnetic kinetic; but if we had started with permanent magnets, and travelled by means of magneto-electric machines to our present knowledge of electric phenomena, I expect we should now be discussing the propagation of magnetostatic potential and magnetoelectric potential, and we should, perhaps, consider the former generated by the latter. This is really the view I take, or, rather, I think both are true. It seems to me that the sideway propagation of electric induction is accompanied by (let us drop 'generated by') magnetic induction, and equally the sideway propagation of magnetic induction is accompanied by electric induction. The two go together when a disturbance is propagated. In a steady state they do not, *i.e*, if we can separate them from each other; at least I do not see how otherwise to interpret the results I have obtained (*see* pp. 284-5 of Paper referred to below). This brings us back to the old point whereon we have differed before. It would be better to give in like the unjust judge for the sake of peace and quietness, and to ward off any more such letters as this.

"I have been going again through a Paper 'On Connection between Electric Current and Electric and Magnetic Induction' (*Phil. Trans.*, II., 1885), in which I tried to work out the equations to the magnetic field on the supposition of this sideway propagation. Ψ ceases to be troublesome, and both electric and magnetic inductions are propagated at the same rate; indeed, they are by Maxwell's equations, though I do not think he ever definitely worked this out. I cannot see any point, in the assumption to begin with, or in the subsequent reasoning, where I have gone astray. If you have any time to spare, would you look at the Paper, pp. 277-281, and 294-300? The rest is not essential, though on 301 I show that Maxwell, pure and simple, gives the same results.—Yours, &c.,

"J. H. POYNTING.

"Mason College, Birmingham, October 12th, 1888."

The following extract from my note in answer may be inserted, in order to make the next letter clear:—

"As regards the proof of the ether, I confess I did not quite see FitzGerald's point as to why Hertz's experiments rendered the existence of ether any more certain; but knowing that I had felt it thoroughly established long ago, I supposed I was not a good judge. Of course he must appreciate all the stock arguments about air, &c., not transmitting transverse disturbances, and about neither it nor glass transmitting anything at the speed 3×10^{10}, &c. And Hertz's experiments only seemed to me to *prove* that electro-magnetic waves existed and travelled at the same speed, thus practically proving that light is electro-magnetic waves, and establishing Maxwell's theory.

"This seems to me far more important than proving once more the existence of ether. At the same time I feel sure FitzGerald has some point. It may be only that an electro-magnetic ether has been proved, and thus the action-at-a-distance-Germans confounded. He spoke as if he meant more than this. Perhaps I have to that extent misrepresented him in my 'sketch.' How does it strike you?

"With regard to Thomson's Paper, it is certainly very anti-Maxwellian, but I believe it only represents a transition stage through which he was somewhat rapidly passing, and through which he may now have almost passed. I certainly do not know now where he is.

"Is it not that finding that displacement currents have no magnetic effect, therefore he ignores them? But then have they no magnetic effect? In some cases they cannot have, for electrostatic displacement is of the nature of an 'expansion,' as Clifford called it; there is no 'spin' about it.

"I cannot find Thomson's Paper this minute to refer to, but I have it somewhere. I will look it up again in the light of your remarks."

After referring to my reply, Prof. Poynting writes, in a second letter:—

"About the ether, I should entirely accept your interpretation of Hertz. I should think, as you say, that Fitzgerald was aiming at believers in action at a distance, and probably he knew where to have them in showing that there is an electro-magnetic medium.

"You say, with regard to Thomson's Paper, 'Is it not that, finding displacement currents have no magnetic effect, therefore he ignores them? But, then, have they no magnetic effect? In some cases they cannot have.'

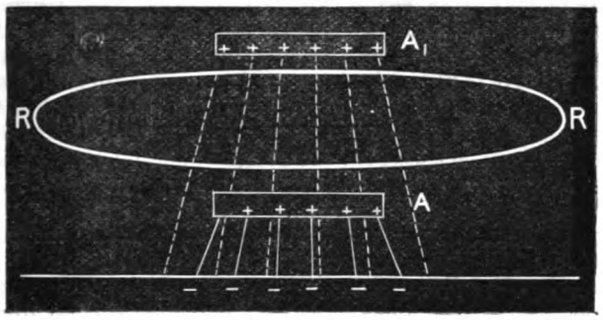
"It is just here that I find the supposition of transverse propagation of electric strain accompanied by magnetic induction so clarifying to my ideas. If the magnetic effect is the whirling of the machinery which is sending electric strain energy onwards, the machinery cannot know whether the energy is going to be dissipated in a Prony-brake-like wire, or whether it is going to increase the electric strain, so pro-

* Reprinted in *The Electrician*, Sept. 14, p. 605.

† *Phil. Mag.*, October, 1879, p. 281, § 11; June, 1881, p. 534; and June, 1885, p. 486. I do not regard this as a "view," however, but as a proved truth.—O. J. L.

Digitized by Google

ducing a 'displacement current.' To use an illustration, I regard a re-entrant line of magnetic force as a kind of ring of Custom House officers registering the amount of electric strain sent in per second (they are porters as well), and they do not know what will happen to the energy. They will register just the same whether the imports are for immediate consumption or go to add to stock. Of course, they will take no account of shooting stars, balloons, or destruction of stock already within the ring; which, being interpreted, is that the line integral of the magnetic force ($4\pi i$, isn't it?) will not be affected by lines of electric force other than those coming in or going out through the boundary. For instance, if A moves through the ring R R to A′ (see figure) conveying a charge, hardly any lines of electric force will cut the ring R R, yet the number of lines through it is increased. And it will not be affected by induction which dissipates itself *in situ* as in a leaky Leyden jar, where the energy changes to heat without moving. I do not know of any other case, but,



being utterly ignorant of pyro-electricity, I imagine it might supply a case of establishment of electric induction without motion of the energy and without magnetic effect.

"Yours, &c., J. H. POYNTING."

ELECTRO-CALORIMETRY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: It is curious that Mr. Evershed, in his criticism (*The Electrician*, October 19th, p. 773) of our method of determining specific heats should have selected as the only point of attack precisely that portion of the arrangement which has been employed by every experimenter who has used coils in series. His remarks must therefore be understood as applying to the work of Joule, Pfaundler, and others, as well as to our own experiments. Mr. Evershed's contention that there is a condition of unstable electrical equilibrium when two resistances having positive temperature coefficients are joined (*in series*) to the same battery, we, nevertheless, will not attempt to deny, but he will admit that since the rate of losing heat in the hotter coil is greater than in the cooler one, a balance between the rates of heating and cooling is possible. The familiar example of copper leads carrying strong currents from the outside of a room where the temperature may be that of freezing point to the much hotter interior of the room is a case in point. A more important illustration is the use of incandescent lamps in *parallel*. Here, since carbon has a *negative* temperature coefficient, the condition is one electrically unstable.

We will next consider what influence the variation of the resistance of the coils will have upon the accuracy of our electro-calorimetrical determinations. In the process of heating a liquid by passing a current through a wire the latter must necessarily be at a much higher temperature than the liquid. In our experiments a sample of the wire to be used for heating purposes was covered with paraffin and placed in water, and a current of such a strength was passed through it as just to melt the paraffin, the water remaining entirely unagitated. The current actually used for heating the contents of the calorimeters was only about half this strength, and, moreover, the calorimeters were shaken up thoroughly during the process of heating, so that we may safely infer that the mean temperature of the wire was at the outside not more than 20°C. above the temperature of the water.

The ideal of accuracy to which we are endeavouring to attain is one part in ten thousand, and for a variety of reasons we do not think it is possible to secure much greater accuracy than this. Now what latitude does this permit us to employ in the temperature difference between the two coils? Platinoid formed the material of the wire, the temperature coefficient of which is, say, ·02 per cent. per degree, so that even if there was a mean temperature difference of the heating coils of 0·5°C., the result would only be effected to the ten-thousandth part. So far as Mr. Evershed's contention goes, we might in *directly balancing* water with, say, alcohol, avail ourselves of a temperature difference of as much as half a degree without sensibly affecting the results. But we do not *directly balance* one liquid with another, but employ the far preferable plan of using *a method of substitution*. Water in calorimeter A is balanced with water in B, then with the same heating current passing for the same time the same water in A is balanced with the liquid in B. As the final temperature of the water and liquid when properly balanced only differ by at most $\frac{1}{50}$°C., the condition, then, that has to be satisfied is *that the wire in B when traversed by the same current as before for the same time shall have the same mean temperature to half a degree, whether it is employed in heating water or its calorimetrical equivalent of the liquid.* Since the agitation is perfect we have no hesitation in saying that this condition is more than fulfilled.

The gist of our answer to Mr. Evershed's criticism is that the method of substitution does not imply equality of heating in the two calorimeters. The more complicated arrangement that he proposes would, therefore, in any case be unnecessary for our purpose.—Yours, &c.,

THE OSCILLATORY DISCHARGE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The following extract from the "Scientific Writings of Joseph Henry," and dated June 17th, 1842, may be of interest to your readers at the present time:—

In magnetising needles by the electrical discharge the needles were always magnetised in a direction conformable to the direction of the electrical discharge, but by employing very fine needles he obtained several changes in the polarity of the needles by merely increasing the quantity of electricity, while the direction of the discharge remained the same. He continues:—"This anomaly, which has remained so long unexplained, and which at first sight appears at variance with all our theoretical ideas of the connection of electricity and magnetism, was, after considerable study, satisfactorily referred by the author to an action of the discharge of the Leyden jar which had never before been recognised. The discharge, whatever may be its nature, is not correctly represented (employing for simplicity the theory of Franklin) by the single transfer of an imponderable fluid from one side of the jar to the other; the phenomena require us to admit *the existence of a principal discharge in one direction, and then several reflex actions backward and forward, each more feeble than the preceding, until the equilibrium is obtained.* All the facts are shown to be in accordance with this hypothesis, and a ready explanation is afforded by it of a number of phenomena which are to be found in the older works on electricity, but which have until this time remained unexplained."

Digitized by Google

A little later, in the same Paper, he gives an explanation of the reversal of polarity of the needles by the oscillatory discharge.—Yours, &c., A. D. RAINE.

THE ELECTRICAL TRADES SECTION OF THE LONDON CHAMBER OF COMMERCE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Now that the result of the election of the working committee of the Electrical Trades Section is known, I should be glad if you would allow me, as one of those who have not yet joined, to make a few remarks.

I was invited by Mr. Crompton to attend a preliminary meeting on the subject held last July, but was unable to attend, and strain of work has hitherto prevented me from an opportunity of urging a different mode of election and constitution of the working committee.

The success of such a scheme as this must depend on the strength of the committee and the feeling that it is an adequate representation of those supporting it. What brought about the present formation was a general feeling of its necessity among the trade, not the professional side of the electrical world at all, but the manufacturers, the contractors, those who by able management and enterprise have been the means of establishing the numerous factories that will in the future enable England to take a foremost place everywhere for her electrical goods.

The telegraph companies, goodness knows, have succeeded in the past well enough without any electrical section at the London Chamber of Commerce, so have the telephone companies, and it was not to meet the wants or demands of these corporate bodies that the present section was formed or was ever likely to be proposed.

And yet what do we find on analysing the list of members and their representation on the committee? Telegraph companies 14 memberships, 5 on the committee; telephone companies 9 memberships, 3 on the committee; electricity supply companies 16 memberships, 6 on the committee—a representation in every case of one-third. For the electrical manufacturers and contractors—those on whom the success of the scheme depends, in fact, without whose support it must remain a dead letter—there is a representation of less than one-seventh: 94 memberships, with 13 on the committee.

It must be apparent that this is wrong, and on increasing the committee up to the allotted 48 it should be borne in mind.

Now, as to the election of the committee, could not this be improved on by the adoption of some such plan as Mr. Mr. Ritchie's scheme for the election of County Councillors—two-thirds of the committee to be elected by the enfranchised subscribers of their guinea, and one-third to be elected by the committee, with a view to strengthening themselves by the addition of able and useful men in the electrical world?

This would be an admirable corrective to a ballot of this kind, and has many advantages.

The two-thirds of the committee to be ballotted for should be principally drawn from the electrical manufacturers, who, as I have already demonstrated, must be the heart and soul of the thing if it is to be any good. A further selection could then be made from gentlemen connected with the telegraph, telephone and electricity supply companies (preferably officials rather than directors), from consulting engineers and others prominently connected with electrical matters, who express their willingness to give suitable time to the work. The selection could be varied every year, and the services of many might be secured who would not feel disposed to put themselves up for invidious distinctions by balloting. The committee would thus have a useful power of obtaining the services of those whose useful knowledge, whether on technical matters, commercial subjects, or the ethics of fire risks, would be of service to them, and at the same it would restrict the committee to those who are able and willing to attend.

It might be argued that this would lead to exclusiveness and to the formation of a clique; but with this I disagree. On carefully scrutinising the list of those already elected it will be seen there are many who from their very positions and their numerous important duties will find it impossible to attend, and therefore the business will be left in the hands of the few, which in the other mode of election would not be the case.

On mentioning this I was told (of course by an irresponsible person, so there is no need for an official disclaimer), "All the better, then a few of us can work it."

Now if there be one thing that will alienate the support of the electrical trade more than another it would be a feeling that the committee is "worked" by a little family party. If it be borne in mind that many of the most prominent members will not attend for reasons before-mentioned, a careful and thoughtful scrutiny of the elected might show that such a feeling is not altogether without foundation.

I do not, however, believe there is any such intention, and such could be readily defeated if only all the members of the committee would attend.

I am pleased to see, at any rate, two of the electrical journals represented, who, in fact, should be *ex-officio* members of the committee. As the means of disseminating all that is interesting and instructive to the trade they constitute an enormous power, and it is important that they should be well in touch with everything that goes on, and identified with every movement of this kind. The success of the present undertaking depends now on the working committee; I and many others who have not yet joined are waiting events. If it is to be the means of airing individual interests, of coercing master and man, or of interfering and generally busy-bodying with matters foreign to it, then it will drift for a time and sink away; but if it can succeed in cementing and protecting trade interests and diminishing trade burdens, it will have fulfilled a duty that for my own part I regret the Society of Telegraph-Engineers and Electricians, with its prestige and position, did not some time ago recognise and undertake.—Yours, &c.,

JOHN B. VERITY.

King-street, Covent Garden, Oct. 29, 1888.

TELEGRAPHY WITHOUT WIRES.

TO THE EDITOR OF THE ELECTRICIAN.

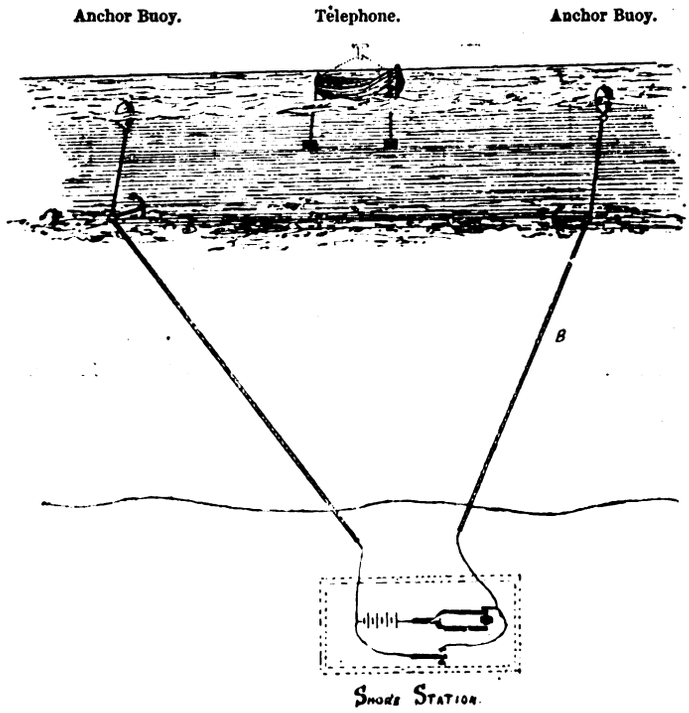
SIR: In February, 1885, I published what experiments I thought necessary to explain what I meant by "Induction and Conduction," my object being to show in what way a current of electricity would affect a good conductor, or one sufficiently bad to be called an insulator or non-conductor. In one of these published experiments I said: "The experiment from which the results here shown were obtained was as follows:—An uninsulated iron tank 6·5 feet long, 5 feet wide, and 3·5 feet deep, was filled with water (about 676 gallons), and the surface divided off into sections of one square inch by means of the arrangement already described. The two ends of a battery of twenty Leclanché cells were attached respectively to two circular copper plates 3·5 inches in diameter, and immersed six inches below the surface of the water, and 3·3 feet apart. The two exploring wires in connection with the galvanometer were ·038 inch in diameter, and insulated so that only a cross section of each wire would be in contact with the water. The ends of these wires were fixed parallel to each other half an inch apart, and so arranged that the uninsulated ends should be immersed below the surface of the water in each test. These two wires, so fixed and immersed, were moved in each section, until the position of maximum potential was obtained. In this manner I was able to trace some of the lines of polarisation into which the current divided itself, not only from its original source, but also its unerring return to the same."

I also stated my views upon the same subject as follows:—"Messages by electrical signals have been sent and correctly received through a submarine cable two thousand miles in length, the earth being one half of the circuit, by the aid of the electricity generated by means of an ordinary gun cap containing one drop of water; and small though the current emanating from such a source naturally was, yet I believe it not only polarised the molecules of the copper conductor,

Digitized by Google

but also in the same manner affected the whole earth through which it dispersed on its way from the outside of the gun cap to its return to the water it contained. I further believe that the time will come, perhaps sooner than may be imagined, when it will be possible to detect even such small currents in any part of the world, in the same way that it is now possible to do in comparatively small sections of it."

For researches of this description it is necessary to employ as sensitive an instrument as it is possible to obtain, to pick up, so to speak, such minute currents. Now there is that wonderful instrument the telephone. I say wonderful advisedly, for, as far as I know, it is not to be equalled for the simplicity of its mechanical construction and the ease with which it can be manipulated; and yet it is so peculiarly sensitive. I have therefore used it in most of my experiments as the receiving instrument, although, of course, there are other well-known instruments that could be employed, as all depends upon the potential of the current to be detected. The sending arrangement was either an ordinary Morse key, so manipulated for a long or short time as to give the necessary sounds in the telephone to represent dots and dashes, and being so interpreted, the senders' meaning was clearly understood; or a double key and two pieces of mechanism, giving dissimilar sounds, were employed with good results. I gave much time and thought to the subject, the results of each experiment giving me so much encouragement to proceed; and of the many experiments made I select the following, as I think it will clearly illustrate my system for telegraphing to a distant point not in metallic connection with the sending station, noticed by you in a recent number of your journal.



A wooden bathing hut on a sandy beach made a good shore station, from which were laid two insulated copper wires, 115 fathoms in length, marked respectively A and B. Sections of the wires were twisted round anchors, as shown, their position being marked by buoys, as indicated, about 100 fathoms apart in a direction N. and S.; midway between the two a boat was anchored with a copper plate hanging fore and aft about 10 fathoms apart, and consequently about 45 fathoms from either end of the anchored shore wires. This boat represented the sea station, and, owing to the state of the sea, a very wet and lively one it proved; therefore, taking this fact into consideration, together with the crude nature of the experiment, in this arrangement it was remarkable with what distinctness and ease messages were passed. The last message sent from shore was: "Thanks, that will do; pick up anchors and return to shore." To this the reply came from the boat, "Understand," and they then proceeded to carry out instructions.

It was slack low water during the laying of the wires, but a strong flood tide was running from N. to S. during the experiment; the sun was shining, but there was sufficient wind from the E. to cause big white crested waves to scamper to the shore; in fact, when I saw how difficult it was for even experienced beachmen to manage the boat in such a sea, I repented of the persuasive powers I had used to induce the men to undertake the work. It was too rough to proceed further with the experiments, as I intended; but still, I had learnt more than sufficient to convince me of the practicability of the system for various purposes, and particularly for telegraphing in the way described.—Yours, &c., WILLOUGHBY SMITH.

THE "MANN" TELEPHONE EXCHANGE SYSTEM.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In an article by Mr. J. Munro, in your issue of Oct. 19, some mention is made of my circuit line systems for telephonic intercommunication, used in Dundee and in other centres of the National Telephone Company's system.

Will you allow me, through the medium of your well-known paper, to make a few statements with regard to this system?

It is always described as an adaptation of the "Law" system. As a matter of fact, when I devised this system, in the spring of 1882, I had not seen or heard of the Law system.

The only similarity between the two systems is that an extra calling wire is made use of.

There is no difficulty in applying this system to the largest towns except the expense, which is always great when an old system has to be replaced by a new.

The National Telephone Company's *employés*, who have used this system, advise its adoption in large centres.—Yours, &c.,

J. J. MANN.

11, Chatham-buildings, Manchester, Oct. 27, 1888.

"REMARKS ON SOME OF OUR TELEPHONE SYSTEM."

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I am obliged to your correspondent "A.S.T.E. and E." for his correction with regard to the Edinburgh poles. The first call offices were opened in London during 1888.—Yours, &c.,

J. MUNRO.

Edinburgh, Oct. 30.

LECTURE ON ELECTRIC LOCOMOTION: PAST AND PRESENT.

On Friday evening last at University College, Nottingham, Dr. J. A. Fleming delivered a public lecture on "Electric Locomotion." The large theatre of the College was completely filled with an attentive and appreciative audience.

The chair was taken by Mr. Alderman Lindley. The CHAIRMAN, in a few preliminary remarks, recalled to the recollection of the audience that Dr. Fleming was the first Professor of Mathematics and Physics in the College on its opening in 1881, and had since that time devoted entire attention to the subject of electrical engineering.

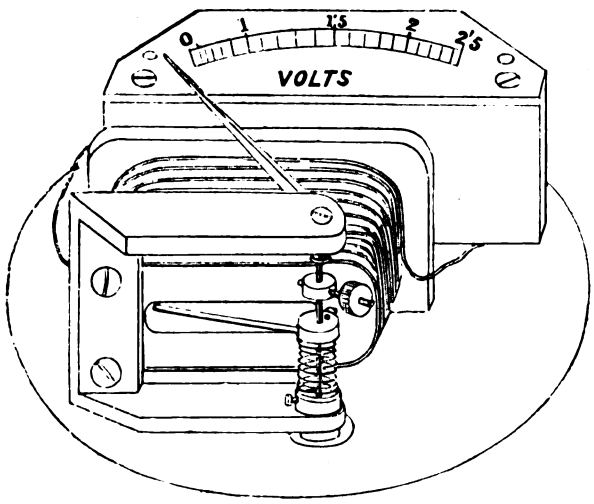
Dr. FLEMING began by a very brief review of the progress of the art of electrical illumination since the date of the opening of the University College in 1881. Passing to the proper subject of his discourse, he proceeded to explain by numerous lantern views, and by experiment, the electrical transmission of power. Amongst other illustrations, a small hand Gramme machine was joined up to a small model of an old-form Edison dynamo placed at the opposite end of the lecture table. On working the winch of the hand Gramme the Edison machine was made to rotate and lift a weight to the ceiling. The audience had thus before them the whole process. In addition a number of machine tools were shown working. A large shearing machine was shown cutting bar iron, being driven by a motor operated by current from the College dynamo, and a lathe was worked in a similar way. The subject of tramcar traction was next treated. The early efforts of Field, Edison and Daft in electric locomotion were fully described and illustrated by lantern photographs, and the more recent work of Sprague, Short and Nesmith, as well as that of the Daft, Thomson-Houston and Van Depoele Companies described. The details and mode of working of the Portrush and Bessbrook tramways, by Siemens and Hopkinson, and the Brighton and Blackpool tramways, were illustrated by views and diagrams, and the storage battery mode of working,

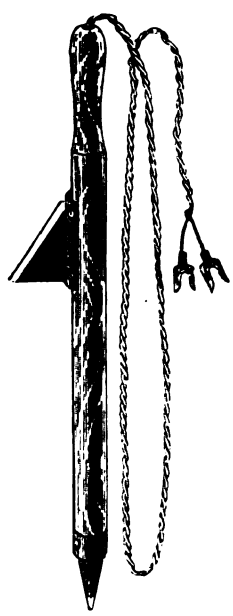
Digitized by Google

as adopted by Reckenzaun and others, explained. Some details of cost of working, as derived from data of the Richmond Sprague railway, were furnished. The hope was expressed that the successful operation of some 40 to 50 actually existing tramways and the projection of many more in the United States would stimulate English tramway directors to vigorous action in this matter. The details of the methods of working by overhead and conduit-laid conductors was explained, and also the comparative merits of the parallel and series system of working cars dwelt upon. The comprehension of the lecture was greatly facilitated by the numerous photographs shown on the screen by the fine optical lantern of the College. In conclusion, the lecturer urged upon his audience the necessity for a still greater fostering in this country of purely scientific research, seeing that it is upon the basis of an accurate knowledge of scientific principles that practical engineers are alone able to erect the structure of applied science. A hearty vote of thanks to the lecturer brought the evening to a close.

DRAKE AND GORHAM'S LOW-READING VOLTMETER.

We have received from Messrs. Drake & Gorham a sample of their new low-reading voltmeter, which we illustrate diagrammatically





below. It is specially designed for use with secondary batteries, reading, as it does, from 0·5 to 2·5 volt. It is accompanied by a special connecting spear for rapidly making contact to the two lead poles of a cell with one hand, the voltmeter being held in the other. The needle system is balanced and controlled by a spring, so that the instrument can be read in any position among others. There is one little point of constructive detail which, we think, is novel, viz., that should the spring get a little strained, as sometimes occurs, this being, of course, shown by the pointer not standing at zero when on open circuit, it may be at once corrected by turning a screw at the back. The resistance for a 2·5-volt instrument is about 13 to 14 ohms, which is low for such a small size. It is made for Messrs. Drake and Gorham by Messrs. Nalder Brothers and Co., of Westminster.

WARING'S LEAD-COVERED CABLES.

The system of insulation and protection adopted by the Waring Electric Cable Company, of Pancras-lane, E.C., which is illustrated below, has already stood the test of several years' experience in the United States, and the results obtained would seem to have been of a highly satisfactory character in every department of electrical industry to which they have been adapted. Many of our readers will have seen specimens of these cables at the American Exhibition last year, and will therefore be familiar with the fact that the external sheathing is of lead. Hitherto, however, little or nothing has been made known in this country with regard to the dielectric. This is a hydro-carbon compound of highly-insulating qualities, which is obtained from the destructive distillation of petroleum. It is remarkably durable under the greatest extremes of heat and cold. It is even said that the copper conductor may be made red hot, or the lead casing may be raised to the melting point without injury to the insulation, and without allowing the conductor to shift from its proper position. This property should render the material very valuable for the insulation of leads in stoke-holes, and alongside of steam pipes, &c.

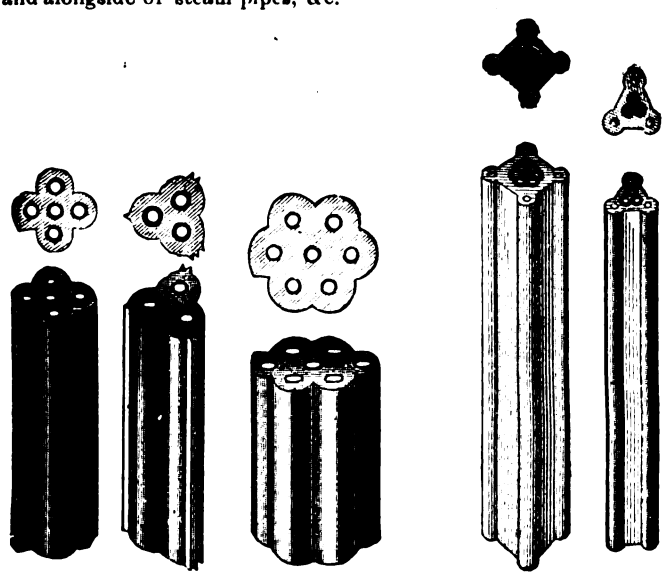


Fig. 1A. Fig. 1B. Fig. 1C. Fig. 2A. Fig. 2B.

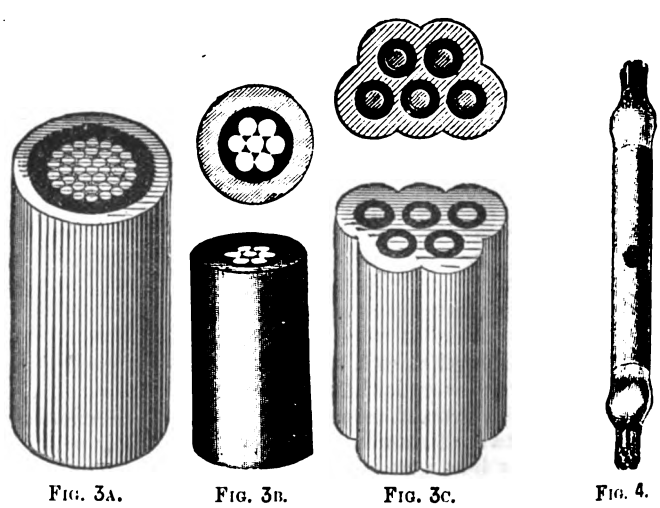

Fig. 3A. Fig. 3B. Fig. 3C. Fig. 4.

The external coating of lead is laid on without any joint, the cables being furnished in lengths of from 1,000ft. to 2,400ft., according to the number of conductors. For telephonic purposes "anti-induction cables" are supplied, in which each conductor is wholly surrounded by the lead. Some of them are illustrated in Figs. 1*a*, 1*b*, 1*c*. For telegraphic purposes the conductors are more usually bunched together, as in Figs. 2*a*, 2*b*. Figs. 3*a*, 3*b*, 3*c* show types of cable suitable for electric lighting. A very light single-wire cable is furnished for house-wiring. One great advantage possessed by the types of cable in which each conductor is separately sheathed in lead is that a ready means is afforded for identifying any one wire at any point. For this purpose one of the ribs is made with a

Digitized by Google

square edge, and by counting from this round to the right or left any other conductor can be designated.

The lengths are united by a simple joint made as follows:—The cable joints are first stripped of the lead, the insulation removed, and the wires substantially joined and soldered. Each wire joint is then wrapped with the Waring insulated tape, and this served with strips of lead to preserve the metallic continuity of the casing. A sleeve of lead pipe, previously slipped over one of the ends, is then brought up over the joint, both ends dressed to fit the cable, and solder wiped joints made, as shown in Fig. 4. The sleeve being tapped near the centre is then filled with insulation and closed. In America many of these cables have been laid in the ground without other protection than a slight wooden troughing.

SOME OBJECTIONS TO THE OVERHEAD CONDUCTOR FOR ELECTRIC RAILWAYS.*

BY MR. M. B. LEONARD, OF RICHMOND, U.S.

Of all the valuable Papers read before the Institute probably none has excited greater interest than Mr. Sprague's admirable contribution on "Electric Railways, the Solution of the Municipal Rapid Transit Problem,"† in which the advantages of electricity in practical operation have been so well set forth as to convince the most sceptical of its superiority over all other methods of traction for this class of traffic. To electrical engineers this comparatively new application of the electric current is one of the most important questions that have come before them, and should be carefully studied in all its details, so that the defects and objections may be pointed out and guarded against, and the most perfect methods evolved as speedily and fully as possible. A point of the utmost importance is the necessity for first-class workmanship.

While it has been successfully demonstrated in the city of Richmond that electric traction is really the solution of the rapid transit problem, and we have felt in the increased value of real estate and the growth of our city in population and reputation the substantial benefits resulting therefrom, I have considered from my daily observation of the operation of this electric road that the overhead wire system cannot be made a perfect or ideal method of operation under all circumstances because of the defects inherent in such a method. But that it will serve as a pioneer in the new field, and will be supplanted in time by a more perfect system, I have not the least doubt, and in the following remarks I will endeavour to show some of the objections that have come to my notice, although there may be others that have escaped my attention, owing to the extreme reticence of all parties connected with the enterprise, doubtless from business reasons.

Of the three most commonly used, the overhead system appears to be the favourite, the latest report of electric street railways in operation in America showing that out of a total of forty-three not less than thirty-six are using the overhead system, and that at least thirty now under construction have arranged to do so. Doubtless the smaller cost, as compared with the other two, was an important factor in deciding so largely in favour of the overhead conductor.

As used in Richmond, the details of operation have been shown so fully and clearly in Mr. Sprague's Paper that it is unnecessary to repeat them here, beyond stating that the rail and earth system is adopted in connection with the overhead wire. During the seven months of active operation of the Richmond Union Passenger Railway many thousands have been successfully transported every day, and at a very much lower cost than could possibly have been done by horse-power, owing to the excessive grades encountered; but the defects of the overhead system are now becoming more apparent as the plant suffers its material depreciation, and we are now in a better position to judge of its value as a permanent institution than we could possibly have done heretofore.

It is an undisputed fact that the encumbering of the streets with the poles required for the overhead system is one of the most serious objections to its use. Although they are hid to a large extent in many places by the shade of trees and foliage, yet on the main streets of our cities, where this system is most likely to be used, they are not only a grevious eyesore, but also increase the liability to accident from runaway horses and other causes. Their appearance would not perhaps be so offensive were it possible for them to maintain an erect position, but on account of the weight of the trolley wires and the pressure of the trolley, the tops of the poles are constantly pulled together, notwithstanding they may have at first been raked in the other direction, and thus the unsightly effect is augmented. Those of us who are acquainted with telegraph line construction can appreciate the great leverage exerted by a heavy strain on the top of a pole twenty-five or thirty feet high, unsupported by guys or otherwise, and will readily understand that it is only a question of time before the poles must be reset or replaced with heavier ones. This has been especially the case on the curves where the strains have been greatest, in some instances approximating a pull of 650lb.; nor does the network of wires, span, trolley, guard and curve, inspire the public with any feeling of toleration for the disfiguring of its streets, but must hasten the time when the clamour for underground wires will compel their removal.

But to my mind the most serious objection is the employment of the bare trolley wire carrying a current of 500 volts and about 90 amperes, which I consider not only dangerous to life on account of the frequent breakages of the wire, which on one occasion last spring in falling struck and killed a horse, but also in damage to property by fire. It is claimed that the use of guard wires will always prevent the possibilities of such an occurrence; but the guard wires did not obviate the burning and melting of the telephone wires when on one occasion the breaking of an exchange telephone pole threw them across the trolley wire, and it was necessary to shut down the railway to prevent the entire destruction of the exchange, and possibly the firing of the subscribers' instruments and houses.

That the trolley wire is liable to breakage at any time has been shown twice during the past week, to the interruption of travel and dissatisfaction of the public; while not so very long ago the wires over one of the curves were pulled down on top of the car by the trolley catching in it, and travel was entirely suspended on that part of the line for one or two days. A very serious defect in the use of the bare trolley is the difficulty of securing proper insulation. Thus far porcelain knobs seem to have been found best adapted for this purpose, and the leakage resulting, especially in damp or rainy weather, must be considerable on the whole length of the line, and must cause a large waste of current. This is probably the reason why it has been impracticable to run over about 30 cars at one time out of the 40 with which the road is equipped, and would seem to indicate a very large loss of energy. In view of the fact that porcelain insulators have been long ago condemned for telegraph purposes, where a comparatively small current is used, it seems strange that they should have been adopted as the best means for securing insulation in circuits of such high potential as are employed on the Richmond road.

The trolley itself seems to be a clear source of trouble and difficult to manage properly. As has been shown, it consists of a grooved wheel at the end of a counterbalanced pole held by a spring against and making contact with the underside of the working conductor. In rounding curves it must be carefully watched by the car conductor to prevent its leaving the trolley wire, and thus stopping the car, and at night extinguishing the lamps, which has proved exceedingly disagreeable to the passengers, while on busy days it has seemed necessary to put a third man on at each car at additional expense for the sole purpose of attending to the trolley. Sometimes the trolley pole has broken, or the springs holding it against the wire have given way, stopping further progress of the car, or requiring a man to stand on the car-roof holding the trolley-pole against the wire until the repair sheds were reached.

One of the most unsatisfactory features about the arrangement of the Richmond road is the ground circuit, not only because of the difficulty of getting a good ground, which has in this case only been accomplished by connecting the track with the whole gas or water works system of the city, to the detriment of our exchange telephone system, but the fact is that it is necessary to have a clean track to work on, otherwise vivid flashes of electricity will appear, to the terror of the horses in the vicinity and damage to the motor; or should it happen that there is a sufficient quantity of dirt on the rail, it will cause a higher resistance than the potential of the current can overcome, and, of course, stop the car. Should the motor man get off to push it over the dirt and fail, as sometimes happens, to switch off the current from the motor, the full current on the line will pass through it just as soon as a good contact is made, and the result is a burnt armature and a disabled car. This seems to have been particularly the case during the recent stormy weather, when I am informed that the number of available cars for traffic on the road was reduced to about ten. Possibly the saturation of the motor by the rain, and the effect of lightning on the trolley wire, had also something to do with the case. Owing to the reticence of the *employés* above referred to, it has been difficult to ascertain just what damage has been caused by lightning striking the trolley wires and injuring the motors, but that there has been serious trouble from this source I have no doubt. The very best forms of lightning arresters have not proved sufficient to prevent injury to electric light dynamos where insulated wires are used in the outdoor circuits, while the bare wire used for the working conductors on overhead electric traction systems must always render them more susceptible to trouble from this direction.

After setting forth the difficulties which have been shown in the practical operation of the most extensive system of electric traction in the world, it gives me pleasure to direct attention to the remarkable behaviour of the Sprague motors under all the conditions to which they have been subjected for the past seven months, which has been indeed remarkable. No load has been too heavy and no grade too steep for them to ascend. Perhaps the severest test they ever received was on the night of July 4th in bringing the crowds from the new Reservoir Park, when the ordinary open cars carried over one hundred passengers and the closed cars over seventy-five each, so many in fact that the axles of one or two of the cars broke down under the load, all of which must be exceedingly satisfactory to the inventor, and places the Sprague motor at the very head of the many excellent types or forms that have been devised at home and abroad.

The objections referred to above apply equally as well to all forms of overhead systems except where a second wire is used for a return instead of the track and earth, and also where the trolley pole is discarded for the movable trolley. But the increased number of aerial wires required as well as the heavier fixtures needed to sustain them render these systems just as objectionable.

We are very anxious to see the effect of ice, sleet and snow upon the operation of our road, as it has not yet passed through a winter in complete running order. A heavy sleet storm has often prostrated our telegraph lines, and I see no reason why the overhead electric railway wires would be exempted from similar trouble, nor why the covering of the rails by ice and snow will not render it difficult to make a sufficient contact to operate the line successfully, not to speak of the loss of current by leakage or escape from the trolley wire, but I have no doubt that the ingenuity of those who have overcome all the problems encountered in opening up with such success the Richmond Union Passenger Railway, will be sufficient to insure its continued operation in spite of wind and weather, and to no one more than myself will this be gratifying, since it was through my efforts that attention was first directed, some three or more years ago, to the splendid opportunities for electric traction that Richmond presented;

* Paper read before the American Institute of Electrical Engineers.

† See *The Electrician* of July 6th, p. 285, and Aug. 3rd, p. 409.

Digitized by Google

although I am free to confess that my inclinations were towards the application of the storage battery, which obviates all the troubles and defects developed by the overhead systems, and against which no more serious objections seem to be brought than the extra weight caused by the batteries and the greater first cost as compared with the aerial systems, all of which, it appears to me, are more than counter-balanced by the difficulties and annoyances in the systems just described.

The very satisfactory results obtained in the operation of the new electric storage cars on the Fourth Avenue Railroad in this city, as well as by Mr. Wharton in Philadelphia, M. Huber in Hamburg, and elsewhere, prove, as I have believed, the storage battery to be the only ideally perfect system of electric traction for municipal purposes.

COMPANIES' MEETINGS.

The Brazilian Submarine Telegraph Company.

The thirtieth ordinary general meeting of the shareholders of this Company was held at Winchester House, Old Broad-street, on Wednesday last, the Right Hon. Viscount Monck presiding.

The SECRETARY (Mr. Richard Collett) read the notice convening the meeting, and the minutes of the twenty-ninth ordinary general meeting, held on the 9th of May last, which were confirmed and signed as correct. The report of the Directors was taken as read.

The CHAIRMAN said it was now his duty to move the adoption of the report. He hoped they would allow him to say that among the duties of this kind which he had to perform there was none that gave him more satisfaction than that of meeting the shareholders in the Brazilian Submarine Telegraph Company. He had now been their chairman for fourteen years. The Directors had managed, he thought, to conduct the business of the Company to the satisfaction of the shareholders. At least they had always expressed it so, and therefore it was a great source of gratification for him to meet them again. He had not a great deal to say on that occasion. The nature of the report, which he hoped would give them satisfaction, was such as to preclude any necessity for argument on his part. He would give a short account of their transactions since their last meeting. They had had a great deal of repairs to do, as they knew, to the Lisbon-Madeira and the Madeira-St. Vincent cables. There were faults in both of those sections, which they had effectually removed, and he was happy to tell them that now the cables tested as well as when first laid down. A fault had been detected in the Lisbon-Madeira cable early in the half year, and for some time they were under the impression that there was a second fault, which, as far as they could locate it, was near Lisbon. They were rather nervous about it, as there were several cables in the sea close by Lisbon. They were afraid that if compelled to repair in that locality they might fall foul of some other cable near. However, they took out the fault that they knew of, and were able to localise the other fault close in shore near Madeira, and had removed it, and the cable was now in perfect condition. The cost of effecting the repair had very largely increased their expenses in the half year. The cost of these two repairs was £7,908; but with that exception the expenditure had been pretty much what it had been the previous half year. The income, he was happy to tell them, showed a growing increase. The revenue for the half year under review was nearly £7,000 greater than that of the previous half year, and it was between £8,000 and £9,000 greater than that of the corresponding period of last year. He was glad to be able to state that the receipts since the end of the current half year showed an equal if not a larger increase. Under these circumstances they felt no hesitation in giving them a dividend of 7 per cent. per annum for the year, and place £30,000 to the reserve fund, which now amounted to £170,000. They had also paid off a considerable sum of the debentures—the money which they raised for the purpose of duplicating the cable—and he thought they might assume that in a very short time they would have paid off the whole of the cost of the duplication of the cable out of revenue by the repayment of the debentures. There were two subjects affecting their general condition which he desired briefly to allude to. One was in regard to the African Direct Telegraph Company, in which they had a considerable interest. They took that interest—as they were all aware, and as he explained at the time—more as a defence against the intrusion of any other people on their ground than as a mere pecuniary speculation. But he was happy to be able to tell them that it was likely to turn out very well for them. That Company now paid its expenses, as far as they were concerned, and he hoped that in the future it would be a source of gain to them, because there was a proposal for an alternative route by the West Coast of Africa to the Cape, which would not only enable the African Direct Company to pay itself, but would introduce a considerable amount of traffic to their own lines between Lisbon and St. Vincent. This would be a source of gain to them as well. The other subject on which he desired to say one word was their position in Brazil. They had been negotiating, as was well known, for a long time with a view to the strengthening of their position there. He was sorry to say that he was not yet able to announce to them the success of those negotiations. The Directors were doing their best for them; and he must ask them to prolong the confidence which they had already shown in the Board by not being too inquisitive with respect to those negotiations. It was a well-known fact that negotiations were not rendered easier by their terms being made known to the public, and, therefore, he would ask the shareholders to trust the Board to carry on those negotiations, which they would try to bring to a satisfactory conclusion. He concluded by moving the following resolution:—

"*That the report of the Directors and accounts to the 30th June, 1888, now submitted, be approved and adopted, and that a dividend be now declared of 3s. per share, making, with the interim dividends already paid, a total dividend of 6 per cent for the year ended 30th June, 1888, and also a bonus of 2s. per share in respect of the profits for the year ended 30th June, 1888, the said dividend and bonus to be respectively free of income-tax.*"

The VICE-CHAIRMAN (Sir James Anderson) seconded the motion.

Mr. HAWKES inquired why the Company did not hold among their investments Brazilian Government Stocks.

Dr. WEAVER asked whether the Directors considered £170,000 a sufficient reserve fund for the Company. He desired also to be informed whether in the opinion of the Directors the prosperity of the Company was attributable to any sudden change of trade, or whether it was owing to the general improvement of the country where they carried on their working.

The CHAIRMAN, in reply, said that the prosperity of the Company had been so gradual and progressive that in his opinion it was derived from the general advance of commercial prosperity in South America. The amount of the receipts every year since the line was opened were given in the reports, and it would be seen from them that the Company's progress had been gradual and progressive, and he should therefore say it was owing to the fact he had stated. With regard to the £170,000, he must admit at once that he did not think it was a sufficient reserve fund, but they were increasing it as fast as they could, even in opposition to some gentlemen who wrote him privately saying that they would prefer larger dividends. He had, however, all his life been the advocate of a large reserve fund in such cases. It had been their policy to limit the investments to English and Colonial securities. He then put the motion, which was carried unanimously.

On the motion of the CHAIRMAN, seconded by Mr. FREDERICK YOULE, Sir Thos. Fairbairn, Bart., was re-elected a Director, as was also Mr. Henry D. Gooch, on the motion of the CHAIRMAN, seconded by the Hon. ST. JOHN F. BRODRICK, M.P.

Dr. WEAVER next moved, and Mr. HAWKES seconded, the re-election of Mr. Henry Dever and Mr. John Gane as auditors of the Company.

The motion was agreed to unanimously.

On the motion of Dr. WEAVER, seconded by Mr. GEO. ANDREWS, a vote of thanks was accorded to the Chairman and Directors.

The CHAIRMAN, in acknowledging the compliment, assured the meeting that the Directors would do their best in the future as they had done in the past to promote the interests of the Company.

The proceedings then terminated.

Edison and Swan United Electric Light Company (Limited).

The fifth annual general meeting of this Company was held on Tuesday, at the Cannon-street Hotel, under the presidency of Mr. James Staats Forbes.

The SECRETARY (Major S. Flood Page) having read the notice convening the meeting the report of the Directors was taken as read.

The CHAIRMAN said: Gentlemen, I think I had better begin by referring at once to the figures of the balance-sheet and profit and loss account. I will deal first with the debit side of the balance-sheet, which represents, as far as substantials are concerned, no change whatever. It shows that the subscribed capital is exactly as it was, but there has been an alteration in the method of stating it in the accounts, and there is a printers' error in that revised statement. It speaks of 5,000 "A" shares of £5 each, fully paid, allotted to the Edison and Swan United Electric Light Company. It should read that there were 5,000 shares of this Company fully paid allotted to the Edison Company. 12,139 "A" shares of £5 each fully paid were allotted to the Swan Company—that was part of the purchase of their concern, just as the next item is part of the purchase of the Swan concern. The capital, therefore, seems to be exactly as it was. The item of sundry credit balances—meaning, in fact, what we owe to our creditors—amounts to £10,214, as compared with £5,799, so that we are in debt a little more. We need not, however, be alarmed at that, because the volume of our business in the year has been considerably greater than in the preceding year; and when you come to the other side of the balance sheet you find that whereas we are somewhat more in debt we have a very much larger amount of good debtors. The profit and loss account for the year shows a balance of £25,123, against £16 246 in the preceding year. That is a matter we shall have to talk of presently. On the other side of the account the cost of patents, goodwill, preliminary outlay, and loss on working, &c., as per last balance-sheet, stands at £300,814, and then there is the further expenditure thereon of £3,213, which brings up the amount to £304,028. But we have been enabled during the year to get rid of some of the bad bargains which came over to us on the union of the two companies by the sale of one installation and of some plant. That has reduced the total by £12,790, which, of course, is credited to capital in that item in the shape of diminution. There was a further item embraced in the general description of the £300,000 odd, namely, loss on working. I daresay, however, proprietors will remember that in the earlier years our working account, instead of showing a profit, showed a loss, and, in accordance with all sound dealing, we determined that these losses in earlier years must be redeemed out of the profits of later years until they disappeared. Happily now they have disappeared, because by diminishing the principal items from year to year by the profits made we have got rid, in fact, of the amount of accumulated losses in the earlier years. There is, therefore, £25,000 of profit in the present balance-sheet, so to speak, free of any claim of that kind. We are on our legs, therefore, as a money-earning concern. You see the item of freehold property. That stands at £27,991, against £13,691 in the last balance-sheet, so that that

Digitized by Google

item has been swollen by £14,300, owing to the fact that we have paid off the mortgage on our property at Ponders End. When the balance-sheet of the previous year was made up we had £14,300 on mortgage, which we have paid off, and our freehold property stands at its real value. Besides Ponders End that entry contains some items with respect to a Green-street property and some property we have at Benewell. The next item of installations in progress stands at £1,867, against £2,794. That is an asset—a good asset—and means the payment we shall receive when certain works in progress are completed. The plant and stock stand at £35,390, against £30,045 in the preceding balance-sheet. We have, as I said before, increased very considerably the volume of our business, and we have had to increase the plant necessary to produce it. The item of office installation and furniture is diminished. We write that down from year to year, and it will disappear. Debtors stand at £24,864, against £12,946 in the preceding year. Cash at bankers and in hand stands at £23,028, against £14,174. These are the items of the balance-sheet, and they divide themselves quite naturally into two parts—there is the tangible thing which represents convertible property, and therefore money, and there are other things which represent the value of the patents, goodwill, trade mark, or whatever that thing is which enables people with a small outlay on plant or premises to make very large revenues. I make out that these latter balances, deducting the difference between what we owe and what is owing to us, amount to £104,000, which we look upon as tangible concrete assets in a going concern like ours. Coming to profit and loss account, we began on the 1st of July, 1887, with a stock of lamps, &c., at £12,868. We have spent during the year in wages, purchases of material, cost of installations, &c., £56,329 this year, against £37,159 last year. There has been much larger expenditure in wages and purchases of material, because our sales of lamps have been much greater. Salaries, directors' fees, rent, &c., stand at £7,393, against £6,917. Mr. Swan's salary is the usual amount. The item of depreciation of plant is £3,145, against £3,281, which means that we write off from year to year a very liberal sum from what may be called the using-up value of our plant. The item of Holborn-viaduct £2 041 means that we had a lease of certain premises on Holborn-viaduct taken over by the Edison Company, where there was an installation originally rather in the nature of an advertisement. The conditions of the lease were onerous, we did not want to continue it; it had a certain time to run, and we compounded with the owner of the property to get out of it at once. Therefore we escaped some onerous conditions that would have two or three years hence to be met. We have made a good bargain, and we have cleared out by paying the costs of getting out of it. We are quite clear of that, and it will involve no further liability. I referred to the fact that we had a large amount of money at our bank. The interest for the year comes to £294. Income-tax on profit, 1886-7, stands at £236, because our friends of the Inland Revenue Department do not understand setting off the profits of one year to cover the losses of another. They do not assess you to income-tax on a loss, but the moment you make a profit they do. There is thus a balance of £25,123 to the good. By sale of lamps, fittings, &c., and charges for work of other kinds, we have received £88,110 against really for the business of the previous year £65,736, although in the accounts of that year that sum is enlarged by a payment of Messrs. Woodhouse and Rawson for royalties of £4,217, which we recovered under the action, but which represents chiefly the royalties on lamps sold in the preceding year. I emphasise that to show that the increase of sales is the difference between £65,736 in the year 1887 and £88,110 now. There is a small running account for interest, £294 against £243. The stock on June 30 was £19,590. That enables me to call your attention to the fact that the stock brought forward last year on the 1st of July was only £12,858 in value, whereas the stock carried forward into the current year was £19,590, and that you will see bears the same proportion to the increased business done, and it arises from what I explained, I think, pretty fully last year—that this business cannot be carried on without a very large reserve of manufactured lamps in stock. A great number of varieties of lamps, to suit the wants of different customers, must always be on hand, so that you must end the year with a considerable amount in stock to meet the demand that may come up from day to day. If the sale of lamps in the year had remained stationary while the stock carried forward had increased it would have been an ill sign, but as it bears about the same proportion to the stock carried forward last year that the increased volume of business bears to the business of last year it is all right. The lamps are put down at approximately cost price. That is the whole story of the accounts, and that is all the story I should have to tell upon the accounts if I had not to come to the question of this balance of £25,123. Supposing we were absolutely free of all legal questions, there is no doubt whatever that on the working of our business for the year we have honestly earned a profit of £25,000, after charging the concern with every proper outlay, and being somewhat liberal in the case of the ordinary depreciation of plant, and so forth. But having left you there I will now go to the report. I have exhausted paragraph 2 by dealing with the accounts. That paragraph is very brief, and states that the sale of lamps has progressed in a satisfactory manner during the year. The volume of the Company's business has increased, and has resulted in a credit balance of £25,123. Now that is putting into concrete words my explanation of the accounts themselves. Then come paragraphs 3, 4, and 5. They are all part of the same story. This time last year we were living in the belief that our patents were not only decided on appeal in the action "Woodhouse and Rawson," but that they were invulnerable. Since then our illusion has been somewhat disturbed by the fact of the action brought by the Brush Company, or in a suit in which they were interested, in which the whole case of these patents had to be reconsidered. It is an illustration of the law of patents that while Mr. Justice Kay decided upon the Cheesborough patent confirming the decision already given in Woodhouse and Rawson's suit, his opinion of the Edison patent was different to that of the prior Courts, both of First Instance and Appeal, upon the Edison, and that he has declared to be invalid. The Cheesbrough, which, after all, must be taken to be the key patent, even in the manufacture of the Edison lamp, is declared again to be a valid patent, while the Edison patent is declared to be invalid. That is the decision of Mr. Justice Kay. Our learned friends, the technical lawyers, whose minds are impregnated with all the minutiæ of these matters, and our technical advisers tell us that Mr. Justice Kay is very wrong. Upon that opinion we are going to appeal, and I am not going to predict what the result of that appeal may be. I can only tell you, what competent experts tell us, that there is every probability that Mr. Justice Kay's decision on that point may be reversed. I hope it will, although I am bound to say that I do not think it is a matter of primary importance that it should be, seeing that the Cheesbrough patent has been confirmed. I cannot say any more about it. It would be presumption on my part and that of my colleagues to express an opinion. We can only tell you what our advisers tell us—that they believe that there is reasonable ground for supposing that that decision is wrong. We shall soon know, because that matter is coming on very shortly. We promise in the report that it will be heard before Christmas, and I dare say if it is settled in our favour we shall eat our Christmas dinner with a little more heartiness. Whether or no it will not, I fancy, have anything like a disastrous effect upon the future of this Company. The Anglo-American Brush Company have brought actions in two suits. We refer to them in para. 6. Very little importance is attached to the first one; as to the second, on the matter of patents, who can tell? If anyone wants to know the enormous dangers that are inherent in patents he can read the proceedings in these two sets of actions. I do not know how it may come out. We are bound, if persons bring actions against us, to defend them; but our legal advisers tell us that we need not be in a state of great alarm. Here we are face to face with a profit legitimately made on the operations of the year, but with indefinite liabilities as to the costs and consequences of these actions. I do not want to alarm anyone, because I do not think myself that there is much ground for alarm; but what I would wish to impress upon the proprietors is this, the great imprudence and unwisdom of dealing with the profits of the year until questions so vital have been settled, because you see at once that though the ultimate consequence of the decision against us on the Edison patent on appeal might not be of great importance to us as lamp makers, the question of costs must be serious. Instead of having costs to receive we should have costs to pay, and to have costs to pay in these patent actions is a most serious thing. Our opponents are most ingenious people, and if their ingenuity can not only get the costs of the proceedings, but can land us in damages, I think it would be most unfortunate that we should have parted with the profits of the year pending such questions. We have considered this matter with very great care, with the assistance of our legal friends, and we shall recommend the shareholders to carry forward that £25,123 as a reserve, and not to distribute it. Then we come to paragraph 7, in which we say:—"Lord Thurlow's Amendment of the Electric Lighting Act of 1883 is leading to a considerable development of electric lighting, and to a corresponding increase in the Company's business." We have reduced our earlier aspirations to the humble *rôle* of lamp makers, and lamps cannot be burned without installations. We are very delighted to see others embark capital and energies into installation work, and it is very gratifying to us that the legislation of 1882—which was disastrous in its result by handicapping electric installations—should have been so far modified that an immediate start in the development of electric lighting has followed on an alteration of the Act. The alteration is very simple. Under the old Act it was provided that wherever public lighting was set up in any area the authorities might at the expiration of 21 years resume possession, so to speak, of the privilege, and take over the plant, &c., at a valuation—after 21 years' occupation. Now, 21 years run very rapidly away in this sort of thing. It takes several years, 8, 10 or 12, to get a thing like this to work, and the remaining period seems to practical men much too short to redeem the loss which must inevitably ensue from early losses and arrears, and the mere day-value of the plant and machinery when taken back by the authorities. There was not, in fact, time to redeem; but now Parliament, after a great deal of difficulty, has extended the period. You can imagine what the difficulty was when the gentleman who was responsible for this 21 years and for the Electric Lighting Act of 1882, was a man so eminent and practical as Mr. Chamberlain. He was President of the Board of Trade, and took very strong views indeed upon this subject, and he pointed to the water companies and the gas companies as a reason why the public should not be submitted to the same sort of tyranny and outrageous treatment as they had met with at the hands of these companies. Therefore he introduced very stringent terms as to the conditions for granting these privileges to electric lighting companies, and he gave a very short term or tenure of occupation. Now, even so great an authority as Mr. Chamberlain at last became convinced that the Board of Trade had gone a little too far, and the term has been extended to forty-two years. Anyone who has got to redeem anything will know what a vast difference there is between a redemption based on forty-two and twenty-one years. It makes perfectly easy and practical in the one case what was extremely difficult in the other. There is a rather important modification in the conditions on which the machinery is to be taken over. It is to be taken over at a valuation, but having reference to the fact that it is there ready to carry on an existing business. It is a little abstruse. Having had a great deal to do with arbitrations, I can say that the few words put into the Act as to extensions, &c., are very valuable, and they put a company, in the event of any authority resuming possession at the end of 42 years, in a much better case to put the valuation of their concern. There is no doubt whatever that the amendment of the Act has given an immediate impetus to the progress of this business. A

Digitized by Google

large installation is going on at Deptford by the London Electric Supply Company. As a matter of fact, I know most of the people in that concern, and I know there is plenty of money in it, and I think also there is some ability in it. I see among other things predicted of it that between now and the winter of next year they will want 250,000 electric lamps. I dare say that the estimated requirement of 250,000 lamps for that Company may be a little exaggerated; but it may be taken as an evidence of what I have said, that the electric lighting business is going on, and I suppose if we can maintain our patents, as we can the Cheesborough, and as I trust we shall the Edison, but most of all, if we can maintain the character we have got of making the best practical lamp in the market, then I think we are likely to participate largely in this great progress, and, fortunately for us, our capital need not be materially enlarged to enable us to meet an enormous additional manufacture of those lamps. He concluded by moving the adoption of the report and accounts.

The DEPUTY-CHAIRMAN (Mr. Frederick Richards Leyland), in seconding the motion, expressed his concurrence in the remarks made by the Chairman as to the wisdom at the present moment of not dividing the balance of £25,000, but that it should be carried to reserve until the pending actions were settled.

Mr. DONOVAN asked the relation of the Company with the Manchester Edison and Swan Company.

The CHAIRMAN replied that the position of the Company with respect to the Manchester Company was that they held a number of the latter company's Deferred Shares. The Company stood in the same position to the Manchester Company that Mr. Edison stood to this Company.

The motion was adopted.

Mr. LEYLAND proposed the re-election of Mr. J. S. Forbes, who retired from the Board and offered himself for re-election. Mr. Leyland spoke in warm terms of Mr. Forbes' qualifications for the post, and of his invaluable services to the Company.

VISCOUNT ANSON, who seconded the motion, said that he fully endorsed all that Mr. Leyland had said respecting their Chairman.

The motion having been unanimously carried,

The CHAIRMAN, in acknowledgment, remarked that Mr. Leyland had spoken about him (Mr. Forbes) in rather too flattering terms. He might, however, re-echo those expressions, and with more justice, as applied to Mr. Leyland, who also offered himself for re-election. He, fortunately for the shareholders, had a class of experience in life which was very useful to them; and he was enormously interested financially in the prosperity of the Company. Those two things—self-interest and a keen appreciation of business—made Mr. Leyland more invaluable to them than he (the speaker) had been. He hoped, therefore, some shareholder would be glad to propose Mr. Leyland's re-election.

Mr. CROMPTON said he was very pleased to move that Mr. Leyland be re-elected a Director of the Company.

Mr. HENRY ROBERTS seconded the resolution, which the Chairman submitted to the meeting, and it was agreed to unanimously.

The CHAIRMAN then said that there was one other matter of business to be transacted, and that was the re-election, if thought desirable, of the auditors, who retired, Messrs. Quilter, Welton and Co. Good wine needed no bush, and Messrs. Quilter and Co. needed no remarks of his to commend them to the favour of the meeting.

Mr. GAY proposed the re-election of Messrs. Quilter, Welton and Co. as auditors.

Mr. LETTS seconded the motion.

The CHAIRMAN put the resolution to the meeting, and it was unanimously carried.

Mr. GAY then proposed a vote of thanks to the Chairman and the Board of Directors for their services to the Company.

The resolution having been duly seconded and agreed to,

The CHAIRMAN, in acknowledgment, said that he and his colleagues accepted with gratitude the shareholders' constant and repeated confidence. They had had that day a pleasanter meeting than had taken place for some time, and he thought that the circumstances fully justified it.

The meeting then separated.

Eastbourne Electric Light Company.

A meeting of the above Company was held on Thursday, Oct. 25, in one of the rooms of the Town Hall, Eastbourne. The Mayor presided, and about a dozen of the shareholders and Directors were present.

The MAYOR said that the Company commenced in a small way, and now had 1,700 lights at Eastbourne. The progress had not been very rapid, but rather slow and sure. The arc lighting had been the great bane of electric lighting; but this drawback was being gradually remedied. In the Town Hall the light had been in use for two years, and a more perfect system they could not have. The electric light, like all "new boys," was bound to be pitched into by the "old boys," but now the old boys were beginning to see that the new boy was not to be put down by mere bullying. The Mayor here read copious extracts from published articles on the new light, and said it had helped to advertise the town even as far as America. The clerk of the Kensington Vestry had also made inquiry in regard to the system of lighting at Eastbourne. At some length the speaker maintained that the supporters of gas lighting had unjustly criticised the new light. But some people seemed to think that the world was made for them, and them alone. They knew to whom he alluded. Having quoted copiously from letters in the local papers against the Electric Light Company, the Mayor disputed the idea that gas was the cheaper light in the long run. The gas company had challenged the Electric Light Company, or he (the Mayor) would not allude to the matter, as there was room in the town for both. By what right did the gas company pay 12½ per cent. dividend? Why not reduce the cost of gas? He contended that the town of Eastbourne had shown the people of London and of America what could be done with the electric light. For six years the company had worked for themselves and others, and had not complained when no dividend had been paid. But a dividend would soon be paid, and the shareholders of the Company, if they would bear with them a little longer, would see that the Directors were doing all they could for them.

The Mayor and Mr. J. G. Langham were re-elected as two retiring Directors, and the latter at some length reviewed the well-known facts of the introduction of the electric light into Eastbourne. He agreed with the Chairman that the Company had started with too little capital. He congratulated the town that the Company was sharp enough to get their wires down before the passing of the Act, so that now they could be independent of the Board of Trade.

After some complimentary remarks by Mr. Hammond on the working of the Company, and some severe strictures on the advocates of the gas company, the meeting closed with the customary vote of thanks to the Chairman.

LEGAL INTELLIGENCE.

The Maxim-Weston Electric Company.

On Saturday last the petition of Mr. H. Watt for a winding-up order came before Mr. Justice Chitty in the Chancery Division.

Mr. Romer, Q.C., and Mr. George Hart appeared for Mr. Watt, and Mr. Bryne, Q.C., and Mr. Gasdar for the company.

PATENT
SILICIUM BRONZE AND SILICIUM COPPER WIRE.
The best for overhead Telephone and Telegraph Lines,
AND ALL ELECTRICAL PURPOSES.
Hard Drawn High Conductivity Copper Wire.

Mr. ROMER said the petitioner claimed to be a creditor of the company for the sum of £784. 12s. 2d. On the 5th September this year he had served the statutory notice upon the company to pay that sum, and the company did not within three weeks pay it. He had also a claim against the company for £900 in addition, but that would not be gone into on this petition. The grounds of opposition were that in the first place the company disputed the debt; he should urge that it was not a *bonâ fide* dispute. Then the company said they had certain counter claims, which he urged were mere bogus claims put forward without any substantial grounds merely for the purpose of trying to prevent a winding-up order. Mr. Hugh Watt was formerly a director and manager of the company, but on the 4th of August, finding that he was unable to get on with the new directorate, he had resigned; and since that date he had had no connection with the company. Under these circumstances one would have thought that it was the duty of the directorate, if they had been able, to pay Mr. Watt; that they had not done so the learned counsel said was clearly due to the fact that they had no means to pay—in fact, at a meeting held on the 3rd of October the chairman of the company stated that unless they had further means there would have to be a winding-up order. Since the service of the notice, on the 5th of September, and till after the presentation of the petition, the petitioner's debt was not challenged in the slightest degree. There was really no *bonâ fide* dispute as to the debt. The reason why the company counter claimed was pretty evident. Mr. Watt had transferred certain shares, and they refused to register, and, as he urged, raised that claim for the purpose of preventing that registration. That, however, was the subject of a separate application. The present claim of £784. 12s. was for salary, rent, and other charges; the counter claim amounted to some thousands of pounds.

Mr. BYRNE, in reply to his lordship, said it amounted to £4,616, but there might be further claims.

Mr. JUSTICE CHITTY asked on what ground the counter-claim was made.

Mr. ROMER said it was found on general statements of misdealings which were unsupported, and general statements on information and belief which were denied. In reply to further questions of his lordship, Mr. Romer said notice of motion to compel the company to register the transfer of shares had been given before the Vacation Judge; the transfer of shares took place in July.

Mr. JUSTICE CHITTY suggested that the company should pay the amount of Mr. Watt's claim into court; that the petition should be dismissed, so that it should no longer hang over them; that an action should be brought by one of the parties; that the money deposited should abide the result of the action; and that the costs should follow the event.

Mr. ROMER said he was willing to agree to that, but it must not be paid in in the name of the company, because, having regard to the chairman's statement, which he had quoted, the company might be wound up. He suggested that the money should be deposited in joint names, and that a sum should also be deposited to abide the question of costs.

Mr. BYRNE said he did not admit the accuracy of the report of the chairman's speech which Mr. Romer had quoted. In the absence of the directors he could hardly assent to the proposal. This petition hanging over the company hampered them, and they were very anxious to get the matter settled.

Mr. JUSTICE CHITTY said that if they paid in the money as proposed (he did not say whether it should cover the whole sum, but at any rate it should cover a substantial part of the sum) the petition would go, and would no longer hamper them, and they would only be standing out of a sum of money until such time as they were able to try their actions. The money, of course, would have to be provided in such a way that Mr. Watt could get it, and that it could not be recovered back from him on some other petition.

Mr. ROMER: We shall be quite safe if it goes to a separate account.

After some further conversation, it was agreed that the company should pay £500 within a fortnight into a bank in joint names, that the petition should be dismissed when the money had been paid in, the petitioner having liberty to apply again if another petition for a winding-up order should be presented; that Mr. Watt should bring the proposed action within a week of the dismissal of the petition, and that the company should then counter-claim or bring a cross-action; and that Mr. Watt should have the costs of the petition if in the result he recovered £50 or over on the balance of account between the parties.

Mr. BRYNE having pointed out that the pending motion for the registration of shares would involve the whole question which would have to be determined in the action,

Mr. ROMER undertook not to go into the question of the debt upon motion, and that the motion should be confined to the question of waiver.

NEW COMPANIES REGISTERED.

AUTOMATIC ELECTRIC SUPPLY COMPANY (LIMITED).—This company was registered on the 22nd inst., with a capital of £25,000, divided into 25,000 shares of £1 each, to manufacture, buy, sell, and deal in automatic boxes, electrical or otherwise, machinery, appliances, and merchandise of all kinds, and generally to carry on the business in all its branches. The first subscribers are :—

	Shares.
William Graham Hannay, 28, Duke-street, W., secretary ...	1
George Edgar Way, 18, Gascony-avenue, N.W., merchant ...	1
Hamen Levites, 13, Hanway-street, W. ...	1
James Golding, 162, Major-road, Stratford, E. ...	1
Samuel J. R. Allen, 49, Endymion-road, Finsbury-park, N., clerk ...	1
August Serraillier, 29, Meek-street, West Brompton, S.W., electrician ...	1
Ernest Desborough Sale, 1, Nelson-street, Greenwich, S.E., clerk	1

Registered without special articles.

THE SOUTH AFRICAN LIGHTING ASSOCIATION (LIMITED).—Registered by Wilkins, Blyth and Dutton, 112, Gresham House, E.C., with a capital of £50,000 in £10 shares. Object, to supply gas, electric, or any other artificial light within Port Elizabeth and King William Town and elsewhere in South Africa, or any islands or countries near thereto. The first subscribers are :—

	Shares.
W. Cash, 90, Cannon-street, E.C. ...	1
E. K. Blyth, 112, Gresham House, E.C. ...	1
A. L. Don, Hillside, Stowbridge, N.W. ...	1
D. F. Goddard, St. Margaret's House, Ipswich ...	1
S. Cutler 11, Vanbrugh Park, Blackheath, S.E. ...	1
C. Woodhall, Palace Chambers, Westminster ...	1
J. Cloudsley, Stonebridge Park, Willesden, N.W. ...	1

There shall not be less than three nor more than seven directors of the company. The first directors shall be D. Ford Goddard, James Mansergh and William Woodhall, M.P. The qualification of a director shall be the holding in his own right of at least 50 shares in the capital of the company. The company in general meeting shall determine the remuneration to be paid to the directors for their services.

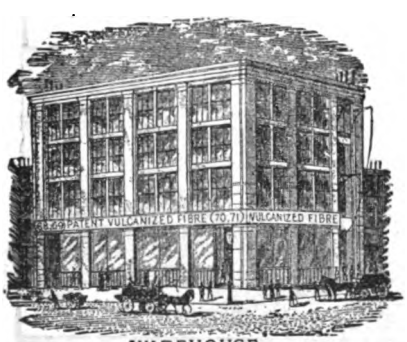
CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended October 26th, 1888, amounted to £5,151.

THE SCHANSCHIEFF ELECTRIC BATTERY SYNDICATE (LIMITED).—We are informed that Mr. David Marks has resigned the office of director of the Schanschieff Battery Syndicate, being about to proceed to Australia; and Mr. T. Grant Wells has been appointed secretary *vice* Mr. John Wright.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended October 26th, 1888, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company, were £4,289.

THE NON-CONDUCTOR OF ELECTRICITY.



WAREHOUSE.

VULCANISED FIBRE,

PATENTED.

This new material is supplied in two qualities, Flexible and Hard.

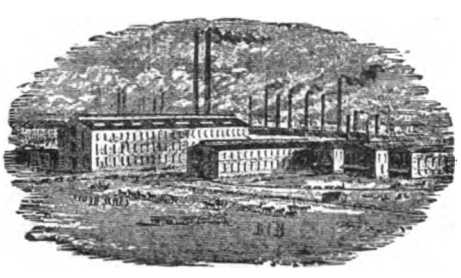
The FLEXIBLE is a substitute for Leather, Rubber, Gutta Percha, &c., and is extensively used by Brass Founders, Axle Makers, Hydraulic, Sanitary, and other Engineers, Pump Makers, Carriage Builders, &c.

It makes the best Hot and Cold Water Packings, and for Axle Washers of all kinds it is unequalled.

The HARD is a substitute for Metals, Hard Wood, Ivory, Vulcanite, Ebonite, &c., and is a good Insulator.

Sold in sheets, 5ft. 6in. by 3ft. 6in., varying in thickness from 1-50in. to 1in.

FLEXIBLE, 2/- per lb.; HARD, 2/3 per lb.



FACTORY.

MOSSES & MITCHELL, 70 Chiswell-st., London, E.C.
